I have noticed the peculiar circumstances of these two cases, because they bear directly on a point of practical importance, viz. the propriety of performing operations on persons thus dangerously depressed by excessive apprehension. The state of system consequent upon great dread, or making up the mind to the endurance of painful operations, is related in some few instances to have had a fatal termination. Mr. Travers, in his work on Constitutional Irritation,† mentions that a man who was the subject of strangulated hernia, expired suddenly during the steps preliminary to the operation, though the circumstances were, in other respects, such as to afford the fairest prospect of relief. Some years ago, a patient of Mr. Headington's, who had an aneurism of the femoral artery, expired at the London Hospital, under similar circumstances. An operation was proposed, to which he readily assented. On entering the theatre, however, he fainted; some wine and water was given

him, which he distinctly swallowed, and the operation was proceeded in, the artery exposed, and the ligature applied, but not tightened. During the operation, it was observed that no pulsation could be felt in the tumor, but this was accounted for by the fainting. Before tightening the ligature, it was suggested by the operator to wait until the pulsation was re-established: some increased attention was then paid to rouse the dormant energies of the patient, and it was remarked, that the syncope had continued an unusual time. After the attempts had been sometime persevered in, a more attentive observation proved that he was quite dead*. In the first case it is not stated that the patient had exhibited beforehand any dread of, or reluctance to undergo, the operation, whilst in the second we find that it was readily assented to. The conduct and exclamations of my patient, and the man whose limb was amputated by Sir W. Blizard, previous to the operation, clearly expressed the mental agony which they suffered, and in this respect they offer a striking contrast to these two, who, in all probability, belonged to that class of persons who suffer the more by striving to repress the internal struggles of the mind. The success of the operation for the removal of the breast in the case which I have here detailed, tends strongly to confirm the soundness of the advice under which I acted, and the value of which, as applicable to other cases, is not in my opinion counterbalanced by the two fatal cases which have been adduced, since death took place before the operation had been commenced in one of them, and probably this was the case in the other. There are few occurrences in our profession more painful to the surgeon than a patient dying under the knife, but I am inclined to think that in these particular cases there is greater danger in delay, and in prolonging the patient's fears, than in an expeditious performance of the operation, which not only proves less trying than is generally anticipated, but which terminates in removing the source of distress, and the chief cause of the alarming symptoms.

* This case is also related by Mr. Travers, at p. 18.

OBSERVATIONS

ON

THE OCCURRENCE OF CEREBRAL DISORDERS,

In connection with diseased Kidneys, in Children.

BY GOLDING BIRD, M.D. A.M.

Physician to the Finsbury Dispensary, &c.

[For the Medical Gazette.]

THE liability to the accession of symptoms indicative of cerebral lesion, when the functions of the kidneys are interfered with, has been so distinctly demonstrated by Dr. Bright, and is now so generally recognized by the profession, that it would be quite superfluous to occupy the pages of the MEDICAL GAZETTE with cases illustrative of this curious complication; more particularly as they are sufficiently frequent to fall under the notice of every practitioner whose field of experience is sufficiently extended.

The connection of cerebral with renal disease, however, becomes interesting in another point of view—from the possibility of detecting the existence of diseased kidneys, from the peculiar character of the cerebral symptoms manifested when œdema of the extremities or even coagulable urine may be absent; a fact lately pointed out by Dr. Addison*.

There is considerable reason to believe that the functional or structural lesion of the kidneys is a much more frequent exciting cause of many of the head affections so frequently presented by children than has been hitherto suspected; especially among those who come under our notice in public practice. Among the children of the poor, in large and crowded towns, scarlet fever often passes off completely unnoticed, save as a reputed cold or sore-throat, in consequence of the too frequent carelessness or neglect of parents, on the one hand, and the often evanescent character of the exanthema on the other; and hence nothing is more frequent than to have children brought to our hospitals and dispensaries in whom the pallid face, and the puffiness under the eyes, with perhaps slight œdema of the extremities, have led to a suspicion of

renal disease, and, on examining the urine, this suspicion has been justified by finding the secretion loaded with albumen; although on questioning the parents, the only assignable clue to a probable cause of these symptoms has been the prevalence of epidemic scarlet fever in the neighbourhood some weeks or months previously; the child at that time having been indisposed, but too slightly to demand confinement or medical attention: and not only is this tendency to the production of that degeneration of the kidney pointed out by Dr. Bright, indicated by the œdema and coagulable urine so frequently met with and recognized, but it is more than probable that careful observation will shew that many of the obscure heart affections of children, characterized by coma or convulsions, and coming on without any obvious cause, may in many instances be traced to lesion of the kidneys, produced in the first instance by the interference with the functions of the skin by neglected scarlet fever, or perhaps even measles. Hence such cases may be referred to the class pointed out by Dr. Addison in the Memoir before alluded to; and thus suspicion will be often awakened to the real nature of the ailment, by the peculiar character of the cerebral symptoms manifested. I have had this conviction forced upon me, by the extraordinary prevalence of reputed hydrocephalic cases, lately occurring in the persons of children who suffered in the severe epidemic scarlet fever of last autumn. On investigating some of these cases, the coagulability of the urine, often independent of œdema of the extremities, has at least rendered the existence of renal disease probable; whilst, in others, the peculiar quiet stupor, almost like that produced by a narcotic poison, with the pale face, slight puffiness under the eyes, and the absence of screaming, have afforded a great evidence of these cases being analogous to those pointed out by Dr. Addison. So many children affected in this manner, have, during this spring, been brought to the Dispensary, that several pages might be filled with the details of their cases, were such desirable. The question of interest appears to be not so much in the positive occurrence of cerebral symptoms connected with diseased kidneys, but as to *how far the peculiar character of*

* Guy's Hospital Reports, No. 8.

such cerebral disturbance is indicative of the existence of renal disease.

So far as my own experience has extended, I am convinced that cases do occur, and by no means unfrequently, in which the peculiar character of the cerebral symptoms developed, even in very young children, would direct attention to the kidneys as the exciting cause of the more prominent affection, where œdema, or even albuminous urine, may be absent. It is, of course, by no means necessary that scarlet fever, or any other exanthem, should have previously existed for the symptoms alluded to, to develop themselves; but, from the frequent existence of this disease, in an epidemic form, in crowded districts, it becomes, in the great majority of cases, the frequent, although often unsuspected, cause of such ailments. Anything that may so interfere with the secreting function of the kidney, so as to prevent the due elimination of azotised matter from the circulating mass, or may prevent its excretion when once separated from the blood, is fully competent to the development of a set of cerebral symptoms analogous to, or identical with, those described by Dr. Addison. The two following cases will serve to illustrate these positions; the first case being an example of head-affection, produced by, and indicating the existence of, positive disease of the kidneys; and the second, illustrating what rarely occurs in young children, viz. the cerebral symptoms produced by a mechanical interference to the excretion of urine.

CASE I.—I was requested by Mr. Bartlett, of Hatton Garden, to see with him a little boy who had been under his care since April 30th. He informed me that when first called to this patient, who was three years of age, he was labouring under excessive irritability of stomach, cough, and dry skin, coming on without any assignable or obvious cause; the urine was scanty, pulse quick and feeble, tongue brown, bowels confined, face pale, and presenting a remarkably torpid appearance. A mercurial purge and some diaphoretic medicines were administered, and on the following day the vomiting ceased. On May 3d this symptom returned, and on the 5th the child fell into a nearly comatose state. Mercurial diaphoretics, blisters to the neck, leeches to the temples, and assafœtida enemata were employed;

the coma, however, increased, and on May 14th I saw the little patient with Mr. Bartlett. He was lying in bed, with his legs stretched out; he was perfectly torpid, without stertor; but each inspiration was accompanied by a hissing sound, as if the air impinged directly upon the half closed lips. The face was pale, the eyes open, pupils moderately dilated, slowly contracting under the stimulus of light; the surface was cool, supple, and soft, although not moist. It appeared that the little patient had been lying in this state since May 9th, since which time it had scarcely taken any food, from the extreme difficulty in arousing him to a sufficiently conscious state to allow him to swallow. On calling loudly to him by name, I succeeded in awakening our patient to a momentary consciousness, during which he took a little beef-tea; but he almost instantly relapsed into his previously torpid state, the lips falling together, and the hissing noise returning at each expiration. There was no evidence of paralysis; and no tendency to convulsion had been manifested during his illness. A little urine was collected, and was found to be slightly coagulable by heat, although no œdema or puffiness under the eyes was present. Upon inquiry, I learnt that this child had suffered from the epidemic scarlatina of last autumn, and had always been more or less indisposed since.

The symptoms presented by this child, closely resembled those seen in the adult, when the function of the kidney had been interfered with, and belonging to the second class of the cases described by Dr. Addison, in Guy's Hospital Reports; and believing, moreover, that serous effusion was taking place into the ventricles of the brain, I had no hesitation in giving an unfavourable prognosis, an opinion verified by the death of the child within twenty-four hours from the time of my visit.

The body was opened 30 hours after death. In the head, a slight tendency to injection of the membrane was observed; the lateral ventricles contained each about an ounce of serum; the substance of the brain was remarkable for its snowy whiteness, and for the absence of blood-points. *Chest*: With the exception of slight emphysema of both lungs, everything was perfectly healthy. *Abdomen*: Both kidneys were turgid with blood; the right presented externally,

a slight although very distinct mottled appearance. The substances of each, on being cut into, appeared of a deep chocolate colour. The tunic could be stripped off with tolerable readiness. No other morbid appearance in any other of the abdominal viscera.

CASE II.—Alfred Buford, an infant eight days old, was brought to the Finsbury Dispensary in the beginning of last April. The nurse stated that it had appeared healthy and vigorous at birth, from which period it had gradually declined, lying in a torpid state all day long, and being aroused with extreme difficulty. On examining the little patient, I was struck with the remarkable appearance of quiet stupor it presented; its face was pale, eyes half-closed, pupils contracting feebly under the influence of light. On raising a limb, it slowly fell on removing the hand, into its previous position. The whole appearance was so like that of a child who had been over-dosed with some of the narcotic preparations which nurses too often administer to irritable children, that I questioned its mother on this point; it appeared, however, that no medicine of any kind, except a little castor oil, had been given to the child since its birth. On holding it to the breast, its lips feebly grasped the nipple, but almost immediately relaxed their hold, the infant relapsing into its previously torpid state. On inquiring concerning the urine, the mother and nurse remarked that they had never observed any signs of that excretion, and on examining the abdomen I found it distended, the scrotum œdematous and the size of an orange. The prepuce was also œdematous, and on attempting to find its orifice I at first failed, but eventually discovered a little opening not larger than a hair; this was dilated with a probe, and a very small catheter with some difficulty passed into the bladder; about half a pint of turbid and rather fetid urine escaped. A hot fomentation was ordered to the abdomen and scrotum, and some stimulants administered. The child revived a little after the urine was removed, and some warmth returned to the surface; it soon, however, relapsed into its previously comatose state, and expired in the evening. During the illness no sign of convulsion was manifested; the quiet stupor and pale surface were the only peculiar symptoms. The child had been, before I saw it, under the care

of a surgeon in the neighbourhood, who had administered some medicine, but appeared to have passed over unnoticed the fact of no urine having been voided since the birth.

A post-mortem examination of the body took place 24 hours after death. The bladder was found very much thicker than natural, its mucous coat injected, and numerous muscular bands appeared developed beneath it, so that this viscus resembled in miniature the state of bladder seen in stricture. The kidneys were turgid with blood, of a chocolate colour, and on squeezing the cones of tubuli an opaque milk-like viscid fluid exuded from the papillæ. No other sign of disease could be detected in any other part of the body.

These cases, I conceive, are of interest, from their pointing out the possibility of detecting, or at least suspecting, the existence of renal disease even in very young children, by the character of the cerebral symptoms presented by the patient: a fact, moreover, of importance, as it shews very satisfactorily that the phenomena described in Dr. Addison's paper are not limited to any particular age, and hence affords a powerful argument in favour of the correctness of the views developed in that essay. Subjects of this importance can alone be tested by experience, and not by the application of previous opinions or assumptions unwarranted even by statements of their authors. It is a dangerous thing to oppose preconceived notions to inductions from the careful observations of facts; and those who are rash enough to do so will generally have the mortification of being corrected by the youngest student who carefully watches the varied phenomena of disease.

22, Wilmington Square.

CASE OF EXTRACTION
OF
PENCIL FROM BLADDER BY THE
LATERAL OPERATION.

BY GEO. W. CAMPBELL, A.M. M.D.,
Lecturer on Surgery in the McGill Coll. Montreal.

[For the Medical Gazette.]

WILLIAM DAVIES, aged 21, of a healthy constitution, was admitted into the Montreal General Hospital in March last. He stated that about five weeks before his admission, while suffering from retention

of urine, he had introduced a short piece of a common black lead pencil into the penis, with the view of relieving himself. The pencil slipped from his grasp, and his attempts to extract it only pushed it further up the urethra. Finally, a surgeon was sent for, and by their *united exertions* the pencil was forced into the bladder. From that period up to the time of his admission into the hospital, he laboured under all the common symptoms of calculus vesicæ, with turbid and highly offensive urine, which he could not retain for a longer period than an hour. Upon introducing a sound, its point was felt to rub against some foreign body, and an operation was determined on. The preliminary steps having been taken, an incision was made into the bladder by the lateral method. Liston's knife and a grooved staff were the instruments used. Upon introducing the finger, the pencil was felt firmly wedged between the pelvis and the superior fundus of the bladder, and was extracted by means of a curved forceps: it measured upwards of three inches, and was incrustated for about half its length with a deposit of the uric acid calculus. A short gum elastic tube was left in the wound for 24 hours; the urine began to flow through the urethra 36 hours after the operation, and before the end of three weeks the wound had completely cicatrized.

Montreal, May 5th, 1840.

ON THE EFFECTS
OF
DIVIDING THE INNER STRAIGHT
MUSCLE OF THE EYE,
FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

THE following particulars of the present condition of the eye, in a patient in whom the inner straight muscle was divided six weeks ago, for strabismus, may be interesting to some of your readers.

Caroline Hebditch, aged 16, living at 9, Upper Dorset Street, Bryanston Square, began to squint with the right eye about the age of eight, upon being put to the employment of picking hair. The right eye became turned in to the utmost degree of ordinary strabismus.

But, as is usual in such cases, when the good eye was closed, the distorted one would recover its proper direction. The sight of the right eye, when thus brought into use, was, however, less perfect than that of the left, and its use in this manner would be followed by pain and aching of the eye-ball.

The operation consisted in dividing the tendon of the inner straight muscle upon the groove of a curette, introduced between it and the sclerotic, after a vertical section of the conjunctiva, near the semilunar fold of the caruncula lacrymalis.

The results of the operation, now that six weeks have elapsed, are the following:—

1. The right eye, upon a superficial examination, might appear to have completely regained its just direction; but it has, in truth, only approximated to it. The patient, as you stand before her, seems to look at you with both eyes; but upon her closing the left eye with her hand, you observe the right to be sensibly turned further outwards, in order to look at you. When she now opens the left eye, the right is seen again to move inwards, reverting to its former direction. Nevertheless, when both eyes are open, and she looks straight forwards, her vision is single. It is, therefore, to be presumed, that when looking straight forwards with both eyes, she disregards impressions made upon the right eye.

2. The right eye is capable of being turned further inwards, and apparently to the same extent as natural. This must be attributed to the agency of the inner fibres of the upper and lower straight muscles.

3. The right and left eye appear to move together with perfect consent. When vision is directed to a near object, the optic axes converge more; when to a remote object they converge less. When an object is moved laterally before her, the same distance being preserved from the eyes, the optic axes, as they follow it, seem to maintain the same inclination towards each other. The same consent, it may be remarked, really obtains between the eyes of persons who squint. So the best account of the effects of the present operation, as yet described, is, that through it the patient squints *less* than before.

4. But, in addition, she can turn her right eye freely outwards, and

uses it habitually to see objects that lie to her right; her range of vision is therefore materially increased. Her right eye, likewise, appears to have gained strength; vision with it she finds now to be as perfect as that of the left, upon trying both alternately.

It is evident that she is so far a material gainer by the operation. But there is the following drawback, which, however, is not constant, and may possibly diminish with time—her right eye appears to be slightly larger than the left. This arises from the action of the two oblique muscles, in drawing the eye forwards, not being now sufficiently antagonised; the right eye looks larger than the left, from being rendered, through this cause, the more prominent of the two.—I am, sir,

Your obedient servant,

HERBERT MAYO.

19, George Street, Hanover Square,
June 2, 1840.

ON THE SITUATION
OF THE
DECIDUOUS MEMBRANE,
IN
Cases of Extra-Uterine Gestation.

BY ROBERT LEE, M.D. F.R.S.

[For the Medical Gazette.]

A LADY died suddenly, in 1829, from internal hæmorrhage, produced by rupture of the right fallopian tube, which contained an ovum. On opening the tube, and examining the different parts of the ovum, I found a deciduous membrane every where surrounding the chorion, and closely adhering to the inner surface of the tube, as the decidua usually does to the lining membrane of the uterus in ordinary gestation. Within the decidua the chorion, placenta, amnion, and embryo, were distinctly seen. The uterus was larger than natural, and there was no appearance of decidua lining its internal membrane. The decidua, and other parts of the ovum in the right fallopian tube, are all distinctly seen in the preparation of the uterus and its appendages, which is now in the museum of St. George's Hospital.

On the 18th July, 1836, Mrs. K—, after suffering for some time with symptoms of inflammation and retroversion of the uterus, was seized with great faintness, and soon expired. A large quantity of fluid blood was found in the ab-

dominal cavity, and the right fallopian tube, which contained an ovum of ten or twelve weeks, was extensively lacerated near the fimbriated extremity. On removing the uterus and its appendages from the body, and carefully examining the ovum contained in the right fallopian tube, it was evident that a deciduous membrane every where surrounded the chorion, and adhered to the inner surface of the tube. The placenta, which was situated at the extremity of the ovum nearest the uterus, was seen covered with the decidua, and coagula of the fibrin of the blood were traced from the interstices of the placenta through the decidua into veins in the thickened muscular coat of the tube. At the part where the placenta was situated, the muscular coat of the tube was a quarter of an inch in thickness, and could readily be separated into layers like the muscular coat of the gravid uterus. In this coat of the tube, the veins were also readily traced from the inner surface outward, opening obliquely into one another, and enlarging as they reached a great vein near the uterus.

The interstices of the villousities of the chorion, filled partially with clots of fibrin, were seen around the whole ovum, and presented nothing different in their appearance from those of ova which have been developed within the uterus.

Between the chorion and amnion, near the placenta, was seen the vesicula umbilicalis, with its slender peduncle, proceeding to the umbilical cord.

The appearance of the amnion, cord, and embryo, was perfectly natural.

The uterus was considerably enlarged, and its inner surface was coated with a very thick layer of a yellowish-white soft substance, like common adipose matter, and bearing no resemblance to deciduous membrane. There was no trace of any arterial or venous canal in this coating. The orifice and neck of the uterus were closed with the usual viscid substance, formed by the Nabothian glands.

There was a corpus luteum in each ovary. Both layers of the Graafian vesicle were inclosed within the yellow matter, and this was in immediate contact with the stroma of the ovary*. In

* On the 25th February last I examined, with Mr. Wharton Jones, a corpus luteum which was removed from the body of a woman who died in the fourth month of her pregnancy. The yellow matter was here likewise in immediate contact

the preparation of the parts, the decidua, placenta, chorion, vesicula umbilicalis, amnion, umbilical cord, and embryo, are all distinctly seen, and likewise the layer of the muscular coat of the fallopian tube, with the veins proceeding from its internal to its external surface. The vesicula umbilicalis has become greatly diminished in size since the parts were immersed in spirit. With the exception of the coagula of blood in the interstices of the placenta, and villi of the chorion, the constituent parts of this ovum are the same as in all cases of intra-uterine gestation, and are in a healthy condition. The preparation of the parts is likewise in the museum of St. George's Hospital.

In the history of a case of fallopian tube gestation which occurred to M. Chaussier, in 1814, it is stated that the walls of the tube were thin and vascular, that the placenta attached to the inner surface was broad and thin, and that, when detached, the membrana decidua surrounded the ovum. I have met with no case, except this, in which the deciduous membrane is distinctly described as surrounding the ovum in the fallopian tube; yet I am certain that this must be the fact in all cases of extra-uterine gestation, the circulation of the maternal blood in the ovum being carried on chiefly by the blood-vessels of the deciduous membrane.

Dr. William Hunter examined a case of fallopian tube gestation, in which the uterus was enlarged, and the membrana decidua was distinctly seen lining the fundus uteri. From this appearance he inferred that the decidua, or outer stratum of the secundines, belongs to the uterus, and not to the ovary, or that part of the conception which is brought from the ovarium.

In all the cases of fallopian tube conception which have since been recorded, except those of Mr. Langstaff and M. Velpeau, a deciduous membrane has

been described as present, lining the cavity of the uterus; and most authors have believed it to be formed in all cases of this description.

"Though the fœtus be extra-uterine," observes Dr. Denman, "the uterus becomes considerably enlarged, and performs its proper office by providing the effluence or deciduous membrane for the reception of the ovum."

"Although it be extremely probable," observes Dr. Baillie, "that the decidua begins to be formed at the time that the ovum passes into the cavity of the uterus, yet it is not absolutely necessary for the formation of the decidua that the ovum should reach that cavity. When an ovum grows in the ovarium or fallopian tube, the decidua is both formed in the uterus, and the uterus is considerably enlarged, so as to undergo, to a certain degree, changes exactly similar to those which take place in a natural pregnancy*."

Dr. Burns says, "It is curious to observe that invariably the uterus enlarges considerably, and, in every instance, decidua is formed," p. 220.

Meckel, Breschet, Velpeau, and every other author, with whose writings I am acquainted, have given the same opinion on this subject; and not only has this been considered an undoubted fact in all cases of extra-uterine gestation, but, in common pregnancy, it has been supposed that a deciduous membrane is invariably formed within the uterus before the ovum enters its cavity. That the decidua is not formed within the uterus in all cases of extra-uterine gestation, the preparations now described clearly demonstrate. That the uterus is usually enlarged, and its lining membrane coated with a viscid substance resembling the decidua, is certain; but this has not been shewn in any instance to possess an organized vascular structure similar to that of the true decidua. If the fact were established, that the cavity of the uterus always contains a deciduous membrane in cases of extra-uterine gestation, it would not follow that, in ordinary conception, the cavity is lined with a decidua in the form of a shutsac before the descent of the ovum.

with the stroma of the ovary, and had no capsule around it. Within the yellow matter, and loosely adhering to it, was seen a small whitish cyst, the outer surface of which adhered loosely to the yellow matter. When this cyst was cut open under water, there was seen a very small cavity in the centre. There were two perfectly distinct coats which formed the walls of this little cyst; and these two layers were separated by a less dense structure, apparently cellular membrane, of a bluish or whitish milky appearance. This observation establishes beyond all doubt the correctness of my views respecting the structure of the corpus luteum.

* Anatomical Description of the Gravid Uterus, by W. Hunter, M.D.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Odontography, or a Treatise on the Comparative Anatomy of the Teeth; their physiological relations, mode of development, and microscopic structure in the vertebrate Animals. Illustrated by upwards of 150 Plates. By RICHARD OWEN, F.R.S. &c. Part I., containing seven sheets of letter-press, and fifty plates, from drawings by Mr. T. Dinkel, and engraved by Mr. L. Aldous. Baillière, 1840.

MR. OWEN'S talents for observation, and his great practice in description, appear to be demonstrated with much effect in the work before us; which, however, as it contains a detailed account of preparations only accessible to the conservators of the Hunterian Museum, and may thus be regarded as forming a part of its descriptive catalogue, is an exception to the ordinary run of books which it is our lot to criticise. This observation, at any rate, holds good of those portions of it which are devoted to comparative anatomy and natural history; for as we have not the especial preparations before us to which they relate, we cannot test their accuracy, and can only arrive at the general conclusion, that they appear to be faithful accounts of the objects which they profess to describe.

This first part of Mr. Owen's present work is devoted to the teeth of fishes, recent and fossil, from the Cyclostomes to the Labroids; and for the description of these we must refer the reader, for the reasons above mentioned, to the work itself: but with respect to the general doctrines of dental development and structure, which we find promulgated in various parts of it, we have several observations to make.

Mr. Owen evidently considers his theories on this subject of considerable value; for he has not only referred to them frequently in the work before us, but we also find that he has been at the trouble of sending them abroad, and submitting them to one of the highest scientific bodies in the world: for, on turning to the Number for December 16th of the *Comptes Rendus* of the Academy of Sciences at Paris, we there find

a French edition of them, with various modifications and additions.

Let us first state, then, what these views are which the author has been so careful in laying before the scientific world both in France and England, as his own original theories. “The uniform result of my researches,” says he (p. 13), “on the structure of the teeth in all grades of vertebrate animals, and in their natural and diseased states, has been a conviction of the untruthfulness of the terms inert and inorganized as applied to the substance of any tooth whatever.”

At p. 37, we have the following passage:—“The formation of the body of the tooth by deposition of earthy particles in pre-existing and pre-arranged cavities is still more satisfactorily demonstrable,” &c. In the extract from his *Mémoire* in the *Comptes Rendus*, which is principally composed of a translation of p. 35, 36, and 37, of the part before us, we find him stating that “Les auteurs les plus récents qui ont écrit sur la nature et le développement des dents, et qui ont résumé en des propositions générales leurs observations relativement à ces organes dans les poissons, les reptiles et les mammifères, les ont décrits comme des corps de nature inorganique, dont l'accroissement s'opère à la manière des corps bruts, par la juxtaposition successive de couches exsudées par un bulbe ou membrane glandulaire.” We thus find him publishing in England the results of his researches, and stating in France that the other recent writers on the subject have arrived at different conclusions.

On first perusing these passages, we were struck with their inconsistency with statements we had lately read, and on inquiring into the subject we soon found that Mr. Owen's discovery of the organic nature of the ivory was far from being original, and that even the pages of our own journal furnished sufficient proof that “les auteurs les plus récents” had not all regarded the ivory as an “inorganic exudation” of a “membrane glandulaire.” In a paper on the structure of the teeth, read by Mr. Nasmyth, at the last meeting of the British Association held at Birmingham, as reported in the *Literary Gazette* for Sept. 21st, 1839, we find that gentleman describing the cells of the ivory as formed by an ossific transformation of the cells of the pulp. In the report of this paper published in

our own columns, a diagram is given of the cells of the pulp, showing them in their state of transition into ivory*.

In Mr. N.'s own report, given in the Transactions of the Association, which has been printed separately, and a copy of which is now before us, we find it expressly stated "that the ivory is neither more nor less than the ossified pulp, and that it can in no wise be regarded as an unorganized body."

Our curiosity having been excited by these singular inaccuracies on the part of Mr. Owen, we were induced to examine his statements more particularly in reference to Mr. Nasmyth's previous publications; and the result is, that we have found that he has been anticipated by Mr. N. in all his main positions respecting the formation and structure of the teeth.

For the proofs of this, as a general assertion, we must content ourselves with referring to the papers of Mr. Nasmyth, and the Memoir of Mr. Owen. But, with respect to the grand question of the organization of the ivory, on which it is worth while to dwell a little longer, we shall shew, by the simple method of juxta-position, the inaccuracy of Mr. Owen's introductory statement to the French Institute.

From *Comptes Rendus*, for Dec. 16th, 1839, p. 784.—"Les auteurs les plus récents qui ont écrit sur la nature et le développement des dents, les ont décrits comme des corps de nature inorganique, &c."

From *Lit. Gazette*, for Sept. 21st, 1839, p. 601.—"The interfibrous substance of the teeth," said Mr. N., "had been improperly described by modern anatomists as presenting no traces of peculiar organization; but his researches had led him to the conviction that it is not only organized, but differently and characteristically so in different animals, so as to be capable of affording valuable aid to the naturalist in the classification of the animal kingdom. This organization he proceeded to describe as cellular, and he exhibited various diagrams of its appearance."

Thus it is clearly impossible that Mr. N. can be considered as regarding the ivory as inorganic.

Throughout this first part of Mr. Owen's work, reference is continually

made to the existence of a capsular investment of the enamel, and of the transformation into coarse bone of the interior residual portion of the pulp, after the ivory has been fully formed, as if these were generally acknowledged and well-known facts, though the truth is, that they are both recent discoveries of Mr. Nasmyth, who has devoted a paper in the *Med. Chir. Transactions* to their announcement and description.

Our limited space renders it impossible for us to quote all the instances of resemblance between Mr. Owen's views and those previously published by Mr. Nasmyth. We must refer the reader who is curious in such scientific analogies to a comparison of the Reports of Mr. N.'s papers read at the British Association, in August last, contained in the 620th No. of the *Athenæum*, and the 1183d No. of the *Lit. Gazette*, with Mr. Owen's Memoir contained in the No. of the *Comptes Rendus* for Dec. 16th, 1839. Such a comparison cannot but lead to the conclusion that Mr. Nasmyth, in his researches on this part of the subject, has anticipated all that Mr. Owen claims as original.

It will also be seen that Mr. Owen's views of the structure of the teeth in the higher animals are only deduced from analogy, whilst Mr. Nasmyth's are the result of direct investigations.

Mr. Owen cannot, of course, be aware that he has been anticipated in these points of dental anatomy by Mr. Nasmyth: at all events, we cannot suppose for an instant, that, had he been acquainted with this fact, he would have omitted to allude to it in some part of his work, or of his communication to the French Institute; particularly when we recollect that he was one of the Council of the British Association, at Birmingham, and might, in this capacity, be considered as more especially called upon to see justice done to any scientific claims or statements made at that meeting. Be this as it may, however, it is our duty, as journalists, to signalize errors and omissions of this kind, and to point them out to their authors for correction. Now that he is made aware that the opening passage of his *Mémoire*, laid before the French Institute, contains an important inaccuracy, he will doubtless think it due to that illustrious body, as well as to the gentleman immediately concerned, to rectify it; and

to acknowledge, at the same time, that most of the ideas he has promulgated in his *Mémoire*, and in the work before us, on the development and structure of the teeth, had been previously published by another author.

We now proceed to make a few general observations which have suggested themselves to us in perusing Mr. Owen's work. First, with respect to the theory of the tubular structure of the dental bone. We are surprised that Mr. Owen should have adopted this theory without any comment or examination of its merits, and without any attempt at explanation of the contradictions in which those who have hitherto supported that doctrine have been uniformly involved.

He also adheres to the theory of the papillary, follicular, and eruptive stages of dentition, as propounded by Arnold and Goodsir; but here, likewise, he furnishes no new evidence in support of a novel and disputed doctrine. He frequently speaks of the ossified capsule, although its existence is incompatible with the doctrine of an eruptive stage, for it is a contradiction to treat of the capsule as remaining to be ossified, after it has been described as having been ruptured by the extrusion of the tooth. On this subject we find, at p. 16, the following singular observation. "In the Balistes, Sparoids, Sphyræna scarus, and many other fishes, the foundation of the teeth presents all the usual stages which have been observed to succeed each other in the dentition of the highest organized animals: the papilla sinks into a follicle, becomes surrounded with a capsule, and is then included in a closed alveolus of the growing jaw, where the development of the tooth takes place, and is followed by the usual eruptive stages." It would be very interesting to us to have the means of verifying this remark.

In respect to the general plan of Mr. Owen's work, it is but doing justice to M. de Blainville to state that it differs in no essential respect from the odontographic department of his '*Osteographie*,' the first part of which was published last year. The application of the micrography of the teeth to the recognition of the type of animal, contained in Mr. Owen's work, had been previously made by Retzius, Nasmith, and others.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in Ibpucum sit, dicendi periculum non recuso." CICERO.

FOUNDLING HOSPITALS AND THEIR EFFECTS.

THERE are few circumstances connected with the distribution of public benevolence, in which the system adopted in this country differs more widely from that of the Continent, than in the provision which is made for the offspring of illegitimate intercourse, or of married parents who are unable to provide a maintenance for their progeny. It would seem (and to foreigners it does generally appear) as if the notorious charity of England were neutralized in this direction by some ill feeling; and it is not easy to render it clear to one accustomed to the extended and almost unrestrained system of providing for the *enfants trouvés* abroad, what are in this country deemed sufficient reasons for the very limited assistance that is afforded to that class from any other source than the poor's-rate, from which it is dealt out with so close and reluctant a hand.

The report of the charity Commissioners on the Foundling Hospital in London (the only institution of the kind, we believe, in the kingdom), affords several facts of considerable interest in evidence of the sufficiency of the grounds upon which only a limited degree of assistance is afforded to charities of this class.

The Foundling Hospital, possessing at present an income of about £15,000 a-year, and in which by the falling-in of leases a very large increase may soon be anticipated, was founded in 1739, by a charter granted on the petition of Thomas Coram, the master of a trading vessel, who had for some years

previously exerted himself strenuously to attain this object. Before presenting his petition, it appears that he obtained three memorials or recommendations of his design, the first signed by 21 "ladies of quality and distinction;" the second by noblemen and gentlemen; and the third by justices and other persons of distinction. One of these memorials recites that no expedient had been found out for preventing the frequent murders of poor infants at their birth, or for suppressing the custom of exposing them to perish in the streets, or putting them out to nurses, who, undertaking to bring them up for small sums, suffered them to starve, or if they permitted them to live, either turned them out to beg or steal, or hired them out to persons by whom they were trained up in that way of living, and sometimes blinded or maimed to move pity, and thereby become fitter instruments of gain to their employers. The petition itself also speaks of frequent murders being committed by the cruel parents to hide their shame.

On these grounds the Hospital was founded and liberally endowed. Happy would it be if, in these days, though its income has increased in full proportion with the population, it were found in any perceptible degree to mitigate the evils that it was hoped to remedy. But even if it did not tend rather to encourage the evil it might propose to mitigate, it would in the present day be but as a drop in the ocean; and few things, perhaps, can illustrate better the total inefficiency, (not to say the utter mischievousness) of recent legislation for the poor, than that all the pleas for the original establishment of this institution might now be urged with much greater force. The frequency of infanticide is undoubtedly greater now than then, and this not so much for the purpose of hiding shame, as to relieve the mother from a burden which she cannot hope to

support, or to have care taken of; the hiring of children for begging and stealing, the apprenticing them to fraudulent and cruel masters, and the starving by workhouse nurses, that *Coram* might now find, would be sufficient to make even him despair, as much of ameliorating the condition of the children themselves, as of reforming the evil system from which their miseries result.

If the need of assistance, therefore, for destitute children be a sufficient ground for establishing institutions of this kind, no time can ever have demanded more loudly for an increase of their number. On a fair calculation, three more hospitals in the metropolis, of the same extent as the present, would not be more than sufficient for the reception of those children who might be deemed proper objects.

But there are some startling facts in the report, which seem to prove beyond a doubt that the most effectual means of augmenting the number of foundlings, is a liberal supply of means for their maintenance in numerous or extensive foundling-hospitals. This, it is well known, is the common argument against such establishments; and it is usually illustrated by the fact of the far greater number of foundlings and illegitimate children in Paris than in London. This example, however, is not unexceptionable; for it remains yet to be shown, how far the numbers in the former city would be reduced if the indiscriminate reception of children in the charities were to cease, or if certain bounds were put to it. The history of our own Foundling-hospital affords much clearer evidence. The hospital was opened on the 25th of March, 1741, notice having been previously given to the public that children would be admitted till the house (then situated in Hatton Garden) was full. The children were merely brought to the door, and if, on examination, they were found free from

any communicable disease, they were admitted, without any questions whatever being asked respecting them. Under this plan, the numbers asking for admission appear gradually to have increased; and, in 1742-3, it was proposed to enlarge the hospital, and obtain funds enough to admit all the children that were brought. At this time it often happened that there were 100 women with children at the door, when only 20 could be admitted; and riots and disturbances often took place. A practice was then introduced of receiving by ballot; and all the women were admitted into the court-room, and drew balls out of a bag.

The plan of indiscriminate admission, however, was not commenced till 1756, when the House of Commons first lent its aid for this purpose to the hospital. It was continued for nearly four years; and the cost which it entailed on the hospital, and which, with some others less important, was defrayed by the House of Commons, amounted to little short of £550,000.

A basket was hung at the gate of the hospital, in which the children were deposited, after ringing a bell to give notice to the officers in attendance. On the 2d of June, 1756, the first day of general reception, 117 children were received; and, between that day and the end of that year, 1783 children, and in the following year, 3727 were admitted. The governors directed, in June, 1757, that advertisements should be issued, apprising the public of the privilege to which they had become entitled; and notices to the same effect were put up at the corners of public streets, and places of public resort.

The consequences of this general admission (says the report) were, indeed, lamentable. Prostitution was greatly encouraged by the unlimited facilities afforded for disposing of the fruits of illicit intercourse. The governors hav-

ing neglected to provide themselves previously with proper means of rearing so many children during the most critical period of human life, by far the greater number of the infants admitted died. Of 14,934 children received during the three years and ten months that this system was continued, no less than 10,389 perished in early infancy. Parish officers, in some cases by fraud, in others by force, sent in the legitimate children of pauper parishioners, to relieve their parishes from the cost of maintaining them. Parents also brought their children when in a dying state, for the purpose of having them buried at the expense of the hospital; strangers were employed by parents to convey their children from the country to the hospital in London at so much per head, and many of them, through the wilful brutality or criminal negligence of those to whom they were consigned, never reached their destination alive.

This system was discontinued in 1760, but its short continuance was amply sufficient to shew, in the above brief history, all its evils, and all those of the same plan, however modified in its details, in other countries. With increased facility, there immediately coincides increased licentiousness, and the strange anomaly is exhibited of charity engendering crime. The harm of such a system is incalculable; for as it effectually removes one of the principal restraints on the production of bastard children—the fear of the burden of maintaining them—it creates a demand for assistance which none but the most enormous funds can possibly meet. With the numbers above mentioned, for example, and at the rate of 6*l.* per head annually for thirteen years (which is about a fair calculation for the necessary expenses for the average), an income of 150,000*l.* a year would have been barely sufficient for the maintenance of the hospital. Nor does the evil stop here:

but it almost of necessity follows that the reception of such numbers of children is accompanied by a constant and great mortality among them. The numbers given above afford a frightful example of the effects of negligence, in part criminal, but, no doubt, in still greater part unavoidable; and the same is deducible from a comparison of the high rate of mortality in the children's hospitals in Paris with the very low rate among the children at present received into the Foundling. Between 1810 and 1831, 754 children were admitted,^e and of these 197 died, being at the rate of 26 per cent.; but of these 197, no less than 130 died under two years of age.

Under the present system adopted at the Foundling, according to which no children are admitted without a previous and satisfactory inquiry into the circumstances of their birth, and the condition of their parents, about thirty-two children are received in the course of the year. It is now, therefore, scarcely an object of medical interest, unless to remark how marvellously well, under good care, and when removed from the mischief that mothers, in their foolish fondness, inflict upon them, children will thrive. Except from epidemics, illness may fairly be said to be a rare occurrence in the hospital; and probably so healthy a body of children could not be found in the kingdom, even were their numbers much greater; therefore, there could not be any opportunity afforded of studying here the peculiarities of their diseases.

With this limited number of admissions, the benefit and injury which such an institution effects scarcely admit of being estimated; but there can be little doubt that the former does, on the whole, preponderate. How far its scope could be enlarged without mischief, is uncertain; but any great increase would unquestionably be dangerous. Indeed, with the exception of the opportunities which they afford for the study of the

diseases of children, we are not certain that, with one exception, any thing but evil results from the existence of large foundling-hospitals. They undoubtedly diminish the frequency of infanticide by removing the chief inducements to it, viz., the fear of shame and the difficulty of maintaining children; but to counter-balance this they fearfully increase licentiousness and bastardy, destroy some of the chief though harsh safeguards of female virtue, and tend to engender a disgusting looseness of manners and morality. The difficulty is, and probably long will be, to find that happy medium in which, while every present restraint upon the multiplication of illegitimate offspring is continued, there shall still be full security for those that are born from starvation, from the brutality of unsympathizing nurses and masters, and, above all, from destruction by their parents. This, however, is another and not the least interesting of the questions involved in that which is in this, as in nearly every other portion of it, the greatest blot and bane of our land—the Poor Law.

SMALL-POX AND VACCINATION.

THERE are two Bills before the House of Commons, both having for their object the extension of vaccination, and prevention of small-pox. One of these was brought in by Lord Ellenborough, and has been sent down from the House of Peers; an account of it will be found in our last volume, at p. 940. The other bill has been introduced by Mr. Wakley in the Lower House. The latter appears to us decidedly the better of the two; and we subjoin a copy that our readers may judge for themselves. But the Member for Finsbury has so little influence, that there appears great risk of Lord Ellenborough's plan being preferred, unless the profession exert themselves by immediately petitioning in favour of the bill "To prevent inoculation for the small-pox, and to extend the practice of vaccination." Such petitions must be presented on or before the 17th of this month.

A BILL

TO PREVENT INOCULATION FOR THE SMALL POX, AND TO EXTEND THE PRACTICE OF VACCINATION.

Preamble.

Whereas it is expedient, and would tend greatly to promote the security and health of the public, to prevent the propagation of the Small-pox by inoculation, and to extend the practice of Vaccination; Be it therefore enacted, by the Queen's most excellent Majesty, by and with the advice and consent of the Lords spiritual and temporal, and Commons, in this present Parliament assembled, and by the authority of the same,

Prohibit of Inoculation with Variolous Matter.

I. That whosoever shall, from and after the *passing of this Act*, produce or attempt to produce in any person by inoculation with variolous matter, or by wilful exposure to variolous matter, or to any matter, article, or thing, impregnated with variolous matter, or wilfully by any other means whatsoever, produce the disease of Small-pox in any person, in any part of England or Ireland, shall be guilty of a misdemeanour, and shall be liable to be proceeded against, and convicted summarily in England before a justice of the peace, and in Ireland (if the offence be committed in Ireland) before the justices of the peace in petty sessions assembled, and for every such offence shall, upon conviction, be imprisoned in the common gaol or house of correction, with or without hard labour as to such justice or justices shall seem meet, for any term not exceeding *three months*, nor less than *seven days*.

Relieving Officers and Overseers to give Orders for Vaccination.

II. And be it enacted, That from and after the *passing of this Act*, every relieving officer or clerk of any Board of Guardians of any Union in England or Ireland, and every overseer of any parish in England wherein relief to the poor is not administered by guardians, is hereby directed, whenever it shall appear to him that the person on whose account any such order as is hereinafter described is demanded, has not been vaccinated, to deliver to any individual applying for the same an order, framed according to the form contained in the schedule marked (A), hereunto annexed, for the vaccination of any person as aforesaid, being then resident in the Union or parish respectively, wherein any such application is made.

Remuneration to Medical Men Vaccinating by order of Relieving Officers or Overseers.

III. And be it enacted, That any legally-

qualified medical practitioner who may by the authority of any such order successfully vaccinate any person as aforesaid, shall, on presenting the said order, within *three calendar months* from the date thereof, to the guardians of the Union or the overseers of the parish wherein the said order was issued, be paid by the said guardians or overseers the sum stated in the schedule marked (B) hereunto annexed: Provided always, That if the said order be not presented within the period of *three calendar months* as aforesaid, the payment of any part of the sum mentioned therein shall not be allowed.

Remuneration to Medical Men to be paid out of Poor's Rate.

IV. And be it enacted, That the guardians of every Union and the overseers of every parish, as aforesaid, are hereby empowered and directed to pay the sum mentioned in any such order aforesaid, not exceeding the amount stated in the schedule hereunto annexed, out of the monies which are in their possession from time to time, collected as rates for the relief of the poor: Provided always, That no such payment shall be made to any vaccinator who is not a legally qualified medical practitioner, nor to any person holding the office of vaccinator by virtue of an appointment from the National Vaccine Board.

Return of Number of Persons Vaccinated to be annually made to National Vaccine Board.

V. And be it enacted, That the guardians of any union or overseers of any parish, as aforesaid, shall, in the month of January in every year, cause to be prepared from the orders returned to them by vaccinators, a summary of the numbers of persons vaccinated, and of the ages of such persons, and of the instances in which the operation was successful; and shall forward the said summary, on or before the *first day of March* then next ensuing, to the office of the National Vaccine Board in London, or to such other place, from time to time, as one of Her Majesty's Principal Secretaries of State may direct or appoint.

Penalty on Persons fraudulently obtaining or signing Order for Vaccination.

VI. And be it enacted, That every person who shall fraudulently apply for, obtain, deliver, or sign any such order for vaccination as is hereinbefore mentioned, or shall wilfully introduce into such order any false statement, shall be guilty of a misdemeanour, and, being convicted thereof, shall be punished accordingly.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

May 26, 1840.

THE PRESIDENT IN THE CHAIR.

—

A Case of Aneurism of the Arteria Innominata, in which the Carotid and Subclavian Arteries were tied. By W. WICKHAM, Surgeon to the Westminster Hospital.

THE patient was a tall spare man, of sallow complexion, 55 years of age, and had followed the occupation of a sailor. He was admitted into the hospital, in September 1839, with a swelling over the right clavicle, about the size of a hen's egg, and having all the characters of aneurism of the arteria innominata. This tumor extended over the carotid artery at its lower part, reaching as high as the omohyoideus muscle, and also reaching outwards over the subclavian artery. As it appeared impossible to place a ligature on the affected artery with success, the author, in consultation with his colleagues and Sir A. Cooper, determined on tying the carotid and subclavian arteries.

In pursuance of this resolution, the carotid was tied on the 25th of September, 1839, without any unusual circumstances. Immediately on the ligature being tightened the sac was evidently reduced in size, and the force of the pulsation in the tumor was diminished. The cough and dyspnœa also were immediately and greatly relieved. At the end of three weeks the patient quitted the hospital, contrary to advice, and promised to return in a week or ten days. The tumor at this time was of the diminished size to which it had been reduced at the time of the operation. Unfortunately, however, the man did not return until compelled to do so by dyspnœa, the consequence of the rapid increase of the tumor to more than double its original size. On the 23d December, it was determined to tie the subclavian artery, notwithstanding that the patient appeared to be almost at his last gasp from suffocation, and that great fears were entertained lest he should expire under the operation. As soon as the artery was tied, the dyspnœa was so much relieved, that the man walked to his bed with ease, and from that time until he died he continued free from any inconvenient pressure on the trachea. Four days after the operation he was suddenly seized with delirium, which, however, was soon relieved. From this time the tumor slowly increased; but he recovered his strength sufficiently to wish to leave the hospital.

On the 5th of February, the ligature having come away previously, he left the

hospital, and lived till the 16th of that month, when he died from hæmorrhage, the consequence of the bursting of the sac. Dissection showed the disease to have been seated, as was supposed, in the arteria innominata.

A preparation of the diseased parts was shown to the Society.

The Secretary of the Society requests us to state that a case was read on the 12th May, by Mr. Blizard Curling, Assistant-Surgeon to the London Hospital, of a rare species of hydatid (the *Echinococcus hominis*), having been found in the human liver.

—

PATHOLOGICAL DEPARTMENT.

June 2, 1840.

MR. ARNOTT IN THE CHAIR.

Polypus of the Heart.

Dr. Boyd placed before the Society a preparation of a heart, to the walls of the left auricle of which there adhered, by a firm pedicle, a true polypus growth. This substance was about the size of a small chestnut, of a globular form, smooth on its surface, and covered by a thin membrane continuous with the endocardium. It hung somewhat loosely in the cavity of the auricle, attached by its pedicle, which was short, and about the thickness of one of the fingers. The heart had been injected with size and vermilion by the coronary arteries. Upon a section of the tumor being made, it was found to consist of a substance which resembled the fibrin of the blood much condensed; presenting only in one part, towards its surface, the appearance of the colouring matter of the blood. When it was examined carefully, two or three small vessels, containing injection, were seen entering into its substance; and when portions taken from near its neck were placed under the microscope, numerous delicate vessels were distinctly apparent. In the centre of the tumor there was some extravasation of the injection. The heart was generally hypertrophied, and weighed 13 ounces, being about one-third above the average weight.

The patient, from whom the specimen was taken, was a man 73 years of age. When brought into the Marylebone Infirmary his vital powers were extremely low: he had hemiplegia, and his pulse could scarcely be felt; hence no particulars of the history of his illness that were satisfactory could be obtained. He died of diarrhœa fourteen days after his admission. Upon examining the brain, a firm clot of blood was found in the left hemisphere.

Dr. Boyd was unwilling to hazard an opinion as to the origin of the morbid structure in the preparation. In favour of the supposition, that it had proceeded in

the first place from a deposition of the fibrin of the blood upon the surface of the auricle, and which had subsequently become organised and adherent, he showed to the Society a preparation, belonging to Mr. Kiernan, of the left iliac vein. This vein contained a clot of fibrin, and, into the interior of the fibrin fine blood-vessels could be traced from the surface of the vein. Mr. Kiernan obtained his preparation from the body of a female, who had died with a large tumor situated in the abdomen, and in which he had carefully injected the arteries of the part. He referred likewise to a tumor in the heart, very similar to the specimen which he exhibited, that had been shown to him by Dr. Hodgkin.

Dr. Clendinning was disposed to consider, that as the tumor in question had the name polypus applied to it, so its growth resembled that of polypi in other organs of the body; for example, the nose. He confessed that he spoke with diffidence on the subject; but he thought it easier to account for the pendulous appearance of the tumor, and the continuity of the membrane which covered it, with that of the interior of the heart, by supposing that the morbid growth commenced beneath the endocardium, and was gradually developed under that membrane, than by any other explanation.

Mr. Arnott remembered to have been present at the examination of a body, some years ago, when a tumor, similar in appearance, and also in regard to its situation, to that shown to the Society by Dr. Boyd, was discovered. It was of a globular form, of firm consistence, and was attached by a neck, having such a degree of strength, that the whole heart could be raised from the table by lifting it by the tumor. In reference to the preparation on the table, of the iliac vein, in which it was supposed that the clot of fibrin contained within it was injected, he could not avoid believing that the appearances were deceptive. These minute vessels were seen on the surface, and the coats of the vein were also observed to be thickened. Now, it was his opinion that the vein had been originally inflamed; that the result of this inflammation was the deposition of lymph on the surface of the inner coat of the vein; that this lymph on the inner coat had become eventually organized; and that the vessels which had been injected were those ramifying in the newly-deposited membrane, and did not enter into the interior of the clot.

Dr. Williams coincided with Dr. Clendinning in the view which that gentleman had taken of the origin and course of development of the morbid growth in the preparation. He thought that the tumor bore an analogy, so far as regarded

its commencement, to the vegetations or excrescences on the valves of the aorta. In reference to that question which so often presents itself to our minds, in making post-mortem examinations, as to whether the clots of fibrin that are found occupying the cavities of the heart can have existed during life, he wished to state the result of certain observations that he had made. Such clots generally embrace the *columnæ carneæ* and *cordæ tendineæ*. Now he has observed, in various cases, that upon making sections of the clot and the tendinous cords, the clot did not, in fact, adhere closely to the cords; but that it surrounded them loosely, so that there was a considerable space between the clot and the cords. The idea had accordingly occurred to him, that by such observations we might be led to prove that the fibrinous clot had existed and embraced the *cordæ tendineæ* during life; and that the disproportioned size of the canals in the clot, compared with the cords, was the consequence of the incessant motion of the cords during the heart's action, and while the patient still lived.

Mr. Shaw had seen, in a heart which he examined for Dr. Wilson, three or four polypous excrescences, resembling in some respects that brought before the Society by Dr. Boyd. They adhered to the walls of the right auricle, were placed at some distance from each other, and varied in size from that of a pea to a hazel-nut. Instead of being smooth on their surface, as in the preparation on the table, or covered by a membrane continuous with the endocardium, they were rough and somewhat soft in texture, and presented every appearance of their consisting of fibrin. They had a general spherical form, and adhered by narrow stems to the surface on which they were placed. No diseased appearance was perceptible in the lining membrane of the auricle. Mr. Shaw had likewise seen a morbid appearance in another heart, which he thought might be described in this place. It was in a case of hypertrophy of the heart. On opening the left ventricle, a large amount of the dark jelly-like coagulum, which usually occupies the right cavities of the heart, was found. Upon removing this, a great extent of the cavity was seen studded with a fibrinous deposit, which filled the interstices of the *columnæ carneæ*, and also adhered to the smoother parts of the surface of the ventricles. This fibrin was of a hard friable nature, and of a dark colour; and it adhered with great tenacity, so that in some places, even where it was not entangled in the meshes of the *columnæ carneæ*, it could not be removed from the substance of the heart. Upon making sections of the walls of the ventricle, the endocardium was seen to be converted, at different

points, but more especially in two circumscribed parts near the apex, into a dense substance like cartilage; and it was at these parts that the adhesion of the fibrin was so firm.

Cartilaginous deposition on the surface of the spleen.

Dr. Clendinning exhibited a preparation of a spleen, on the convex surface of which a thick layer of a substance like cartilage was deposited. A section of the spleen had been made through the centre of the newly-formed part, so as to exhibit its thickness, which was about a third of an inch at the most prominent point, gradually decreasing towards the circumference. The cartilaginous deposit covered a space about an inch and a half in diameter. It appeared to involve both the fibrous and peritoneal tunic of the spleen. No particular symptoms had been observed during life in connection with the morbid structure.

Dr. Clendinning offered some observations as to the probable origin of this deposition; and likewise as to the formation of those opaque patches, so frequently observed on the surface of the various solid viscera of the abdomen and the heart. He combated the idea that they were invariably the result of inflammation, and considered that they depended on a modified action of the nutritive process. He possessed the most extensive opportunities of witnessing the dissection of bodies at an advanced age; and in scarcely one did he fail to find those changes in the surfaces of the organs referred to more or less distinctly marked. He was therefore induced to think, that the appearances in question were the result of a kind of action to which he would give the name of *aging*, in the particular parts.

Dr. Williams entered at some length into the history of the opinions as to the origin of the opaque spots so often seen on the surface of the heart, and alluded to by the former speaker. When he reflected on the largeness of the proportion of those cases of rheumatism in which the heart was affected coetaneously by inflammation seated either in the endocardiac or pericardiac lining, he was led to entertain the view, that these partial opacities resulted from inflammatory action.

Mr. Shaw saw many difficulties in endeavouring to comprehend how inflammation, affecting a membrane, prone like the pericardium to have the inflammation attacking it rapidly diffused over its whole extent when once it has commenced, and to have layers of lymph thrown out in abundance, so as to glue the two surfaces together, should occasionally be limited in its action within the narrow compass of the spots alluded to in the discussion, and give rise to no other change but opacity. Scarcely was a heart to be examined in

which an opaque spot on the anterior surface, near the base, was not to be seen. However beautifully transparent might be the pericardium covering the greater part of the surface of the heart, and however healthy the subject, still the patch of opaque membrane referred to was visible in nearly every body that was dissected. Such considerations made him slow to believe that they resulted from inflammation, especially an inflammation such as that which accompanies rheumatism. Nevertheless, he had observed, during the last winter, an appearance which seemed to bear upon the question. Upon showing at lecture the structure of the heart, in a heart removed from a patient about ten years of age, and who had died from the effects of an accident, he observed a circumscribed spot of inflammation on the very part where the opacity is generally seen. There was a bright red appearance, caused by increased vascularity, and a certain softening of the pericardium, in a space not larger than what might be covered with a shilling, just in the line of the septum ventriculorum, near the base of the heart. Every other part presented a perfectly natural appearance. Mr. Shaw considered it highly probable that, if this patient had survived, and the inflammation had subsided, an opacity in the pericardium would have been the result.

Mr. Charles Hawkins described a tumor that was found lying perfectly detached in the peritoneal cavity of a man whose body he had examined. It consisted of a dense substance like cartilage, and was about the size of a hen's egg. He conjectured that it had originally been a growth formed upon one of the viscera of the abdomen, and adhering only by a narrow pedicle, and that the pedicle had been gradually absorbed, so as to allow the tumor to fall loosely into the abdominal cavity.

Ununited fracture through a node on the tibia.

Mr. Arnott exhibited portions of the bones of the leg of a patient now under his care in the Middlesex Hospital. Before describing the appearances of the bones, he related briefly the history of the case. The patient, about twenty-two years of age, in the months of May and June of last year had been under the care of a surgeon for eruptions on the skin, and a node upon the right tibia. Mercury was given, and the patient left the hospital cured of the eruption, yet without the swelling over the tibia having entirely disappeared. After seven days he was brought to the Middlesex Hospital with a simple fracture of the bones of the right leg, in the situation of the node. It had occurred by his tripping and falling. The fracture was found to be oblique; and spasms of the muscles made it impracticable to

keep the ends in correct apposition. Within a few days after his admission ulceration took place in the integument covering the sharp projecting point of the upper broken portion, and matter gathered around the ends of the bones. Various plans were pursued to subdue the disposition in the muscles to be spasmodically affected, and to regain the proper length of the limb, which was much shortened in consequence of the retraction of the lower portion. Nothing, however, succeeded; and, in the meanwhile, the matter surrounding the seat of the fracture increased in quantity, and had a sanious appearance: sinuses formed in the direction of the knee, and the bone became more and more swollen where it was broken. Believing that the chief cause of the unfavourable condition of the limb depended on the peculiar state of constitution of the patient when he met with the accident, Mr Arnott endeavoured, by various plans of treatment, to correct that condition. He was reluctant at first to administer mercury, and accordingly gave him sarsaparilla combined with iodide of potassium. Subsequently he gave him the bichloride of mercury, from which the patient derived temporary benefit: the discharge diminished, and presented a more healthy appearance. No union, however, had taken place, although many months had elapsed. Mr Arnott determined next to try the effect of bandaging the limb with splints, so as to permit the patient to walk on crutches; but this plan was attended with no good results. He had recourse now to tonics, and gave him quinine, preserving the opening for the discharge of the matter at the wound free. Afterwards, he returned once more to mercury, and put him under a course of blue-pill till salivation was produced. As all these means failed, he felt himself called on to cut down upon the bones at the seat of the fracture, to endeavour to ascertain whether any detached portion of dead bone was interposed between the fractured extremities, so as to prevent their union. He could not, however, find any such loose piece of bone. During the months of February and March, the patient was seized with repeated attacks of erysipelas, and great fears were entertained for his life. Upon his recovery from these attacks, Mr. Arnott determined to remove the limb below the knee, and amputation was accordingly performed in the end of April. It has to be added, that no indications of syphilitic disease were to be observed in any of the other bones, during the long period that he remained in the hospital.

On examining the condition of the bones of the leg, it was first noticed that union had taken place in a perfectly solid manner, and without any preternatural ap-

pearance, except a certain degree of shortening, in the fibula. In regard to the tibia, the two fragments were joined together by a thin bridge of bone at the back part. They were displaced very considerably. Both ends were swollen by the accumulation of granulations of new bone, which assumed the appearance of caries.

Mr. Arnott observed that the dissection of the limb had convinced him that it was not in consequence of any peculiar state of constitution of the patient that union had not been procured. This was evinced by the perfect union that had taken place in the fibula. He conceived that the unfavourable course which the accident took was owing to the fracture having occurred in a part where the bone had been previously diseased. It followed from there being this disease seated in the bone, that matter very early accumulated around the broken extremities of the tibia; so that the fracture was converted from a simple into a compound one, and caries then commenced in the ends of the bone. Moreover, the retraction of the inferior portion of the tibia, caused by the spasmodic action of the muscles of the calf, aided by the oblique course of the fracture, could not be counteracted so as to bring the surfaces into a favourable position for effecting a union.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

— FRACTURES.

Fracture of the Neck of the Femur, continued.

—Treatment—Osseous Union of Neck, why unfrequent?—PATELLA—Symptoms—Diagnosis—Prognosis—Treatment.—Bones of the Leg—Tibia—Fibula—Bones of the Foot—Calcis—other bones.—STARCH BANDAGE—Inflammation of bone—Abscess.

Treatment.—The reduction of fracture of the neck of the femur is as easy to accomplish as it is difficult to maintain. Counter extension is made either by an assistant holding firmly the pelvis, or by passing under the injured thigh a band; another assistant seizes the foot, and makes extension at first in the direction of the displacement, and afterwards in its natural direction, until it is restored to its proper length.

Here the hand applied to the point is almost useless, because of the thickness of the part surrounding the joint, yet, in some cases, the surgeon raises the great trochanter and directs it forward, to lessen the tension of the posterior part of the capsular ligament, and to facilitate reduction.

Before we proceed further, I must refer you to Sir A. Cooper: he says, "Deceived in my endeavours to cure intra-capsular fractures, and seeing the health of patients suffer under the action of the means employed to procure union, if I were myself the subject of this kind of fracture I

should place a pillow under the whole length of the limb, another should be rolled up and placed under the knee, and the limb should remain in this state for ten days, or a fortnight—until, in fact, pain and inflammation had disappeared; then I should get up, sit in a high chair, and, for the purpose of preventing painful flexion, and going on crutches, I should at first rest the foot lightly on the ground; gradually I should rest more upon it until the ligament was thickened, and the muscles had recovered their power; then I should use a high heel shoe to lessen my lameness. Thus treated, patients in an hospital get about on crutches in a few days, and, after some months, they can get about without any assistance." This advice has been a good deal followed at home and abroad; but a question here suggests itself—are we never to attempt to procure union in intra-capsular fracture? This would be an unhappy conclusion to come to, because, in the first place, I believe osseous union may take place in intra-capsular fracture, and, if the parts were kept in apposition, I believe it would frequently happen; and, in the second place, how are we to ascertain whether a fracture be intra- or extra-capsular? So long as this doubt remains, so long all appropriate means of treatment should be employed.

There are few fractures for which so many machines have been invented, and the insufficiency of most of them has been freely acknowledged. It is necessary to use such an apparatus as will permanently oppose displacement: those by which continued extension is applied are, I think, alone capable of fulfilling this indication.

Among the apparatuses for making continued extension, many incompletely accomplish the object; that of Vermandois is one of the earliest extension apparatuses in which the principle is properly carried out: it resembles that of Desault, though

more complicated, and, therefore, less generally applicable; but I think the straight splint, with all its simplicity, answers the purpose better. In many cases, Mayor's apparatus succeeds, especially where the fracture is complicated; but probably, of all, Hagedorn's idea is the most ingenious: he has a long outside splint, from which proceeds a foot board wide enough to receive both feet, which are fixed upon it; thus extension of the fractured thigh is made, whilst counter-extension is kept up by the sound limb.

The semi-flexed position of Pott is open to more serious objection than in fracture of the shaft: the position on a double inclined plane is better, as in the method of Earle, Bell, Dupuytren, Amesbury, and others. Some surgeons employ exclusively the semi-flexed method; they prefer it to the straight position, because "the inconvenience to the patient is less, and because the results are more advantageous."

Yet it is scarcely possible, unless the fragments be involved one within the other, to obtain by this plan a cure free from deformity or shortening. For these reasons I prefer the extended position, because I believe a cure almost without shortening may thus be obtained. Still I have no hesitation in expressing my belief that the advantages of this position have been much exaggerated, and that, in most cases, shortening, to a certain extent, exists.

Here I terminate what I have to say upon the means employed in the treatment of fractures of the femur. I have alluded to many plans, but it is impossible, at this time, to consider them more at length.

We have seen that permanent extension forms the basis of most of them; there are certain circumstances connected with this plan of treatment which must not be lost sight of. In many persons, in consequence of the extreme delicacy of the skin, compression excites severe pain, inflammation, and even gangrenous spots; and this is particularly to be looked for in women, and old or debilitated persons. Often they oblige us to abandon permanent extension, and to limit our treatment to position; yet these inconveniences are not of such a nature as should cause us to discard this method; but they should induce us to watch carefully that no improper pressure is made. When well applied, the plan has this great advantage, that the necessary motion of the patient will not derange the fragments. It has been recommended, as a means of facilitating those movements, that a broad strap should surround the pelvis; that a cord should be attached to it, and pass through a pulley; that one end of the cord should be within the patient's reach, who can thus

raise himself with very little trouble. Under favourable circumstances, consolidation of a fracture of the neck of the femur is a tedious business: the patient should not get up in less than two months, and should rest no weight on that limb in less than three months, and even then not without crutches. But even with all our appliances, perfect coaptation of the fragments can scarcely be expected; all that our art can do is to restore the limb to its proper length, to struggle against the tendency to rotation outwards, and to maintain things in this state long enough to allow of fair consolidation. Again I say, our means for accomplishing these objects are imperfect: permanent extension is I believe the only means by which the proper length of the limb can be maintained; but, in many cases, patients, and especially aged persons, cannot bear it. The tendency to rotation outwards is, perhaps, never completely overcome: the means which are employed upon the foot for the purpose do not completely overcome it; for a portion of their action is lost at the ankle and knee joints.

THE PATELLA.

The form, the size, and the mobility of the patella, enable it to elude many of those shocks which tend to fracture it, and to the action of which it is greatly exposed; but its peculiar position predisposes it to fracture from muscular action. Those fractures produced by muscular action are more or less completely transverse; those occasioned by violence applied directly on the part are very variable. The patella, when fractured by the contraction of the extensors of the thigh, usually suffers, in the action of jumping, kicking, or in an attempt to balance the body at the moment of falling: when fractured by direct violence, it happens in a fall upon the knee—in striking the knee against some hard body. In the former case, the patella is placed in a very unfavourable position; for when the leg is flexed on the thigh, its posterior surface no longer corresponds in its whole extent to the former, whilst its inferior angle, deprived of all support, is firmly held by the ligament, as in fig. 1; but the extensors have as much more facility in rupturing it as the limb is more flexed, and the power is applied more perpendicularly to its fibres. See diagram 2.

In many cases, the fall is not the cause, but the effect of the fracture; and thus it happens, frequently, that the contusion of the part does not seem to bear any proportion to the presumed intensity of the force of a blow sufficiently violent to fracture the bone. When a patient is in the erect position at the moment of the accident, the first effect is usually to fall on the knee, in

Fig. 1.

Fig. 2.

consequence of the sudden and involuntary flexion of the leg. If, on the contrary, the injury has happened in a fall, he cannot get up: if we place him on his legs, he cannot step forward without falling, because the moment the femur and tibia are removed from the straight position, nothing can arrest the disposition to flexion; he may, however, make many steps if the injured leg be slid along the ground, provided he support the body on the sound leg.

These symptoms are common to rupture of the rectus tendon, the ligament of the patella, and fracture of the patella itself; but, in the affection we are considering, it is at the level of the patella, and not above or below it, that the depression caused by the separation of the fragments is to be looked for. In transverse, oblique, compound, or comminuted fracture of the patella, the rectus tends to draw up the fragment into which it is inserted. The displacement which results from the action of this muscle is comparatively trifling, when the fibrous tissue investing the bone is not much injured; and this is usually the case, when the bone is not fractured by muscular contraction: it may be very considerable when that investment is completely destroyed, as is commonly the case, when produced by muscular action. The extent of separation is increased when the limb is flexed, because the inferior fragment is depressed by this action; it is diminished, on the contrary, when the patient is placed in bed, and the heel is raised. The muscles are then relaxed; the fragments are brought nearer to each other; they may be brought into absolute contact, and crepitation may be produced: this Sir A. Cooper denies.

Prognosis.—Fracture of the patella, when simple, has very little tendency to interfere with life; but when comminuted or compound, for obvious reasons, it may involve the knee joint in danger. Even when simple, if it be transverse, it rarely happens that union by bone takes place, and this,

not because "there is not enough of injury done to the part, not because synovia prevents the formation of callus, not because the subpatellar adipose matter is insinuated between the fragments," but because the aponeurosis is completely divided, and the fragments are not in absolute contact. Usually the union takes place through the medium of fibrous tissues, thus described by Sir A. Cooper. The process of ossification is little developed, the inferior retains anteriorly very nearly its natural appearance; the superior fragment is covered by a slight stratum of bone, therefore the process of ossification is rather more active in the superior than the inferior fragment. The posterior surface of each fragment is unchanged. Between the edges of the torn aponeurosis a small quantity of blood is effused; this is absorbed; in a few days replaced by plastic lymph, which is insinuated between the fragments to which it is strongly adherent; this lymph becomes organized, and changed into a fibrous tissue. If the fragments be nearly in contact, this fibrous tissue will be dense, and the fibres short; if they be separated, the medium will be less dense, and the fibres longer. If, after the fibrous union, the fragments be near each other, the functions of the limb are little deranged; but when the interval between them is considerable, the action of the extensor muscles is more or less completely destroyed; the knee is involuntarily flexed, and without a knee-cap progression is impossible. Where the fracture is vertical, or when oblique or transverse, if apposition has been preserved, osseous union will occur: can stronger evidence be required to prove the cause of non-union by bone in the majority of cases? Besides, Mr. Gulliver has shown, that in many cases of transverse fracture, where bony union has failed, osseous deposit frequently takes place on the fractured extremities, so that the fragments assume the appearance of two symmetrical bones. His experiments clearly show that when the aponeurosis is completely divided, as in the fracture from muscular violence, osseous union is not to be expected; that in those transverse fractures in which bony union fails, the fragments and intervening fibrous tissue are plentifully supplied with blood vessels; (the defective reparation therefore is not referable to imperfect nutrition;) that osseous union is simply the effect of irremovable coaptation of the fragments, the provision for which, in certain forms of fracture, is the integrity of the aponeurosis in front of the bone.

Treatment.—The treatment of fracture of the patella consists in a particular position of the limb, and the application of an apparatus for keeping the fragments as

nearly as may be in contact; and this must be speedily accomplished, because the cure is rapid. The proper position is one in which the extensor muscles are relaxed to the utmost extent: this object is obtained by flexion of the thigh and extension of the leg: to accomplish this, we place the leg on an ascending plane, so that the heel may be raised from nine to eighteen inches above the bed on which the patient lies. Sabatier, to avoid the pain in the ham, of which patients complain, when placed in this position, laid the patient on the injured side, the thigh forcibly flexed, and the leg slightly flexed on the leg. If there be much tumefaction or inflammation at the part, it can be properly treated during the time the patient maintains the ascending position; as soon as the tumefaction has subsided, an apparatus for keeping the bones in contact may be applied. I say an apparatus, because the mechanism of all is similar, whether it be the least perfect, the *kiastre*, those of Purmann, of Bass, of Petit, the capsule of Kaltschmidt, the concave plates of Bel-

and others, placed above and below the fragments, those of Brambilla, of Aitken, and Cooper; the principal difference being, that in some cases a long splint was placed at the back of the leg, and in others, a circular compression was made above the knee for the purpose of paralyzing the extensors. All have acknowledged the necessity for acting upon the superior fragment, so as to bring it towards the inferior, which is prevented from descending. The following figure (fig. 3) would represent the more simple of them.

FIG. 3.

The following ingenious apparatus is proposed by Mr. Lonsdale for the purpose. (fig. 4.) What is important in transverse fracture, is strong flexion of the thigh, and

FIG. 4.

continued extension of the leg. Sabatier's position is unsafe, and there is much security against flexion in the long back splint; the endeavour to deaden the action of the muscle is not advisable, and if the other means are attended to, will be totally unnecessary. Although it is well to bandage the limb to prevent œdema, I do not like to rely on the figure of 8 bandage alone, for the purpose of preserving the fragments in contact; I prefer the leather bracelet of Bell and Cooper; but this is one of the injuries in which, if bandages are used, they should be starched. The treatment of longitudinal fracture is much more simple, rest and position are usually sufficient; the knee should be extended, but, except as a matter of comfort, flexion of the thigh is not necessary; a horizontal plane will suffice. But as these longitudinal fractures are caused by direct injury, they are sometimes complicated; inflammation may be intense, and may require very active antiphlogistic treatment: Sir A. Cooper thinks we ought to apply lateral compres-

sion to the patella in these cases. If the injury be complicated by an opening into the joint, the accident is a very serious one; it may be sufficiently so to require immediate amputation. If the circumstances be less unfavourable, we may try to save the limb; we should then endeavour to bring the wound together, and in such a case I knew the white-of-egg compress, placed over the joint, to succeed admirably. Sir A. Cooper suggests the employment of a suture, to make the apposition so exact as to prevent the escape of synovia, and never to use poultices or fomentations, as they prevent adhesion. Two or three months are necessary for complete consolidation; by that time the medium of union has acquired solidity enough to resist the action of the extensor muscles. A case occurred to Dupuytren, where, soon after recovery from fractured patella, the patient was subjected anew to causes of fracture, and instead of the bone the ligament gave way.

In all fractures of this bone passive mo-

tion at the knee should be practised as early as it prudently can. Sir A. Cooper advises that the apparatus should be removed after five weeks in adults; after six weeks in old men; and from the time the fibrous substance which unites the fragments is resistant enough, the limb should be moved each day up to complete flexion. Boyer leaves the apparatus on for two months without moving the limb; but this plan is more likely to be followed by ankylosis.

If, after the cure, the power of flexion be lost, unless a long time has passed we should not relinquish the hope of obtaining the power of moving the knee. Sir A. Cooper succeeded, by frequent exercise, in restoring power to a woman who, eight months before, had fractured both patellæ. In such cases we flex the limb, then desire the patient to extend it; at first, his power of doing so is very small, but after a time we succeed in restoring much of the ability to use the knee.

BONES OF THE LEG.

The bones of the leg may be fractured together or separately, but they most frequently suffer together. They may be fractured at different points of their extent, but the most frequent seat of the injury is the point of junction of the inferior with the middle third—the point where the tibia is thinnest, and is, as it were slightly twisted upon itself. The two bones may be fractured at the same or at different levels, depending on the manner in which the injury has been occasioned. In children the fracture is commonly transverse; in adults it is generally oblique, and in that case, usually, its direction is downwards and inwards, so that the superior fragment projects under the skin at the inner side and front of the leg. The fracture may be simple or compound, with much muscular, or vascular, laceration. If the bone be healthy, I doubt whether muscular action alone has ever been sufficient to fracture it; but where the bone has undergone certain changes in structure, muscular contraction has produced fracture. It has been known to occur in persons suffering from scorbutus and cancer. It may

occur in consequence of a fall upon the feet from a height; and in such cases the superior fragment has been known to be driven through the integuments into the ground, but in the greater number of cases it is fractured by direct violence—the kick of a horse, the passage of a wheel, the fall of a stone, or other violence.

If the fracture be transverse and high, there is little displacement, and patients have often walked about after it; if it be situated near the middle or lower portion of the leg, there may be much displacement; the muscles of the calf, and the deeper posterior muscles, by drawing the foot upwards and backwards, force up the inferior fragment behind the superior, and shorten the limb.

Diagnosis.—Fractures of the leg, in consequence of the superficial situation of the bones, are usually easily distinguished. If the fingers be passed along the inner side of the spine of the tibia, or the outer border of the fibula, an irregularity is easily discovered; this, with the mobility at the point, crepitation, projection of the fragment, and deformity of the limb, render the diagnosis easy.

Prognosis.—These fractures are less serious than those of the thigh; they are rarely accompanied by so much displacement, and are more easily reduced and maintained. When the fracture is near the knee or ankle-joint, motion is for a time interfered with, and the injury more serious.

Treatment.—Reduction is usually easy: an assistant holds the knee firmly, whilst another makes extension of the foot; the hand is then pressed gently upon the part, and the fragments brought into coaptation. Some people apply a compress between the two bones, to preserve the interosseous space; but this is less important than in fractures of the forearm, and is commonly useless. The limb may be laid on a pillow, in the semiflexed position, after the manner of Pott, or on one of the variously modified apparatus in which the semiflexed position is maintained, but the limb should not be laid on its side. The following instrument is used commonly (fig. 5). The bandage, in either case, may

Fig. 5.

Fig. 6.

be of starch, or it may be simple, or the limb may be maintained by junks (fig. 6). It may be extended, and so maintained, by starch or other bandage, or junks, or splints; for certainly position is of much less importance here than in fracture of the femur: it may be treated after the plan of Larrey or that of Mayor; but, on the whole, some modification of the semiflexed position answers best. It is necessary to be careful about the heel, because pressure upon it will sometimes induce a slough. In the machine (fig. 5), there is a hollow to receive the heel.

Whichever means may be employed, it is necessary to be upon our guard against accidents; and before the fortieth day it is not wise to substitute the simple roller for any apparatus which may have been previously used. My own impression is decidedly favourable to the use of one or other of the modifications of the immoveable apparatus; by facilitating moving the limb, in or out of bed, many inconveniences attaching to keeping the bed for a month or six weeks are avoided; and in most cases the patient may move about as soon as the bandage is dry.

TIBIA.

Fracture of the *tibia* alone often follows violence directly applied upon the leg, while the *fibula* escapes. It may be fractured at any point of its extent; it is often transverse, and sometimes the symptoms are obscure. The displacement is not usually great; the fragments do not ride, because the *fibula* acts as a splint to prevent it.

In the majority of cases, this is not a serious injury, and the treatment is simple: it will often do well even with a simple roller, but generally, unless starched, more is required. Where the fracture implicates the knee or ankle joint, the case is very different. In oblique fracture of the superior extremity of the bone, Sir A. Cooper recommends that the limb should be placed in extension; "the femur, in this attitude, tending to preserve coaptation, maintaining the articular surfaces in their exact position." At the same time, a

paste-board splint and a roller must be used. He also advises the use of the double inclined plane when the fracture does not penetrate the joint; but the apparatus, fig. 5, perfectly accomplishes the object. When the inferior extremity of the bone suffers, crepitation is felt at the ankle-joint during flexion, extension, or rotation, and generally there is a slight inclination of the foot outwards or inwards, according to its direction. Sir A. Cooper recommends, as in fracture of the *fibula*, that means be taken to incline the foot in a direction opposite to that which the fracture has given it, and to bring the great-toe in the line of the patella.

FIBULA.

Fracture of the *fibula* is an accident which has excited much more attention than that of the *tibia*. This is at once evident on referring to the elaborate essays on the subject by Bromfield, Petit, Pott, David, Desault, Bell, Boyer, Richerand, and Dupuytren.

The frequency of this fracture is explained by the tenuity of the bone, its superficial situation on the outside of the leg, and by the important part it plays in the mechanism of the ankle-joint. Though the *fibula* may be fractured at any point of its extent, Dupuytren believed that fracture of the inferior extremity of the bone was, as compared to all other fractures of the leg, in the proportion of one to three.

Pott and Fabre first made known the mechanism of this fracture. The *tibia*, resting on the surface of the astragalus, transmits through it the whole weight of the body. The *fibula* has nothing to do with this vertical pressure; it is only destined to complete externally what the internal malleolus does internally. It opposes, like the internal malleolus, lateral motion of the ankle-joint. If the foot be violently abducted or adducted, which may happen in falls, or false steps, the astragalus, in the latter case, presses outwards the inferior extremity of the *fibula*; in the former, the calcis presses the same upwards, with a force equal to the weight of the

fall. In either case, the immediate effect of the effort to which the fibula is subjected is directed, on the one hand, upon its inferior tibial articulation, which might be ruptured were its ligaments not so powerful; in the other, upon the superior tibial articulation, whose surfaces are brought more closely in contact. These articulations resisting, and the bone not suffering outward or upward displacement, it gives way at the point where the least resistance is offered, generally the outer ankle.

When the fibula is fractured, as a consequence of such distortion of the foot, it is almost always at its inferior extremity that it occurs. Directly after the accident, the displacement is not usually great, and its articulation with the tibia, unless the ligaments be ruptured, prevents riding. The displacement is produced principally by the action of the long flexor of the great toe, which draws the fragments inwards towards the tibia. As the upper part of the inferior fragment is drawn inwards, its inferior extremity is directed outwards, and there is no longer any obstacle to the outward displacement of the astragalus; the foot then assumes the position of abduction, and this is as much more decided as the fracture is near the ankle joint, and the outward projection of the inferior fragment greater, (fig. 7*.) The

Fig. 7.

abduction may be so great as to cause the superior articular surface of the astragalus to be directed inwards, and the sole

of the foot outwards. Whatever may be the mechanism by which this fracture is produced, the displacement is always nearly the same; the foot being no longer restrained externally, yields to the action of the peroneal muscles, and carries still further, with it, the outer ankle.

Diagnosis.—Mistaken or unskillfully treated, the astragalus at last may project under the inner ankle; may painfully distend the ligaments and the soft parts; the articular surface may become inflamed; at last the skin may give way, and the joint be opened; then follow suppuration, caries, and amputation, or death. It is, therefore, of serious importance to form a correct diagnosis in these cases, a mistake exposing the patient to vicious consolidation, consecutive luxation, as well as the effects I have just named. Whenever, therefore, we have reason to suspect the existence of this fracture, the part should be examined with the greatest care. When the fracture is seated at the middle or upper part of the bone, it is not so easy to distinguish it, because of the thickness of the soft parts which cover it, and the tumefaction which is often produced in them. When, on the contrary, its inferior portion suffers, surrounded only by tendons, and subcutaneous, the diagnosis is generally easy. We must not, however, be deceived by the apparent depression between the peronei tendons, which is often found in sprains, when the bone is intact.

Symptoms.—Extreme facility in the lateral motions of the joint, unnatural mobility of the inferior extremity of the fibula, severe pain felt by the patient when under examination, the inequality of the fragments, and crepitation, are the ordinary signs of this fracture. Often, the tumefaction is so considerable as to prevent our making out these signs. In those cases we must employ the necessary antiphlogistic means of dissipating the tumefaction, and then ascertain the exact nature of the injury.

The *prognosis*, in ordinary cases, is not unfavourable, if proper means be used; but, if the affection be not recognised, unfavourable or even fatal consequences may result. It is often complicated with luxation of the foot. The occurrence of luxation has now and then caused the surgeon to overlook the fracture, and the most formidable consequences have followed.

Treatment.—Riding of the fragments can rarely happen, because the tibia prevents it, so that extension and counter-extension are not necessary. What is necessary is to bring the fragments together; to slightly adduct the foot, that the external lateral ligament may carry downward the inferior fragment, whilst the inferior extremity of the external ankle is pressed inwards for

* This and several other diagrams we owe to the liberality of Mr. Lensdale, who used them in his very excellent treatise on Fractures.

the purpose of directing outwards the upper end of this same fragment. The reduction having been accomplished, such an apparatus should be applied as will be opposed to the turning out of the foot. For this purpose what is required is, to continue what is done in reducing the bone, fix the

foot in adduction, and impress upon the outer ankle, by means of the lateral ligaments, a sort of continued extension, by which it is kept in a direction downwards and inwards. For this purpose some modification, the following, for instance, of the apparatus of Dupuytren, will be

Fig. 8.

found to answer the purpose best: (fig. 8.) What is essential is, to apply a splint, which shall extend from the knee to four inches below the inner ankle, under which a cushion should extend from the knee to the ankle. A roller is applied, from the knee downwards, to fix them. When it gets to the small of the leg it is passed over the instep, and through the notches at the inferior end of the splint. In this way the foot is inclined towards the splint, is fixed in adduction, and is prevented from being everted; and no painful pressure is exercised upon the seat of injury. The immoveable apparatus answers very well if this principle be kept steadily in view.

Whatever be the apparatus, the consolidation is completed by the fortieth day. The ankle is then bandaged, and the patient must not be allowed to walk without crutches. When the fracture is at the middle of the bone the injury is more easily repaired, and there is usually less tumefaction.

FOOT.

The form of the bones of the foot, the little advantage they offer for the action of external violence, their power compared to their length, the resistance offered by the fibrous tissue which unites them, and their mobility, are so many circumstances which render their isolated fractures almost impossible, especially by indirect violence. A direct cause, acting with violence upon a small surface, is alone capable of producing it, and then there is always either a wound of the soft parts, or a severe contusion, which constitutes a more serious injury than that of the bone. In such cases, generally, several bones belonging to the tarsus, or metatarsus, or toes, are fractured by direct injury, when applied over a large surface. It is thus that the passage of a wheel, the falling of a heavy body, or a fall from a great height upon the foot, usually

produces this kind of accident. In these cases the injury of the soft parts requires most attention, the fracture not requiring the application of any bandage. What was said of similar injuries to the carpus and metacarpus perfectly applies here. Still, among the bones of the foot, there is one whose fractures are susceptible of particular description, because they differ from the others as to causes, symptoms, and curative indications—I mean the calcis.

THE CALCIS, from its size, and the point of insertion it furnishes to the extensor muscles of the foot, is not unfrequently subject to fracture. The more common causes of it are, gun-shot, or other violence, directly applied, pressure between the astragalus and the ground, by coming upon the heel in a fall from a height. In these cases the fracture may occupy different points, and be in different directions. There is also a fracture which is produced by contraction of those muscles which are inserted into the tendo Achillis. This may happen from a fall upon the toes during the exertion of jumping, and in such other circumstances as occasionally produce rupture of the tendon; these fractures, owing to muscular action, are always transverse, and behind its articulation with the astragalus. The posterior fragment is alone displaced by the action of the muscles ending in the tendo Achillis, and it is generally trifling; thirty to forty days are usually sufficient for its consolidation. In some cases the medium of union is fibrous, but in a majority of cases it is osseous.

It is thus characterised: at the moment of a fall upon the feet, or a violent contraction of the muscles of the calf, the patient feels a crackling, and falls down; an acute pain is felt at the heel, and he can neither raise himself, walk, nor move the foot. The heel is a little less projecting and higher than usual, but this is not con-

siderable, because the posterior fragment is retained by the aponeurotic fibres which are fixed upon it.

A simple fracture of the calcis is not a serious injury, but it may be so, when complicated by a wound or violent inflammation, or the presence of a bullet or other projectile; it may cause caries or necrosis. It is easy to reduce this fracture; the knee is flexed, and the foot is completely extended; the fragment is then usually replaced without difficulty; but it is not so easily maintained. For this purpose, the position in which the limb is placed, to reduce it, must be continued, as in the rupture of the tendo Achillis. Heister states that a surgeon of Paris, finding it difficult to maintain reduction, cut the tendon. The apparatus we figured in treating of rupture of the tendo Achillis brings up the inferior fragment, but beyond relaxation of the muscles of the calf, it is necessary to act upon the superior fragment. This may be done by using such an apparatus as Monro employed for making perfect extension in rupture of the tendon. Elastic gum rings will serve to keep down the upper fragments, and the whole may be well kept together by a starch bandage. The patient must not too soon begin to move. To avoid the great dragging of the muscles upon the posterior fragment, the patient should at first use a high-heeled shoe, the height of which may be diminished from day to day until the foot is restored to full freedom of action.

STARCH BANDAGE.

Having made frequent allusions, while treating of fracture, to the starched bandage, some further remarks may not be out of place. The old treatment of fractures necessitated long confinement to bed, which, besides other inconvenience, caused at certain points by pressure, generally produced considerable derangement of the digestive and other functions, even when the accident occurred in a person in good health; all these matters were aggravated if the patient were out of health or advanced in age. The plan of Amesbury was intended to remove these inconveniences, to preserve immobility of the injured part, without confining every other part; the young man was no longer to be ennuied; the old man was no longer to exhaust his little remaining power by confinement in bed; both might in many cases, after three or four days, attend to their ordinary occupation.

The starch bandage invented by Seutin, may be constituted of a common roller or a tail bandage; in either case the starch is not applied upon the skin, but upon the outside of the first turns; over this a second turn of the bandage is passed, over that a second layer of starch, and so on.

A tail bandage, or a common roller, may be used; if the latter, each toe is rolled; extension and counter-extension are then made by assistants; the bandage is rolled from the foot to the knee. The first layer being applied, it is covered over with starch; two card-board splints, previously softened by immersion in starch water, are placed on the sides of the leg, in front of the limb; they leave between them an interval of an inch, in which, when necessary, the bandage can be easily cut. A second bandage is rolled over these splints, another thick layer of starch is laid on, and over this a simple roller. The limb is now put to rest on a simple cushion, and the bandage tied: if left to itself, this may occupy from 36 to 48 hours, but it may be accelerated by bags of hot sand, by heat of the sun, or other contrivances. When the fracture is simple and without wound, this is the ordinary apparatus; but if it be compound, holes are made in the apparatus to correspond with the wounds; the fragments are thus kept steady when the wound is dressed. As soon as the apparatus is quite dry, it forms a firm cast, which surrounds the limb, maintains perfect immobility, and allows of the patient moving freely in bed, or about on crutches, the limb being supported in a stirrup. Seutin applies the apparatus at once; neither tumefaction, nor inflammation, are with him obstacles; he has no fear of gangrene; if, by inspecting a toe, any suspicion of evil is raised, the bandage is slit down for a certain distance, and another roller applied to sustain the parts. Although the apparatus does not relax, after a certain time it is less exactly applied upon the limb than it was at first; the tumefaction has disappeared, or the soft parts are to a certain extent atrophied; in this case, if considerable, he makes a section of the apparatus, and applies another roller which causes the cut borders to overlap.

Although Seutin and Velpeau have no hesitation in advising the use of the apparatus whenever the patient applies for relief, whatever may be the state of the parts, I have. If you apply the apparatus before tumefaction has come on, gentle compression will restrain it; if great tumefaction be already developed or in progress, you had better wait for it to subside, or you will find the apparatus soon very loose, or strangulation and gangrene may occur. Seutin also believes, that the moving about tends to produce a more rapid consolidation; this may be fairly doubted, as we know that perfect immobility of the fragments is probably the most essential element of cure. I readily admit that it is a serious evil for an aged, emaciated, or debilitated person to be confined to bed, and to respire a vitiated

air; but still it does not follow that we ought to order him to move about. To give him the power of changing his position in bed as often as he likes, to remove him to a sofa or a carriage, all of which the starch apparatus admits of, is no slight boon; but if you go beyond this, you go, in my opinion, further than is prudent, and expose your patient to the danger of an artificial joint, or a deformed callus. And even to admit of this, it is necessary that the adaptation of the apparatus to the limb should be exact; and for this, careful watching and the longitudinal section may be required, which defeats one of the objects accomplished by the bandage, cheapness. It seems to me better to renew the apparatus than to do this; or it may be accomplished by softening, with warm water, the part between the edges of the mill-board, and then applying a roller which will bring all in contact, or by pouring into the space enough of semi-fluid plaster to fill it up.

The assertions of Sautin are not simple theoretical speculations, but deduced from numerous cases observed by him, or communicated by eminent Belgian surgeons who have adopted the plan. Those cases, in his last report, amounted to 151. It has been much used in France; Velpeau alone, twelve months ago, stated that he had particulars of 150 cases treated in this way. To what extent it has been used in this country I cannot say; Mr. Arnott has used it with good effect, and my own experience of it, during the last two years, is very favourable. Its inventor uses it in all kinds of fracture, and it certainly is a good auxiliary to any system of treatment which may be employed. He also uses it in luxations, sprains, wounds of joints; in fact, wherever immobility is desirable. In wounds, in sarcocele, in tumors of the breast or other glandular structures, in club-foot, and a great variety of other affections.

OSTEITIS.

In spite of the numerous observations which we possess relative to inflammation of bone, I am not satisfied that we possess, even at the present moment, any facts which present all the characters of inflammation of other organs, namely redness, heat, pain, and swelling. It is not that we do not often meet with, in patients, some of these symptoms, because we often see persons suffering from severe pain in the interior of a bone which is enlarged, and the hand applied to the limb experiences considerable heat; but is there here a great vascular injection of the bone itself? These are points yet remaining to be verified. I have seen bones slightly reddened, and presenting very much of the appearance produced by madder, but the

periosteum was not injected, so that I doubt whether it constituted true osteitis. I have known bones to be evidently tumefied; grasping them I have felt a burning heat, and pressure caused pain. These bones were so hard that I could not refer their enlargement to tumefaction of the periosteum alone, and therefore I judged that the substance of the bone itself was tumefied by the distension of the numerous blood-vessels which penetrate it. Farther, these bones were reduced to their natural condition by antiphlogistic means, long employed. In such a case a fluctuation under the *fascia lata* was apparent; an incision was made, and medullary matter, such as I described in speaking of the periosteum, was exposed.

When, after a fracture, the action is set up by which callus is to be formed, we have often seen, besides tumefaction and infiltration of the periosteum and the soft parts, a certain softening of the fragments of bone, a disappearance of their angles, and consequently, I apprehend, an organic action in the bone itself, characterised by increased vitality. This state, I think, may fairly be called inflammation, though the physical phenomena proper to inflammation of soft parts are wanting. In certain cases of caries, the bone is unquestionably inflamed; this is proved by the redness of the ulcer, and the state of injection of the delicate web which lines the cells. Again, in certain cases of regeneration of bone, it is not only the external and internal periosteum which are charged with the work of reparation, but also the laminae of the healthy bone itself. Now how could this happen without inflammation?

I therefore assume that there is true inflammation of bone, not that it is manifested by the ordinary signs of inflammation of the soft parts, such as a vivid redness, and an evident vascularity; but by a very sensible development of the vessels of the external and internal periosteum, and those which creep between the laminae and fibres of the bone itself; probably by an injection of the membranes, which, according to Howship, line the osseous canals; by an increased activity of the whole vascular apparatus, whose business it is to secrete the materials for repairing that which has been destroyed. What I have now said more particularly applies to inflammation of the compact substance of bones; in the spongy structure the signs are more decided.

Inflammation of bone may be acute or chronic; but although this distinction can be made out, the progress of the acute form is so slow, as compared with the acute inflammation of other tissues, that, by some persons, it is held to be always chronic. It is hardly necessary for

me to point out, in this place, the various pieces of evidence upon which those opinions rest, because the distinction is practically of no importance; it is simply a difference in duration; the causes, the symptoms, the consequences, and the treatment, of one and the other, are similar. I prefer, therefore, to include both varieties in a single description, merely wishing you to understand, that while the one passes through its period in some weeks or months, the other may exist for years.

The disease is more common during childhood than in after life; it may affect any bone, but most commonly attacks those whose texture is spongy; those of the carpus, the tarsus, the spine, and the articular extremities of long bones.

Causes.—The causes of this disease are numerous. They may be local or general. Among the local external causes are contusions, wounds, fractures, pressure. Among the local internal causes are periostitis, purulent collections in the neighbourhood of joints. Among the general causes are, it is said, scrofula, scorbutus, syphilis, rheumatism, and gout. With respect to syphilis, it is proper to state, that some pathologists attribute the affection of the bone to the use of mercury; others, to a combination of syphilis and mercury. The difficulty which attends our endeavours to estimate this joint cause is, that most persons suffering from syphilis take mercury; and that the cases in which syphilis, left to itself, affects the bone are very rare. Rheumatism again seems first to attack the fibrous tissue which invests the bone, and is from thence propagated to the bone itself; therefore it is, I apprehend, that rheumatic caries is generally superficial.

Symptoms.—When the affected bone is superficial, the symptoms are very conclusive; there is tumefaction, sometimes limited to a part, sometimes extending to the whole bone: this tumefaction is usually preceded and accompanied by a sense of weight, and an obtuse pain, which is particularly felt whenever the limb is shaken. If the affection be syphilitic, the pains are acute, deep seated, seeming to occupy the centre of the bone, more severe by night than by day, and commonly depriving the patient of sleep. When the inflammation is owing to other causes, the pains are rarely severe, before those tissues which adhere to the bone are affected. When the affected bone is accessible to the touch, the tumefaction is easily distinguished and appreciated; but when it is deep-seated, this symptom is either wanting or difficult to appreciate; and it is only by the weight, general tumefaction, and the deep heavy pains which are felt, that we can recognize the disease; and even then they may be confounded with the symptoms of peri-

ostitis. The extreme hardness of tumors formed by inflammation of bone, and the slow progress it makes, are not always sufficient to distinguish it from chronic periostitis.

Some persons have denied that tumefaction of the spongy extremities of bone can occur; but there are specimens to prove that it really can happen. Under the influence of syphilis, the diaphysis suffers; but these extremities suffer where scrofula is the exciting cause.

Sometimes it terminates in resolution or ulceration, suppuration or necrosis; sometimes it ends in a kind of induration, which has been termed ivory exostosis.

Anatomical characters.—It is less easy than is commonly thought to determine the anatomical characters of osteitis, and to distinguish them from caries or tuberculous infiltration. The dilatation of the cells of the spongy tissue, the separation of the laminae of the compact tissue, are the most constant and best established changes of structure in osteitis. Another common change is a modification in the consistency of the bone; it becomes more fragile or softer; it may, however, become harder and more resistant. The change of colour is important: when inflammation has extended from the circumference to the centre, a brownish red spot appears on the surface, and the periosteum at this point is irritated and thickened. As the inflammation extends in depth, tumefaction increases, the cells and laminae are dilated, and the vascular system is developed. Between the laminae, and in the cells, a reddish or greyish-brown sanious fluid is seen, and caries or abscess is then impending; in the latter case the pain is very distressing, and the sympathetic re-action very great: this is principally owing to the pus being secreted in a part where the tissues have very little disposition to expand.

Treatment.—The treatment of osteitis is rarely simple, because the cause is rarely so. Syphilis, scorbutus, scrofula, rheumatism, and gout, must be treated appropriately; local remedies alone will not subdue the disease produced by these causes; neither will the general treatment always suffice. The local treatment will be directed against the inflammatory action and the pain. Leeches applied again and again, with intervals of two or three days, are often useful, associated with emollients; they may be followed by blisters, by iodine, by mercurial inunctions, and even issues; but, in using the latter, they must not be applied too near the diseased point, or they may aggravate the evil.

ABSCESS.

Deep-seated inflammation of bone may end in abscess, an affection of great severity,

which, from the time of David to that of Brodie, has been completely overlooked. In 1764, David's Memoir, on the mode of opening abscesses in different parts of the body, was crowned, with a double prize, by the Ancient Academy of Surgery. In speaking of abscess of bone, he says, "Bones are susceptible of inflammation and of tumor in their substance; these tumors may end in a species of suppuration which is proper to bones. If the swelling proceed very slowly, the pain will not be very severe; but if it be less slow, the pain will be very severe; the heat at the part will increase, and, in the proper substance of the bone, a kind of suppuration takes place, which may take an outward or inward course, towards the medullary membrane or the periosteum. It is very difficult (desirable as it is to open them early) to determine their existence, especially when there is no perceptible external tumor. The symptoms upon which we must rely are a heavy pain in the bone, confined to one spot, and becoming more and more severe; over the point there is a doughy or œdematous sensation; soon the pain becomes severe and gnawing, accompanied by sleeplessness, irregular rigors, fever, &c. Abscess, formed in the substance of bone, is one of the cases in which a speedy opening is necessary to prevent serious consequences. It must be done by applying a crown of a trepan over the abscess, provided the bone presents a sufficiently large surface for the purpose, as the tibia. If the surface be too small, a strong forceps or other instrument may be available to procure the escape of the pus." Nothing can be clearer than this description; and yet, strange to say, surgical works published since his time do not at all allude to it. The sagacity of Sir B. Brodie in this, as in many other diseases, enabled him, (unaware of David's description), to discover this affection, and to lay down clear and decisive rules as applicable to its treatment.

AQUO-CAPSULITIS,

WITH HYPOPION AND ULCER OF CORNEA.

To the Editor of the Medical Gazette.

SIR,

I SHOULD feel obliged by your finding a place for the following observations on aquo-capsulitis, with hypopion and ulcer of cornea, in your valuable columns.—I am, sir,

Your obedient servant,

EDWARD HOCKEN.

Exeter, May 20th, 1840.

Aquo-capsulitis, with hypopion and ulcer, is a form of disease which not unfrequently presents itself at the West of England Eye Infirmary, as a consequence of injuries of the cornea, produced by the impingement of angular pieces of flint or stone, projected with violence by the blow of the hammer in stone breaking. As I have nowhere seen aquo-capsulitis thus produced, mentioned in any of the written accounts of authors on the subject, much less as the most frequent cause, I have necessarily come to the conclusion that such cases are peculiar to the situation mentioned, where they infinitely preponderate over the idiopathic forms.

The symptoms have almost invariably reached the conditions already mentioned, before the case is seen: namely, the formation of hypopion, and a deep extending ulcer of the cornea. The incipient symptoms of the inflammation quickly succeed to the immediate effects of the blow—the pain and hyperæmia: the eye becomes painful, intolerant of light, and profuse lachrymation is induced by examination. A pinkish zone is developed around the cornea, reaching to its edge, a condition which exists in all corneal affections, depending on inflammatory congestion of its own vessels, as distinct from the anterior ciliary. Ulceration commences and progresses in the injured point of the cornea, whilst the conjunctiva inflames, and is finally elevated over the corneal edge by subconjunctival effusion, constituting chemosis. At this stage the patient complains of pain in the globe, of a tensive, lancinating character, increased in paroxysms; some cephalalgia, occasionally dull, but oftener shooting; pain over the brow, especially towards night. The constitutional symptoms are more or less general indisposition, a hard frequent pulse, when the individual is plethoric, or, if the contrary, small, easily accelerated, with apparent power (irritable), but readily compressible; hot skin, thirst, and disturbance of the digestive and excreting organs. This is the usual progress and order of succession of the primary morbid signs, when an opportunity is afforded of tracing their development and existence; but, as before remarked, they have in general already reached this stage before the patient applies for relief. When now examined, the inner surface of the cornea—the aqueous membrane—

is dull and cloudy; usually uniformly so, but occasionally aggravated here and there into spots or rings. There is seen, at the most depending situation, more or less of that morbid secretion constituting hypopion; a deep extending ulcer in the cornea, and the conjunctiva of the globe and lids scarlet, from distended vessels, and elevated around the cornea by chemosis. The pain, the intolerance of light, and lachrymation, and the constitutional symptoms, are as already described. Not unfrequently, the iris is somewhat changed in colour, denoting the complication of the membrane covering its anterior surface, but this rarely to a degree so as to be easily distinguished through the cloudy capsule.

As these cases occur in labouring men, usually plethoric and healthy, they almost invariably demand the active employment of antiphlogistic means, with calomel and opium; under which treatment the generality recover, with complete restoration of vision, unless the unavoidable leucoma which results from the cicatrization of the ulcer immediately cover the pupil.

Idiopathic aquo-capsulitis is undoubtedly most common in early life; but estimating the average from all cases admitted at the West of England Eye Infirmary, their occurrence in the adult preponderates. When occurring in children, they usually present more or less evident marks of a strumous diathesis, and in some cases to so great a degree, and so greatly modify the duration and symptoms, as to have received a separate consideration, under the head of "strumous aquo-membranitis."

As regards the secretion from the inflamed membrane, under all circumstances the aqueous humour is increased, rendering the cornea preternaturally convex, and causing the painful sensation of tension. But, we may inquire, is it the usual termination (result) of such inflammation, to produce that morbid secretion denominated hypopion? Our answer must undoubtedly be certainly, yes; and this quite independent of iritic complication. The usual result of aquo-capsulitis is the production of hypopion, unless the process be previously stopped by active and appropriate treatment; although I am aware that Mr. Middlemore thinks differently on this point. In his excellent description of the affection, he states that such a termination is

rare; and that the occurrence alluded to by Mr. Lawrence (namely, the formation of hypopion) can only be considered as the termination of inflammation of the membrane of the aqueous humour, by admitting that the extension of inflammatory action to the proper iritic substance by which hypopion is produced, may be properly represented as the termination of that inflammation which originally led to the affection of the true iritic structure (Treatise on Dis. of the Eye, vol. i. p. 587.)

The effused matter renders the aqueous humour itself opaque, as is the case in inflammatory effusions from serous membranes. But what is the nature of the effused fluid — what that of the aqueous capsule itself?

That the effusion is not ordinary pus, is evident, although a globular fluid which gravitates to the most depending position, changing its situation according to the situation of the eye, as nothing escapes by an incision through the cornea; nor does it present, when removed, any resemblance in its physical characters to that fluid. Is the secretion lymph? If so, it deviates materially from the usual changes occurring in that effusion under ordinary circumstances. When lymph is thrown out from an inflamed serous membrane, it is so in a fluid state, together with an increased quantity of its own specific secretion; coagulation of the liquid fibrin (lymph) succeeds, part rendering the serum turbid, the rest adhering to by deposition the originating inflamed surface, either as a layer, or in more or less irregular patches or spots, finally becoming organized, and assuming the character of cellular tissue, or as a rigid investing membrane. Part of the changes occur in aquo-capsulitis; the humour is rendered turbid, a few opaque spots may or may not appear on the inner surface of the membrane; but the greater part falls to the bottom as a dense granular fluid, having no disposition to become organized, and possessing physical characters distinct both from lymph and pus; it is, therefore, a fluid secretion *sui generis*.

The aqueous membrane itself is not a common serous tunic, although in early life it doubtless formed a shut sac. Its texture is hard and cartilaginous, extremely elastic, and curls up when removed, exactly similar to the crystalline capsule, which it resembles in every

point: its resemblance to a serous sac consists only, then, as to its original form, and in its normal secretion.

THE INFLUENCE OF WOOLLEN MANUFACTURES ON HEALTH.

By J. B. THOMSON, Surgeon,
Tillicoultry.

[For the London Medical Gazette.]

THE extreme healthfulness enjoyed in woollen factories has probably not attracted that attention from the public or the profession which it deserves. During a residence of several years in a district where the population is much employed in woollen manufactories, no fact connected with our medical topography has impressed me more than the thriving appearance and great exemption from disease peculiar to the children in these mills. So remarkable is this fact that it has become quite proverbial, and puny and weakly children in a few weeks after entering these factories exhibit the most marked improvement in physical appearance. In Yorkshire, I am informed on the best authority that the same opinion prevails, and even the better classes have been known to send the delicate members of their families to the woollen factories for the benefit of their health, and the effect has been to give new stamina to the system. The salutary nature of this occupation has been with much plausibility referred by the working classes themselves to the impregnation of the body in some way or other with the oils among which they are constantly employed: that this manifest health should continue in spite of the confinement so many hours a-day from the open air and free exercise during the growing period of youth, makes the matter still more striking; and although according to the Factory Act, the children work the same number of hours as those in the cotton trade, these sleek-haired, rosy-cheeked boys and girls, form quite a contrast to the puny creatures of the cotton factories, sicklied o'er, as they too often are, with the pale cast of disease and premature decay.

I am disposed to impute the healthfulness of the woollen manufacturers to the quantity of oils they are constantly using, and this is the popular opinion on the subject. When we enter these mills we find the boys and girls appearing

literally as if they had been dipped in oil; and hence the well-merited epithet of Burns, the "*creeshie nations*," belongs especially to these children.

The application of oleaginous substances to the surface of the human body, both as a prophylactic and pharmaceutical agent, has been long in use, and seems to have been known and valued by the earliest practitioners of the healing art. In the present day, as a local remedy, oil is highly esteemed for medicinal purposes; but, we believe, as a general means of procuring and preserving health, it deserves greater attention than it has yet received. Here is the testimony of the illustrious Bacon to its efficacy: "*Ante omnia igitur usum olei vel olivarum vel amygdali dulcis, ad cutem ab extra unguendum ad longevitatem conducere, existimamus.*" In proof of this opinion being sound, we are told by travellers that in eastern countries wonderful effects are seen to follow the use of oils applied externally; and we know that those employed in the olive oil factories, and that oilmen, fishermen, tallow-chandlers, tanners, butchers, and others occupied among greasy substances, are singularly free from the influence of epidemic diseases, and have even resisted the virus of plague when all around has been laid waste by its ravages.

In the periodicals of the day, occasional cases of supposed phthisis and atrophy have been stated to be cured by inunction with lard and oil. The healthful appearance of the children in woollen factories seems to add to the amount of evidence, that oils, applied to the surface of the body, are exceedingly useful for invigorating the system, and ought to lead to their more general application.

As to the *rationale* of the process by which healthy action is induced by oils and unguents, is it not probable that absorption through the skin is one of the adjuvants? Probably, also, the exhalants are relaxed, and free perspiration is promoted. The constant oiliness of the skin would naturally lead us to think the oil must be absorbed; and modern physiologists have given us abundant proof that absorption of fluids may go on to a large extent from the cutaneous surface even when unabraded. May not oil be absorbed by the surface as well as other fluids, and in this way add to the health of those whose bodies are much exposed to it in their daily occupations?

There is nothing in the mere climate or other peculiarities of this locality sufficient to account for the phenomena alluded to; for the average annual amount of disease and of mortality is great among the population generally, and we are visited with most of the diseases which "flesh is heir to," and epidemics frequently spread dismay and desolation among our villages. It may be said, that there is a native constitutional vigour to which the appearance of the factory children may be traced; but this is answered by the observation, that even weak and puny children rapidly improve when sent to the factory. Neither can their health arise from the improved diet or clothing which their wages enable them to procure; for their clothing is very mean, and there is scarcely such a thing anywhere in this thriving district as poverty so great as to make the health suffer from bad diet or deficient clothing. From all these considerations I conclude there is something in the woollen manufactures themselves that has a specific influence upon the health of those employed in them, and especially marked in the *children*, who are most engaged in working among the oil.

When alluding to the exemption from disease which seems to belong to workers among woollen, I cannot help adding a sentence by way of *per contra*. I have never seen anywhere so many cases of the itch as among these woollen mills. But this might surely be obviated by cleanliness. These observations are intended to call forth the experience of other members of the profession, who have, on a larger scale, opportunities of marking the effect of the woollen trade upon health.

ON DIVIDING THE INTERNAL RECTUS MUSCLE

FOR THE CURE OF STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

I BEG to forward you an additional case to those of Dieffenbach and others, illustrative of the utility of dividing the internal-rectus muscle of the eye for the cure of strabismus, an operation giving results as beautiful as they are desirable.

Your obedient servant,

EDWD. J. SCOTT, M.D., M.R.C.S.L.

Surgeon to the Portsmouth General Dispensary.
Portsea, May 6, 1840.

Sarah French, aged 16, has had a squint of the right eye since she was two years old, which was attributed by the mother to a fright the girl received at that period; the eye is turned so much inwards, that but little of the cornea is visible when she takes a direct view.

On Monday, April 27th, I performed the operation in the following manner, being assisted by my friend Mr. Henderson, surgeon of this dock-yard, and by my pupil Mr. Huish:—A cloth was passed round the girl's arms and body, and secured behind the chair in which she was seated: her head was placed against the breast of one assistant, who raised the upper lid of the eye; a hook was passed through the conjunctiva about three lines from the cornea on the inner side, by which the eye was everted. The conjunctiva was now divided about a line internal to the hook: this was followed by a few drops of blood, which were cleared away by a wet dossil of lint, and a bent probe (as employed by my friend Mr. Lucas,) was introduced and easily passed under the tendon of the rectus; this, exposed to view by gentle traction, was divided by curved scissors, and the eye gradually assumed its normal position. Lint, moistened with cold water, was applied, and she was ordered to take a dose of Epsom salts.

28th.—There is slight chemosis of the conjunctiva, but she has been perfectly free from pain; the wet lint was discontinued, and a shade applied over the eye.

May 1st.—She walks about the house without any protection to the eye, which is looking well and straight; the chemosis is fading.

5th.—The chemosis is now nearly disappeared, and the squinting apparently cured; she pursues her ordinary occupations, and says she felt so little pain from the operation that, if the other eye squinted, she would not hesitate at its being repeated.

REMARKS.—The mode of operating in this case may be observed to be very similar to that adopted by Mr. Lucas in the cases which he has recently published. I perfectly agree with him that it is important to lessen the number of hooks as used by Dieffenbach: a probe or a fine blunt hook bent at an obtuse angle gives great facility in discovering and bringing forwards the tendon, expediting and rendering more certain the entire division of it.

There is one curious circumstance in the case I have just related, that although since the operation the axes of the eyes correspond in all their movements, yet, when the originally sound eye is shut, and the girl is directed to look at an object with the other, the external edge of the cornea reaches the outer angle of the eye, giving the appearance as if she were regarding something away, though she has a distinct view of the object directly before her.

ERGOT OF RYE.

To the Editor of the Medical Gazette.

SIR,

I PERCEIVE, from the last number of the GAZETTE, that you are inclined to adopt the opinion of the late gifted Dr. Hamilton, respecting the ergot of rye—that it “can act in no other way than by influencing the imagination, and that it possesses no superiority in this respect over any other medicine.”

Now I have so very generally observed an increased action of the uterus follow the exhibition of the ergot, that I expect such an effect to be produced by it, as much as I should expect sleep by an appropriate dose of laudanum; and it really appears to me adapted to supersede the necessity for the application of the short forceps, in many cases, where the head rests on the perineum, and the external parts are well dilated, but the unaided efforts of the uterus are insufficient to occasion expulsion. I find, indeed, on inquiry among my medical friends, who are engaged in extensive obstetric practice, that they are well satisfied of the efficacy of the medicine. I have myself in a few instances given it, with seemingly marked effect, when the patient did not know whether it was intended to diminish or increase uterine action; and, consequently, I am at a loss to account for its utility in these cases, on the principle of its influencing the imagination.

I am well aware that generally, and in medicine especially, it is very difficult to trace effects to their proper causes; but, in proportion to the number of cases, I have as frequently found action of the uterus follow the employment of ergot of rye, as I have an increased flow of urine succeed the use of squills, or bilious dejections the use of calomel. It

may be objected, that the specific action of the squills is upon the secretion, while that of the ergot is upon the muscular structure of an organ; but still the analogy appears to me sufficiently perfect for the illustration of the present subject. We find, moreover, the involuntary action of particular muscles occasionally induced, as in ordinary cramp, by irregularities in diet, and other causes.

If, however, you, or any of your numerous readers, more competent than myself, would be kind enough to enter into this subject a little more at large, or inform me, through the medium of your valuable periodical, what medicinal preparation has been found of equal power and advantage with the ergot of rye, in exciting action of the uterus in parturition, I shall feel much obliged.

I am, sir,

Your obedient servant,

T. C. BUCHANAN.

Gloucester, June 4, 1840.

RUPTURE OF THE HEART.

To the Editor of the Medical Gazette.

SIR,

I SHOULD feel obliged by your allowing the following case of rupture of the heart to be recorded in the pages of your journal.—I remain, sir,

Your obedient servant,

J. D. JEFFERY.

Sidmouth, June 1st, 1840.

May 20th, 1840.—By direction of the coroner, I examined the body of Chichester Meddett, æt. 28, about 5 feet 8 inches in height, stout made, sallow complexion. He was found dead under the cliffs, having fallen from a height of about 100 feet, whilst being drawn up with some kegs of spirits, in the act of smuggling. There were a few slight bruises about the body. No penetrating wound, or fracture of bone, that could be discovered. On opening the chest, the pericardial sac was found to be distended with dark fluid blood, which proceeded from a ragged transverse opening, more than large enough to admit the middle finger, in the anterior portion of the right auricle. The heart did not seem to be softened in texture, nor did I discover any symptoms of ossification. I have been informed by his friends that the man enjoyed very good health.

OBSERVATIONS. — I am aware that there is not much of practical interest connected with this case; but rupture of the heart, under any circumstances, is a rare occurrence, and rupture of the right auricle still more so; and I think that every rare accident, as well as every irregularity and anomaly of structure, met with by individuals, should be recorded, for the benefit of the whole profession, and of science.

CASES OF STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

PERMIT me to forward you a few more cases of strabismus, cured upon the method of Dieffenbach, an early insertion of which will greatly oblige, sir,

Your obedient servant,

A. FRANZ, M.D.

19, Golden Square, May 26th, 1840.*

CASE IV.—Arthur M'D—, aged 18, a healthy robust person, who had been affected with squinting since his third year, for which his mother could assign no satisfactory cause, subjected himself to the operation on May 11th, in order to be freed from the deformity. On examination, the right eye was found to be inverted to such an extent, that the inner canthus concealed more than a quarter of the cornea, when the organ was left in its usual position. When the sound eye was closed, he could, with some effort, direct the affected eye so as to look straight before him, but could not turn it in the slightest degree outwards. He could farther only distinguish large objects, and could not read even the largest print. The operation was performed, as already described in the first case, which appeared in the *MEDICAL GAZETTE* on April the 17th. The hæmorrhage was inconsiderable; the edges of the wound in the conjunctiva were brought in apposition by means of a probe. After the operation the eye was found to be slightly everted, its motions being free, except internally. Cold water applications were ordered; a powder, containing Hyd. Chlor. gr. iv., Pulv. Jalap. gr. x., to be taken at night, followed by an opening draught in the morning.

* This paper was accidentally mislaid. It ought to have appeared a fortnight ago.—*ED. GAZ.*

May 12th.—The patient had slept well, and suffered no pain; the medicines had operated freely. No inflammation was present in the eye, only a slight increased vascularity in the neighbourhood of the wound. The pupil was yet directed a little outwards, but on the following day it occupied the proper position.

CASE V.—Mary M'D—, aged 16, the sister of the former patient, also a healthy person, who had contracted this deformity, by imitative instinct, in her third year, desired the operation for the same reason as her brother. The left eye was considerably turned inwards, nearly a quarter of the cornea being bidden by the inner angle. On closing the sound eye, she could evert the affected somewhat beyond the orbital axis towards the outer corner, but could only read large print. The operation was performed on the same day as above, and the hæmorrhage was also very trifling. After the operation the eye was slightly turned outwards; its motions were perfectly free, and sufficed to bring the edges of the wound in the conjunctiva in contact. The same orders for the after treatment were given.

May 12th.—The patient was doing well; the eye presented similar appearances as that of her brother, except that in this case the pupil already occupied its proper position.

Both these patients have gone on favourably since, and were allowed to return home into the country on the tenth day after the operation, when the wound in the conjunctiva had perfectly healed, and no signs of the operation, beyond some redness of the conjunctiva in the inner angle of the eye, could be detected. The motions of the eye, moreover, were perfectly free; not the slightest inversion could be observed, and both eyes acted harmoniously.

CASE VI.—William Nicholson, aged 18, a young man in the full enjoyment of health, had squinted since his fourth year, after suffering from small-pox. The left was turned slightly upwards and inwards, so that one-fourth of the cornea was covered by the nasal canthus. When he closed the right eye he could distinguish large objects, but could not read any print. He possessed, however, the power of turning the eye outwards, a little beyond the orbital axis. The operation was performed on the 14th of May, in the same man-

ner as on the other cases; but the hæmorrhage was more considerable, although not of sufficient extent to impede the progress of the operation. The eye was now in a slight degree everted, its movements being free, except internally. The edges of the wound in the conjunctiva were brought into juxta-position by means of a probe, and the patient dismissed, with the same injunctions as regards the after treatment.

May 15th.—No inflammation was present. The motions of the eye were free. The pupil occupied its proper position. As the outer edge of the wound in the conjunctiva had retracted from the inner, and presented the appearance of being somewhat thickened in texture, and was also a little prolapsed between the tarsal margins of the lids when the eye was closed, this portion of the conjunctiva was removed with a pair of curved scissors, a proceeding which caused neither pain nor bleeding.

20th.—The wound had perfectly healed, and a slight irregularity of surface and an increased vascularity were only observable on the conjunctiva of the inner angle.

26th.—The irregularity of surface of the conjunctiva, which was still reddened in the inner canthus, had nearly disappeared, the motions of the eye were perfectly free, the pupil occupied a proper position, and both eyes moved harmoniously.

CASE VII.—Susan Ridgow, aged 22, a girl of plethoric habit of body, with large light eyes, had squinted since her fifth year, after having suffered from measles. The right eye was inverted, so that one-fourth of the cornea was hidden by the inner angle. On closing the left eye she could not read large print, but could move the affected eye externally somewhat beyond the orbital axis. The same operation was performed on the 20th of May, in which she materially assisted by her determination and courage, so that a wound of not more than four lines in length sufficed to bring the muscle into view, which was readily divided. There were but a few drops of blood lost in this case. The movements of the ball were free, and brought the edges of the wound in the conjunctiva in contact. After the operation the eye was considerably everted. The same directions were given for the after treatment.

May 21st.—The patient was doing well, did not complain of pain; only a slight redness of the conjunctiva in the immediate vicinity of the wound was to be observed; the motions of the eye were free, the pupil being still everted, and did not assume its proper place in the centre of the orbit until the third day after the operation.

26th.—The wound had perfectly healed. The pupil continued in a right position. Both eyes acted freely and in perfect unison.

I take this opportunity of making my public acknowledgments to several of my medical friends who have been of assistance to me in bringing forward this operation, and especially to Dr. T. Hodgkin, who kindly afforded me the opportunity of presenting several of my cases to the Harveian Society on May 16, the members of which were perfectly satisfied with the success of this new operation.

COLLEGE OF SURGEONS.

HUNTERIAN MUSEUM.

To the Editor of the Medical Gazette.

SIR,

THE perusal of a remarkable review, in your last week's columns, of Mr. Owen's *Odontography*, has induced me to trouble you with a few observations on a subject which is of vital importance to the profession, and most intimately connected with the progress of medical science in this country. To your criticism it is not my intention further to allude; indeed, it does not require any comment; the facts it reveals speak for themselves, and it is best to leave them to make their due impression upon the minds of all friends of truth and justice, without any further remark: but I deem it right to call your attention to some glaring facts respecting the state of the national museum, of which Mr. Owen is one of the conservators, and from whence the materials of Mr. Owen's work seem to be drawn. A short time ago, being engaged in a course of investigations of great interest to myself, and, I venture to hope, of some importance and value to science, I required to consult and examine many of the series of preparations contained in

the Hunterian museum. Residing at a distance from London, I could not attend there myself, and I therefore availed myself of the assistance of an intelligent professional friend, whom I requested to procure information on certain topics which I communicated to him. He went accordingly to the museum, and wrote to me, on returning to his own house, the same evening, the following note, containing the result of his labours for the day.

“London, 1839.

“My dear Sir,—From the regulations of the Council of the College, or of its servants, I had a very imperfect sight of the preparations, contained, as they were, in cases which only allowed of the display of a few of them, the majority being contained in drawers inaccessible to strangers, as I understood from the officers of the establishment; and of those that were exposed, the majority had no names affixed, and so were of no use to me. Upon inquiring for a catalogue, I was told they were preparing one, and that the catalogue which Hunter had made was not allowed to be shewn. Thus you will not wonder I left as wise as when I entered, but I trust not to do so when next I visit the museum. In the meantime, believe me, your very obedient servant,

“—————*”

My disappointment and surprise on receiving this note were considerable, for I was well acquainted with the zeal which the Council of the College have shewn of late years in their endeavours to render the treasures of our national institution, over which they so ably preside, available and useful to all the members of the profession—to throw them open, as it were, as much as possible, to all students and scientific inquirers; and I was also not ignorant of the reputation of the conservators for ability and industry. Anxious to discover the real state of affairs in the museum, with a view to ascertain what materials might be at my command, I instantly set about making inquiries on the subject in well-informed quarters, and soon found that the state of the case is as follows:—

The first four volumes of the catalogue of the museum were published four or

five years ago; that is, before the completion of the present building. Since that time one additional volume only has appeared, and consequently a great part of the specimens in the physiological gallery remain undescribed. In the gallery of the zoological series, most of the preparations are not even properly numbered. What is still more important, there is no description of the great mass of pathological specimens. Now the Hunterian museum is professedly a pathological one, all its other departments being accessory; that these are necessary I am well aware, and also that they are highly interesting to the accomplished professional student; but in practical importance it must at once be confessed that they are altogether secondary to those pathological stores from which we are to derive the information necessary for our daily practice. Though this is undeniably the case, it is, nevertheless, a fact, that the collection of pathological preparations, including, besides Hunter's specimens, several hundreds of others of a high value, purchased by, or given to, the College of late years, has for *its catalogue only the few pages left by Hunter himself*; and, therefore, there exists no efficient arrangement of it, which can be of any assistance to the student. Besides, of numbers of preparations in the body of the museum, no notice whatever is extant. There is no published description of the magnificent fossil specimens, but merely a scrap of inaccessible manuscript; and of the numerous and highly valuable calculi there is no description whatever. Hearing that the microscope had arrived at great perfection, and that much had been done with it by one of our conservators, in the investigation of osseous tissues, and that specimens of these had been used to illustrate lectures in the College, and had created some curious discussions in geology, I felt desirous to see the preparations, and when in town I inquired for them, but they were not forthcoming. The departments of the museum just mentioned are therefore a sealed book to the profession at large, and cannot be rendered practically available, for any purpose whatever, by any individual except the conservators themselves. Those who are anxiously waiting to study the subjects connected with them must make up their minds to wait on for an indefinite period; and were I, for instance, to

* Our correspondent has sent us the original of this letter, as well as authenticating his own.—
ED. GAZ.

desire to study the subjects, the descriptions of which are contained in the work you last week reviewed, by an examination of the specimens from which the author has drawn them, the wish would be vain. I am well aware that, if it should be inquired what have been the results of the labours of the two intelligent conservators, since the publication of the fourth volume of the museum catalogue, there would be no difficulty in finding an answer to that question, which, as far as Mr. Owen is concerned, would be highly creditable to the industry and talents of that gentleman: the scientific world are well acquainted with his labours; he has annually delivered twenty-four lectures to the members of the College as their Hunterian lecturer, and has been the author of innumerable papers, read at the Royal, Geological, Zoological, Linnean, and Microscopic Societies; he has made lengthy communications to the British and Foreign Associations for the Advancement of Science; he has furnished contributions to the French Institute; has been the author of numerous articles in the Cyclopædia of Anatomy, in Darwin's Journal, and other similar publications; and last, but not least, as I learn from the last No. of your journal, has given to the world his "Odontography"; all of which labours have doubtless contributed to the promotion of science, and have greatly redounded to his own fame; but they have tended, in a very subordinate degree, to benefit the science of surgery, and fulfil the desires of the profession with regard to their conservator. We thus see that one of the gentlemen whom the Council of the College have appointed conservators of the museum, is remarkable for industry and varied activity, yet unfortunately these qualities, from some cause or other, have hitherto been of but very little service to the institution of which he is a salaried officer. I am sure that the just complaints of a member of the College, which moreover are not those of an individual merely, but have been loudly raised in several quarters, will not be disregarded by the liberal and enlightened heads of our profession, upon whom devolves the important duty of regulating its institutions and guarding its scientific treasures; and in a spirit of deference and sincere respect, I will also venture to offer a suggestion

towards the removal of the evils of which I have complained. Would it not be desirable to make such an addition to Mr. Owen's salary as would render him independent of the laborious speculations in which he is engaged, and as would secure the devotion of the energies and great experience of such a valuable servant to the duties of his office, from the non-fulfilment of which the profession at large is suffering; whilst he is engaged in other pursuits. Certain I am, that had he bestowed half the zeal and activity on the various parts of the Museum Catalogue that he has displayed in his private works enumerated above, the complaints which the deficiencies in the catalogues and general arrangement of the museum have naturally produced, would never have been heard of.

Your obedient servant,

M. R. C. S.

June 6th, 1840.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Practical Observations on Abortion.

By J. S. STREETER, M.R.C.S., President of the Westminster Medical Society, &c. With Plates and Woodcuts. London: 1840. 8vo. pp. x. and 70.

THIS work is divided into five chapters. The first contains general observations; the second is on the structure of the ovum; the third discusses the nature, symptoms, and causes of abortion; the fourth is on the treatment of abortion; and the fifth on the "prevention of abortion in any future pregnancy."

Our author remarks, in the third chapter, that the causes of abortion, however numerous, may all be resolved into three great classes:—

"1st, An imperfect or abnormal formation of the ovum. This may take place either in the fœtus or its membranes, or in the decidua and placenta, those structures which fasten the ovum to the uterus, and finally connect the embryonic and the maternal systems.

"2dly, Morbid states, functional or organic, of the uterus and its appendages.

"3dly, Morbid states generally of the constitution of the mother." (p. 33.)

This division is a very good one; and we will just add, as a commentary upon the first class, an observation of Jörg, in his *Kinderkrankheiten*; namely, that morbid states of the ovum may owe their origin to disease of the father. If this is a frequent cause, it must often nullify the best concerted measures of the accoucheur to prevent abortion in a future pregnancy. The following extract from the chapter on treatment shows the prudence learned by experience; indeed, the whole book is the work of a man who is thoroughly in earnest with his profession; and studies its theory with zeal, that he may become more efficient in its practice.

"When called to attend a female, who, from any unpleasant occurrence, or from any premonitory sensations, is for the first time apprehensive of miscarriage, the accoucheur should first ascertain whether either of the essential symptoms of abortion, uterine pain, or hæmorrhage, is present. If the essential symptoms are not present, he should then carefully investigate the state of his patient, and whenever he finds any thing constitutionally or locally amiss, treat her precisely as he would if she were not pregnant. Where there is general plethora, or inflammation of any important organ, as of the brain, the lungs, &c. he must not abstain from the more active antiphlogistic remedies. Bleeding, indeed, if not excessive, is usually borne well by pregnant females, and the whole of the treatment should be so chosen as not only not to excite, but should be combined with such remedies as will allay irritation of the uterine. Active emetics, stimulating diuretics, and drastic purgatives, especially the aloetic, should be avoided, and the bowels cleared out and kept soluble by the milder laxatives or simple clysters. Some interval should elapse between the doses of purgatives; for these medicines, when too quickly repeated, are very apt to bring on expulsive action of the uterine. A full opiate may commonly be prescribed with advantage after the purgative action has been secured, and especially at bed-time. Cohabitation should be strictly forbidden, and as carefully abstained from during the whole period of convalescence.

"When uterine pain has commenced, the use of a full opiate, and especially of its repetition at bed-time for several successive nights, in preventing prema-

ture labour and miscarriage in the latter months of gestation, is fully established; but the propriety of employing it in the earlier weeks and months is very questionable. There are undoubtedly a very few cases in which its use would be serviceable, but far more commonly its exhibition fails to produce the effect desired, the prevention of miscarriage, and then it leads to injurious consequences; so that I now seldom employ opiates in any case where abortion is threatened *before* the third month of pregnancy is completed. When, however, in addition to uterine pain, these early cases are attended with any hæmorrhage, I lay it down as a canon of treatment that the practitioner ought not to employ opium, or any drug that has the property of suspending or lessening uterine contraction. The results of inquiries show that miscarriage in almost all instances arises from causes over which, when its *essential symptoms* have set in, the accoucheur has lost all control. Fœtal or uterine disease or imperfection has accomplished its work of destruction, and the blighted embryonic thing must now be cast out from the womb. If the ovum is not so blighted, rest in the recumbent or horizontal position, mental quietude, the abstaining from stimulating articles of food, the cleaning out of the bowels by a simple enema or mild purgative, the administration of common salines, such as the citrate of potass with small doses of digitalis and hyoscyamus, will suffice to allay the symptoms. When, however, the ovum is blighted, it must necessarily be thrown off by miscarriage, and the suspending the uterine pains by the administration of opium only retards, and in too many instances disarranges, that process altogether. If, therefore, hæmorrhage continues or recurs after a few hours' trial of the above means, it seems to me that it then becomes a duty to ascertain by vaginal examination whether the os uteri has begun to dilate or not. If dilatation of this part has commenced, or if the hæmorrhage steadily increases, even before it becomes profuse or tells upon the constitution, the ergot of rye should be freely and fearlessly employed in larger or smaller doses, and given at longer or shorter intervals according to the effects which it produces. The accoucheur should, from time to time, as gently as possible, ascertain the extent of dilatation of the os uteri, re-

move all clots from the vagina, and dislodge the ovum if, as sometimes happens, it is merely adhering to the os uteri, and keeping up hæmorrhage by the irritation which it occasions there. He should keep the room of a moderate temperature, give cool or positively cold drinks, and mild nonstimulating articles of food. If the tone of the muscular symptom is failing from syncope, he should order port-wine negus, or brandy and ammonia, sufficient to restore and sustain it.

Should the symptoms become alarming notwithstanding a steady perseverance in these measures, or have already become so from peculiarity of constitution, or the extent of the hæmorrhage before assistance was sought for, the practitioner must sit down at the bedside; he must trust nothing to attendants and friends, but devote a few hours to the recovery of his patient. He, indeed, that would treat uterine hæmorrhage successfully, must have reduced the means of treatment to general principles. These means of treatment should be methodized and duly subordinated, like those which the surgeon calls in aid for arresting hæmorrhage from a wounded artery. As the thumb of the surgeon now almost instinctively tourniquets the subclavian or femoral artery in bleeding from a limb, so should the hand of the accoucheur seek to compress, where it is possible, the abdominal aorta against the spine. Pressure there will certainly restrain the uterine gush for the time, and we are assured on good authority that it often commands the hæmorrhage entirely." (pp. 47-52.)

We recommend Mr. Streeter's treatise, as the production of a sensible and judicious practitioner.

Hippopathology; a Systematic Treatise on the Disorders and Lamenesses of the Horse, with their modern and most approved methods of Cure, &c. By WILLIAM PERCIVALL, M.R.C.S. Licentiate of the Company of Apothecaries, Veterinary Surgeon in the First Life Guards, &c. Vol. II. Part I. London, 1840. 8vo. pp. 170.

THE first volume of this excellent work appeared in 1834. The part now before us is dedicated to the diseases of the air-passages, lungs, and heart of the horse; comprising, among other maladies, catarrh, bronchitis, laryngitis, nasal gleet, scarlatina, cough, roaring, phthisis, pleu-

risy, hydrothorax, broken-wind, rupture of the heart, aneurism of the aorta, and aneurism of the iliac artery.

The following passages will give our readers some notion of Mr. Percivall's manner: we may premise, that "roaring" means "breathing with a loud or unnatural sound, under exertion of any kind." (P. 36.)

"*Roaring in Man.*—Of this, one instance only has come to my knowledge. I was out shooting one day with two friends, one of whom was quite a lad; when, as I was walking by the side of the other up a hill, I suddenly heard such a whistling behind me, that I sprang round with alarm, thinking there was a roaring, or rather, a whistling horse galloping close at my heels. My fright subsided, but surprise and curiosity took its place, at finding it was my young friend, who was making all this noise in his efforts in climbing the hill. On laughing and telling him he was "a regular whistler," he informed me he had, not long before, been the subject of a severe bronchitis."—(P. 40-1.)

"*Harness-Horses constitute a large class of Roarers.*—We shall probably regard these views as well founded. When we look around us, as we pass through the streets of London, and count the numbers of fine, high-spirited horses there are in carriages, waiting for hours and hours together for their masters and mistresses, and all the while reined up, with their necks crooked in a form unnatural and constrained, and painful even to behold, much more to be borne, as is sufficiently manifest to any one from the continual jerks up and down of the suffering animals' heads; and when we come to consider the constriction, nay, compression, that must all this while be exerted on the larynx, together with the forced bend that must in many take place in the upper portion of the windpipe, can we wonder that these parts should undergo distortion? At first, it is true, the distortion is but a temporary grievance; the intervals of relaxation affording the parts, by nature highly elastic, an opportunity of recovering their shape and tone. Repeated and long-continued acts, however, of such violence gradually enfeeble the elastic powers of the cartilages and their ligaments, and the result is permanent deformity of the larynx or windpipe, or of both together." (P. 43-4.)

Delafond found, that out of fifty-four

broken-winded horses, forty-five had emphysema, including dilatation of the air-cells of the lungs ; so that one-fourth only of the cases arose from other causes.

With care and attention, horses affected with broken wind are far from useless :—

“ By proper feeding, and by condition, it is that we render our broken-winded servant, while free from exacerbation, of the greatest service to us. By a judicious plan of regimen in respect to exercise or work, and feeding and grooming, the animal must be got into the best possible condition. All his grossness, all redundant fat about his body and bowels, must be got rid of, so that nothing remains but sheer hard muscle ; and when this—which is condition—shall be attained, the horse (be he broken-winded, or roarer, or otherwise defective in his “ pipes,”) will do his work with so much comparative facility and comfort, that he will no longer appear like the same animal. His food should be of that kind which will not greatly distend his bowels or be hard of digestion, or prove astringent in effect ; at the same time it must be nutritive, and such as he can work upon. Take care that he does not fill his stomach, and that he gets not water enough to load his bowels, just before he is required for work ; but only sufficient water and food to maintain his stamina, and these given some two, or three, or four hours before his work is likely to commence. The object of all this is, that his respiratory powers—above all, his diaphragm—may play as unencumbered as possible, while at the same time his body is lightened and his stamina strengthened. Give him a peck and a half of oats a-day, and not more than six or eight pounds of hay, and of the best upland quality—no clover, nor sainfoin, nor lucern, nor, in fact, any gross and filling rack-meat—and let him have his hay *after* he has done his work, and, for the most part, his water too. It has often been remarked how well broken-winded horses work when fed on green food, even of almost any description—vetches, clover, lucern, &c. ; which at first appears like a paradox to the above : but, no !—this arises from the easily digestible and laxative properties of the recent vegetable, inasmuch that it remains but a short time within the stomach, and is, during any bodily

exertion, speedily ejected from the bowels.”

Mr. Percivall's treatise is a valuable addition to the veterinarian library.

MEDICAL GAZETTE.

Friday, June 12, 1840.

“ Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri ; potestas modo veniendi in *lpuicum* sit, dicendi periculum non recuso.”
CICERO.

CASES OR CONCLUSIONS?

MUCH is to be said in favour of those medical writers who report a number of cases in detail, and leave their readers to draw their conclusions ; or who, at any rate, do not force any deduction upon the student, without giving him the evidence upon which it is founded. As much, however, or perhaps more, is to be said in favour of those thinkers, who, possessing the *fiduciam magnarum rerum*, the unruffled consciousness of having done great things, claim to be believed upon their bare word, and feel assured that the accents of truth cannot be mistaken, nor their witness rejected by any competent tribunal.

M. Andral made some observations last winter in favour of the latter class of authors, which we find recorded in the *Gazette des Médecins Praticiens*, for Dec. 20th, 1839. He does not wish to be plagued with all the raw material of medical experience, but is satisfied with its essence, after it has been distilled in the alembic of genius. After dividing medical authors into the two classes above mentioned, he observes that among those who have given merely the general results of their experience, there have been ordinary as well as great men ; and that the eminent observers have been those who by the accuracy of their views, as well as by the energy of their descriptions, have given us a guarantee for the truth of what they have advanced. Thus,

the description of small-pox by Rhazes, is perfect; and the picture of phthisis by Aretæus is of striking truth. Sydenham, after having grown old in the practice of physic, sketched the prominent features of the diseases which he had seen, and his descriptions, which are still admired for their surprising fidelity, are not accompanied by the particular cases that occurred in his practice. With one stroke of genius he altered the treatment of small-pox; and this, without counting up so many cases for the method he proposed, and so many against it. Sydenham was the first who pointed out the danger of the word *malignity* applied to diseases. Huxham, again, was not a collector of cases; and yet all that has been said, and said again, for so many years, about typhoid fever, is to be found in Huxham. Pringle, who passed his life in the midst of camps and armies, has handed down the most accurate descriptions of what he saw, without giving the details of a single case. Lind, who was so long in the navy, took advantage of his situation, and published some excellent works on the scurvy. Torti, who is universally known for his treatise on intermittent fever, has favoured us with the results of his experience, but has not told us through how many cases he came to the knowledge of his facts. Broussais, with his eagle glance, looked upon the irritative diseases of the chest, the abdomen, &c. and wrote their history; and we still follow his therapeutic rules. Does the importance of his work on chronic diseases consist in the cases with which it is interspersed? By no means; they are no longer on a level with science: but the hand of a great master is stamped on the book; and it is his theories, and not his cases, which made Broussais effect a revolution in medicine in which we have been both spectators and actors. Follow him, continues Andral, when he surveys Germany or the north of Italy, and paints,

with the boldest touches, the march of disease; such details cannot be drawn from your own single cases. Nor would Broussais have been able to deduce his admirable reflections from the minutæ of particular instances. Or, to finish this rapid sketch, is the *Traité d'Auscultation* made up of cases? Oh, no; all single instances are swallowed up in the exquisite descriptions of Laennec. Omit the cases in his work, and medicine will sustain no loss, for pupils write others as good. But few men compose works like Laennec and Broussais.

Such are Andral's observations on one side of the question; it is very possible that he afterwards gave those on the other, but we cannot lay them before our readers, as we do not happen to have seen the promised continuation of this fragment. It is clear that the chief argument in favour of the publication of cases in detail rests on the distrust felt for the generalization of the majority of practitioners. The inductions so often drawn from an insufficient number of instances, or from cases hastily noted and imperfectly understood, make us hesitate ere we give our confidence even to the true observer, till he adduces the facts on which he has built his conclusions. Perhaps, too, scepticism goes a step farther, and we wish to combine the cases of many writers before we make them the guide to our practice. In other words, the medical pyrrhonist looks forwards to the time when medicine shall be founded on statistics, and considers each good author, for the present, chiefly as a contributor of well-attested facts. Meantime, however, the practice of physic cannot stand still; and when a Sydenham or a Laennec starts up, men of sense do not refuse their assent to his conclusions, nor consider him merely as a compounder of the faultless tables of some future age. It might be objected to Andral, that

Sydenham does give cases. Thus, to mention half a dozen, in his account of the *Febris pestilentialis et pestis annorum*, 1655 et 1666, we find the account of a lady ill of fever, who died in a fortnight, and whose case, says Sydenham, was really a masked pleurisy or pneumonia, and ought to have been treated accordingly; and in the same chapter, there is the case of an apothecary's brother, in whom perspiration was very difficult to produce, but who got better as soon as this function of the skin was restored. In the history of the regular small-pox of the years 1667, 68, and part of 69, there is that instructive example of the patient who was laid out for dead at Bristol, during the absence of his nurse, and who recovered, apparently, from being placed on a table, and covered with a sheet alone. To these, we may add the cases of Dr. Coxe, and the Chaplain of the Earl of St. Albans, both cured of dysentery, and the recovery of Lord Salisbury from continued fever. Yet, it is clear Andral is quite right on this point, and that the value of Sydenham's writings consists, not in the cases which he gives, but in the conclusions that he draws from the boundless stores of his experience, rather registered in his head, than his notebook. Our profession, in truth, has its poetry as well as its prose. The simple record of facts (a useful and meritorious employment) belongs to the latter; while the former claims those generalizations of great writers, those vivid mixtures of fact and theory, where the memory and the imagination combine to form a whole, to which each would have been, singly, inadequate. On the whole, we cannot wonder at Andral's repugnance to those critics who would confine their applause solely to the enumeration of cases, and who would thus censure, by implication, some of the brightest ornaments of medical literature. As to the parrot-cry, "we want facts, and

not theories," it is hardly requisite to observe, that facts are useful only in as far as theories can be founded on them. "But the theories ought to be perfect, else" — perfect when possible; in the interim, let us be satisfied if they are serviceable.

ALARMING ANNOUNCEMENT.

Dona presentis rape lætus horæ.—HORACE.

THE judicious reader sees, at a glance, that the line which we have quoted is of very extensive application. The poet, indeed, means that his friend should snatch at goblets of wine, wreaths of roses, and so forth; but place, pension, and title, often depend on a similar quickness. On the 5th of January you might be elected physician to the Sun-Street Dispensary; at least you might make sure of the election by securing several of the tip-top committee-men; but you hesitate—you doubt, *quid ferre valeant humeri*, whether you are stout enough for so many alleys without, and so many disputes within. On the 6th, another candidate comes up, strong in hopes and sinews, and carries off the nothing per annum (including the occasional censures of the committee) with flying colours. Again, in June, Sempronius might be a baronet if he chose; in July his friends go out of office, on the hop question or the starch question, and Sempronius has no choice but Hobson's.

Yet it may not be immediately obvious that Horace's maxim is applicable to medical degrees. But so it is; these honours are not accessible at all times, but have "their exits and their entrances," as well as the persons who bestow and who receive them. It is not merely that diplomas, like dividends, are given only at certain periods of the year, but they sometimes stop abruptly, as if they were dividends on Columbian bonds—Niagara turns to a quick-sand.

In plain English, universities, instead of growing mellow with time, like pictures and medlars, occasionally resemble too many human beings, and grow more acrid as age advances. This change may take place most rapidly. Strong port, as years roll on, deposits its crust, but retains its flavour; while your *vin ordinaire*, which was originally of the smallest, becomes vinegar within the space of a biennium, without the trouble of any formal process.

These reflections have naturally passed through our mind on reading an advertisement, which appeared in the *Times* about ten days ago. See, here it is, in all its alarmingness :—

“*To Medical Men.*—Any gentleman wishing to obtain the degree of doctor of medicine has now an opportunity of procuring it from one of the highest Continental Universities. In about three months there is great probability alterations will take place in the University, which would interfere with the advertiser’s power to render assistance.”

Observe that the university which is to be occluded about the first of September, and to which the advertiser is a temporary deobstruent, is a considerable one. None of your little gymnasia which are called universities,

As hounds, and greyhounds, mongrels, spaniels, curs, Shoughs, water-rugs, and demi-wolves, are cleped All by the name of dogs :

No, no, it is one of the “highest continental universities.”

It is not, we repeat, a minute academy vegetating in some village known only to compilers of road-books, a university of Anclam, or Kallwang, or Peggau, that intends to be ill-natured; we fear that Heidelberg is going to be crabbed, or perchance Erlangen itself means to scoff at the question

Lenior et melior fis accedente senectâ?

In short, there is no disguising the fact, that some cheap and accessible fountain of honour is to be almost bricked up, and its streams dealt out in a very

niggardly manner. A pint bottle will cost more than a quart did formerly—it will be harder to become an M.B. in 1841, than an M.D. in 1840! The easy remedy is for the ambitious to hasten their steps. Borrow the £20, say we, at any interest, rather than delay; otherwise, what you save in usury, you will spend in grinding. We might observe, too, that after the words which we have quoted as our motto, the poet immediately adds *ac linque severa*; leave severe things, *i.e.* keep away from plucking universities. Yet, after all, a ray of light breaks in upon us; the advertisement is susceptible of a double interpretation, and perhaps the anticipated change is slighter than we had imagined. It is possible that the unknown but distinguished university is about to change, not its examination, but its agent; and that its honours will still be purchaseable, but at some other office.

RUSSIAN PRACTICE.

In a late number of the *Zeitschrift für die gesammte Medicin*, we find an abstract of a Russian medical journal for the year 1838. The German translator has very properly omitted all that Dr. Grum, the Russian editor, had translated from foreign journals, and has also abridged the original matter. The following is a part of what he has retained.

Cure of old ulcers.—Dr. Schreiber, chief physician to the Brestlitofski military hospital, gives a number of cases where old ulcers were rapidly healed by the application of fresh soft cheese; the slices being renewed every two hours. This application diminishes the pain and fœtor at the same time, and has succeeded in cases where the ordinary pharmaceutical remedies had been used in vain.

On the external use of living ants, (formica rufa), by Dr. Schreiber.

The summer division of the author’s hospital lies in a wood, where there are so many ant-hills, that the thought struck him of drawing some advantage from them for his patients. As ant-baths and tincture of ants were of no great use, he tried the living insects in paralysis, hemiplegia, paresis, and invete-

rate arthritis. The ants are to be taken directly from their hill, and put in a bag; and this bag is to be tied over the limb in such a manner that the ants cannot escape [but obtain access to the skin.] Some time after their application to the paralyzed limb, the patient begins to feel the running and biting of the ants, by which they gradually excite a kind of electrical twitches, and a feeling of warmth, which gradually extends over the whole body. Moreover, by their ethereal principle, they cause as violent a perspiration over the whole body, as if the patient were in a vapour bath. The paralyzed part must be kept in the bag with the ants for two or three days; the patient is then to rest for a day, after which the ants are to be applied again; and this is to be repeated till the object is attained. In 1835, Dr. Schreiber obtained a favourable result in seven cases of paralysis; in 1836, in four; and in 1837, in three; by which he was encouraged to use the same remedy in chronic rheumatism and gout. It is unnecessary to remark that this remedy alone cannot be of much service, if the case is complicated with syphilis, scurvy, or scrofula; but the military hospitals have plenty of uncomplicated cases, and in three years forty-six patients under this head were cured.

Dr. Schreiber now began to use the remedy in dropsy proceeding from inactivity of the skin. In anasarca it was found sufficient to tie up the lower extremities in bags with living ants, and thus obtain profuse sweating and a cure. This method of treatment, supported by gentle purgatives and sudorifics, succeeded in twenty-one cases. (The German translator here remarks that he cannot call ten grains of jalap with the same quantity of calomel, a "gentle purgative.")

In a case resembling elephantiasis, where the leg was cold, hard, and swollen, and a variety of treatment had been employed in vain, the disease was entirely removed within twenty days, under the use of living ants, and the patient was dismissed cured. The author mentions incidentally, that, in Little Russia, they employ a home-made spirit of ants, called *murashkowka*, to prepare a punch which is used in many varieties of colds, with very great advantage.

Russian Baths, as remedies against the Bite of Mad Beasts.

As soon as the patient is admitted into the hospital, Dr. Miroff directs him to be placed in a Russian bath, and exposed for an hour, with the wound uncovered, to a temperature of 50°*. As soon as he is in

the bath he drinks a pint and a half of a decoction, made with equal parts of sarsaparilla and guaiacum wood. While in the bath the wound is rubbed with mercurial ointment, and is afterwards kept open for two months by irritating ointments. The baths are at first repeated every other day, during the second and third week every three days, and afterwards twice a week, until the expiration of two months from the beginning of the treatment. Light diet is the only additional point to be observed during its continuance. The patient remains under superintendence during the third month. The author gives five histories of cases occurring at different times, and all terminating favourably.

Allium ursinum in Scurvy.

The efficacy of this remedy is known throughout all Grusia; but as it is to be obtained in a few places only, and soon spoils, and, when fresh, suffers much from carriage, it has been tried to preserve it acidulously†, and then eat it with vinegar. But the remedy, when preserved in this manner, not only obtained a peculiar sharpness and unpleasantness, but also lost its specific effect. Dr. Miroff, therefore, attempted to dry it carefully, which succeeded beyond his expectations. The remedy not only loses none of its efficacy, but is diminished nine-tenths in weight, making it more convenient for carriage. He gave the dried plant in scurvy with advantage, mingled with the patient's food.

Delirium Tremens from Debauchery.

Dr. Bileff, after narrating the history of the case at great length, gives the effective prescription, which was as follows:—

R. Morph. Acet. gr. j.; Mosch. Opt gr. iij.; Calom. gr. xij.; Sacch. ʒj M. disp. tal. dos. No. vj.

The patient took one of these powders every two hours, and had five in all.

The German translator complains of this formula as too complicated, and thinks that if the morphia had been given alone, it might have done its duty earlier than in combination with twelve grains of calomel in each dose. So large a quantity of calomel every two hours seems the more dangerous, he adds, as the patient had already sunk very low through continual drunkenness, syphilis, and the frequent use of mercury, and, therefore, had not much more strength to lose.

Practical Remarks, by Dr. Krassnogludoff, of the village of Suchadi, in Mingrelia.

1. He directs our attention to the affec-

It is hardly necessary to add, that the vapour-bath is intended.—TRANSLATOR'S NOTE.

† In the original, *es zu sauern*, to sour it; that is, probably, to preserve it after the manner of sour-cROUT.—TRANSLATOR.

* If the centigrade thermometer is meant, this will be equivalent to 122 deg. of Fahrenheit; if Reaumur's, it will be equal to 144½ deg. of Fahr.

tions of the spinal marrow in intermittent fever, which so commonly occur in Mingrelia. The complaints of the patient of pain in the back during the fit are at first commonly disregarded; but when they occur, bark does not cure the case, and then the practitioner begins to pay greater regard to this symptom in the following paroxysms. Moreover, when the patient after the paroxysm complains of a severe sensation of being bruised, and paralysis of the upper or lower extremities, the corresponding part of the spinal marrow is affected, a fact which is clearly ascertained on examination. Blisters on the part soon relieve the patient, and eight grains of quinine will now cure an intermittent, where a drachm between two paroxysms had previously been of no avail.

2. As the itch insect, and its propagation under the skin, have been demonstrated, Dr. Krassnogládoff proposes the question, whether these animalculæ are not able to enter the body, live in the alimentary canal, and multiply there, as well as under the skin? This question is prompted by the following case:—"In August, 1837, a peasant was brought to me from a village in Mingrelia. He had had the itch for several years, which is extremely common among his country people, until it covered the whole surface of his body. It is unnecessary to mention, that the head, palms of hands, and soles of the feet, were free from pustules; but, with these exceptions, no part of the body had remained unscathed, only that there were vacant spaces between the clusters on the chest and abdomen. The patient could not do his work, but went to bed at noon, in order to mitigate the itching by scratching. But it was not the external eruption that annoyed him so much. In the thorax, along the course of the œsophagus, and in the direction of the stomach, he had an unceasing and unbearable itching, which gave him the most uneasiness. I employed the English method of treating itch, and prescribed flowers of sulphur internally, adding a drop of oil of lavender to each dose. The patient also suffered much from constipation, so that frequent purgatives were necessary. The internal itching decreased with the decline of the eruption, and on the sixteenth day the patient was free from both. The internal eruption, therefore, had a close connection with the itch, and we may assume that this itching was caused by scabies, as it was removed simply by the use of a specific against that disease."

Hydrophobia.—At the meeting of the Society of Russian Physicians at Petersburg, on the 20th Dec., 1837, Dr. Brikoff stated that, in the government of Koursk, the *Thalictrum flavum* (Spanish meadow-rue) is used with advantage against hydro-

phobia. An infusion is made with two ounces of the herb, and sufficient water to produce sixteen ounces after straining, and this quantity is taken in twenty-four hours. Dr. Grum remarks upon this that the plant was long ago described, and that Professor Smelofski was sent by the medical board into that country, in order to collect what was known about it on the spot.

[To be continued.]

GOUT PAPER.

ACCORDING to Mr. G. Berg, an apothecary in Stuttgart, English gout paper, which is also known under the name of *Charta anti-rheumatica*, may be made in the following manner:

℞ Euphorbii, ʒj., Cantharid. ʒss., Alcoholicis, ʒv. Digere per viij. dies, cola et filtra; tum adde

Colophonii albi, ʒj., Terebinth. Venet. ʒiss. M. F. l. a. vernix.

Common letter paper is to be pencilled over three times with this varnish. Gout paper thus prepared sticks fast to the skin, and does not shift its place.

Mr. C. F. Pirwitz, an apothecary at Petersburg, gives the following prescription for a *charta derivans*:

℞ Cantharid. pulv. ʒss., Resin. Guaiaci, ʒijj., Galbani, ʒvj., Alcoholicis, ʒvj. Digere l. a., tum cola et adde

Colophonii, ʒiiss., Terebinth. Laric. ʒj. Solve l. a., ut f. vernix.

This varnish is to be warmed in a water bath, and then rubbed upon fine writing paper, two or three times with a pencil; observing, that the first layer is to be perfectly dry before the next is put on.

Schmidt's Jahrbücher, Jan. 25, 1840.

EXAMINATIONS AT THE COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

So many misstatements have, at different times, been promulgated with regard to the character of those examinations which every candidate for the diplomata of the Hall and College is compelled, and rightly too, to undergo, that I cannot but feel it due, not merely to the examining courts of those Bodies, but to the students and the public generally, to beg a corner in your valuable publication, in order to testify, that my experience, at least, is entirely at variance with those statements which have been so industriously circulated; and in bearing this testimony, sir, I believe I shall be supported by all who, with myself, have obtained the distinction of which I write. I wish, then, to affirm, in opposition to those statements with regard to the ex-

amination to which I have alluded, at the Royal College of Surgeons, that not only was invidious and clap-trap interrogation avoided, and the examination of such a character as to become an excellent test of an individual's real anatomical and surgical acquirements, but the mode in which it was conducted was such as to impress the mind of the student with the highest opinion of the attainments and gentlemanly bearing of the examiners, and with the inspiring conviction that it was their evident and anxious wish that he should succeed in the object he had in view. So plainly and so earnestly was this displayed, that I feel it no less a gratification than a duty, considering the glaring misrepresentations which have abounded, and how entirely they appear to be believed by the great bulk of medical students, to record that the hour and a half I spent before the Council of the Royal College, was not only one of the proudest, but in honest truth, one of the pleasantest in my life.

Immediately after my examination had concluded, I employed myself in recalling to memory, and committing to paper, the various questions which had been proposed to me during the evening; and I have no doubt, sir, that by inserting them, you would do far more to rectify those false impressions which students so generally entertain, than by any other plan which could be named.—I am, sir,

Your obedient Servant,

JOSEPH B. GRAY, M.R.C.S.

Licentiate of the Company of Apothecaries.

Duke Street, Chelmsford.

June 1st, 1840.

SIR ASTLEY COOPER.—How many bones form the pelvis? Where is the os sacrum situated? With what bones is it connected? Of how many bones does it consist? How is it developed in the fœtus? What substance is interposed between its separate bones in the young subject? What form is the sacrum anteriorly? Why? What does it present in the centre? What do you observe on the posterior surface? How many are its foramina? What joins it below? What do you notice laterally? What is the structure of the bone? At what part do the great sciatic ligaments arise?

Where is the os coccygis? Of how many bones is it formed? Are they connected by bony union in the adult? Have its bones any motion? And why?

Tell me the origin and insertion of the sciatic ligaments? What passes through the sciatic notch? Give me the origin and insertion of the pyriformis? Of what artery is the superior gluteal a branch? Can it be tied, and where? Tell me the point at which the internal pudic artery re-enters the pelvis? What is its course? Where does it terminate? What nerve accompanies it? Of what plexus is that a

branch? What are the branches which the pudic artery first gives off? Tell me its branches in its third stage? What artery is invariably wounded in the operation of lithotomy? Is any other endangered? To what parts of the penis is the arteria dorsalis penis distributed? What vein returns the blood from the penis? Where does that terminate, and what is its course?

What would you do in cases of hæmorrhage from the penis, arising from sloughing ulcers or ruptured urethra, &c.? How would you restrain hæmorrhage from the urethra? Where would you compress the pudic artery? What should be your guide in tying the pudic artery?

MR. ANDREWS.—What are the earliest symptoms of scrofulous disease of the hip-joint? At what period of life does it usually occur? At what period is treatment most likely to be beneficial? How does the disease generally terminate? What is the cause of the pain in the knee? What nerve is affected? Where does the anterior crural nerve issue from the abdomen? What are the most useful counter-irritants in affections of the hip-joint? Would you blister?

Do not small-pox, measles, and scarlatina, frequently dispose to swelling of the cervical glands? Would you leech these? What then would you do? And what medicines would you give internally?

MR. VINCENT.—Give me the origin and insertion of the external oblique muscle of the abdomen? What are the pillars of the ring? Describe the inter-columnar fascia? Tell me the origin and insertion of the internal oblique? How is the sheath of the rectus formed? Give me the origin and insertion of the transversalis? What muscles does the external oblique interdigitate with? What nerves form the cervical plexus? What nerves form the phrenic? Does it receive a filament from the fifth cervical nerve? Upon what muscle does it descend in the neck? Between what vessels does it enter the chest? What nerve does it here communicate with? To what organ is it distributed?

MR. GUTHRIE.—Why is hæmorrhage from arteries most difficult to control? How is arterial bleeding characterized? What would you do in hæmorrhage of the smaller arteries? What would you do if called to a patient who had received a stab in the femoral artery? Why would you tie "both ends"? What are the means nature adopts to stop hæmorrhage? What would you do in treating a wound of the axillary artery, below the lower edge of the pectoralis minor? What in a case of wound of the radial artery? How would you know when inflammatory action had ceased in the knee-joint?

CALOMEL WITH IODINE AND SUGAR.

THIS combination is employed in Riga, for the hydrocephalus of children, with marked success. The usual prescription is as follows:—

R. Calomel, gr. viij., Iodin. gr. j., Sacchari albi, gr. lxxx. M. ft. pulv. divid. in xvj partes æquales.

Powdered digitalis with *pulvis gummosus* are sometimes combined with it. If the calomel is first rubbed with the iodine, and the sugar then added, the powder becomes red; but if the calomel is first mixed with the sugar, and then the iodine added, the colour is greenish; deuto-ioduret of mercury being formed in the first case, and the proto-ioduret in the second. This supposition has been pretty well confirmed by analysis. The red powder has effected the greatest number of cures. According to theory, eight grains of calomel, mixed with one of iodine, should afford, of

Protochloride of mercury (calomel), 6·124 gr.

Dento-chloride of mercury (corrosive sublimate), 1·078 gr.

Dento-ioduret of mercury 1·798 gr.

The only difference in the result of actual analysis was, that the powder contained a trace of proto-ioduret of mercury, and in consequence rather more corrosive sublimate than the theory supposes.

As each powder is made, according to the above prescription, with half a grain of calomel and one-sixteenth of a grain of iodine, it contains after the manipulation:

Corrosive sublimate 0·067 or about 1·16th of a grain.

Calomel 0·383 or about 2 5ths of a grain.
Red ioduret of mercury 0·112 or about 1·9th of a grain.

Schmidt's Jahrbücher, Jan. 25th, 1840.

SMALL-POX PUSTULE IN THE BLADDER.

DR. GREENE presented a remarkable specimen of small pox on the mucous membrane of the bladder. The patient, a young man, died of small-pox. While convalescent from fever, he caught infection from another person in the same room, and had the disease in a confluent form. He died on the fifth day after the appearance of the eruption, and shortly before his death was attacked with severe diarrhœa. There were no pustules in the respiratory passages or intestinal tube. —*Dublin Journal of Medical Science*.

PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF BONE, *continued.*

CARIES — NECROSIS — TUBERCLES —
EXOSTOSIS.—*Their Nature — Symptoms —
Diagnosis — Prognosis — Treatment.*

CARIES.

CARIES is a disease of bones characterised by alteration and destruction of their organic structure, by softening, by friability, and ultimately by the secretion of a sanio-purulent fluid.

Galen, who very sagaciously remarked that the diseased bone became fatty and then black, compared it to ulceration of the soft parts; he thought the disease resulted from the corrosive action of the sanies or pus, exhaled from surrounding parts, upon the bony tissue. Ambroise Paré, on this, as on most other subjects, was the first to carry the investigation further. Still no great advance was made, not even enough to separate caries from necrosis, before the investigations of Duverney and Monro. Duverney described two forms of caries, one dry, which he compared to the mortification of the bark of a tree, this is necrosis; the other humid, or proper caries. Monro refined too much: he described seven species of caries; of these, two were necrosis, two were cancer, the three others were different degrees of caries. Louis applied the term necrosis to mortification of bone, and placed a definite distinction between the two diseases.

In discussing the anatomical characters

of caries, we may, with Sanson, divide the disease into three periods. In the first, the disease may begin on the surface, or in the substance of bone: in the former case, reddish and brownish spots are here and there observable: the periosteum at these points has ceased to adhere; and at surrounding points it is red, softened, thickened, and easily detached; the bone has lost its hardness, and a cutting instrument easily divides it. If the affection be seated below the surface, but not deep, there is tumefaction perceptible on the surface, the cells are enlarged, in their cavities a reddish liquid is found, the cohesion of the bone is diminished, so that it yields to the knife, sometimes even to the finger. When the centre of the bone is the seat of the affection, the changes are the same, except the tumefaction, which is sometimes greater. In the second stage, if superficial, the surface is red, softened and unequal, the colour is yellowish, brown or blackish, the sanious fluid of the cells is mixed with pus, which smells like rancid lard. The cells may enlarge so as to constitute true abscesses. Through the cellular structure a probe easily passes, breaking down the lamellæ. In the third stage, the bone is black, its earthy portion is gradually lessened, either by absorption, or by being mixed with, or dissolved in, the pus or sanies, and carried away. Much of the bone may thus disappear, and unless nature or art interfere to arrest its progress, it may implicate new portions, until the patient sinks exhausted by profuse suppuration, hectic, and other accidents. Sometimes we see new osseous vegetations forming almost around the disease; sometimes they are furnished by the periosteum, sometimes from the surface of neighbouring bone. These are very commonly seen in cases of caries of the spine. Cloquet saw a case in which a bony cylinder, pierced with holes for the escape of pus, replaced four vertebræ destroyed by caries; another

case is mentioned, where the humerus being fractured by a bullet, no attempt at union occurred; the fragments suffered from caries: the specimen was examined twelve months after, when an osseous column, covered with delicate periosteum, connected the two fragments, which were distant from each other more than an inch.

If caries occupy the shaft of a bone, the periosteum at the part is destroyed; at a short distance it is thickened: the pus which is secreted makes its way out, but its course is rarely direct. It is usually sanious, fetid, ammoniacal, and contains broken-down portions of bony matter.

If we macerate a carious bone, after a time the water will be covered with oily or fatty matter: removed from the water, it dries with difficulty; if the caries be very advanced, the quantity of oily matter is much greater: its blackish colour is not lost by drying, but it becomes very brittle.

Chemically examined, if the disease be not much advanced, it is found that the organic framework is transformed partly into fatty matter, and that the proportion of this matter is as much greater as the disease is more advanced; and that where the fragility is very great, and the black colour denotes that the disease has arrived at its last stage, the animal substance has completely disappeared. To verify these results, Sanson macerated a portion of carious rib in dilute acetic acid, and the whole dissolved; another portion of the same rib, in which caries was less advanced, similarly macerated, left only a very small portion of gelatinous matter. These circumstances tend to prove, that caries is a disease of the organic structure, that this structure is at first transformed into fatty matter, and afterwards destroyed.

Though the general tendency of caries is to extend, cases sometimes occur in which the disease is spontaneously cured. Two means have been pointed out by which this fortunate termination is effected. In the first and most frequent, the inflamed bone reddens around the carious point, and a line of demarcation is set up between the healthy and carious bone; in this line granulations are developed, and beyond this line the disease does not extend. In the second mode the ulcerated point of bone seems to clean, to granulate, and ultimately it cicatrises. In both cases the granulations acquire daily more consistency, unite, and form a mass in which calcareous matter is deposited. The fistulous openings in the soft parts contract, close, and leave after them more or less unsightly cicatrices.

In a few words we may now consider what is the nature of caries. Is it analogous to ulcers in the soft parts? Is it a form of necrosis, or is it an inflammation of bone—osteitis?

Galen inclined to the first opinion; so did Monro, Soemmerring, and with slight modifications Petit, Lobstein, and Rieherand; but the history of the disease is very little advanced by saying it is like an ulcer of the soft parts, because ulcers are very varied; they may be cancerous, syphilitic, atonic: both, it is true, present a suppurating surface, but that is not enough to make out an analogy between them.

It is only in the last century that caries was distinguished from necrosis; previously they were described as humid and dry caries. Louis established, that in necrosis there was death of the affected part, and an eliminatory process set up by which it was removed; that in caries the affected part continued to live, and that no well-defined separation takes place. Some persons still cling to the opinion that the diseases are identical, the only difference being, say they, difference of seat: when the compact tissue is affected, it is necrosis; when the spongy suffers, it is caries. It is not difficult to refute this opinion; exfoliation is the capital circumstance in necrosis; nothing similar is observed in caries. As to seat, caries of compact bones is not a very rare circumstance; it has been seen in the patella (Petit), the olecranon (Blandin), the calcis (Crucillier), the metatarsus (Malgaigne), superior extremity of tibia (Brodie), of humerus (Weidmann), femur (Cooper); and the spongy extremities of long bones may be necrosed. Certainly nothing is less logical than to confound two diseases because they happen to depend on similar causes. A current of cold may produce in one case rheumatism, in another catarrh. Now should we call these affections identical? It is much more reasonable to confound caries with osteitis; between caries and inflammation the following analogies may be traced: in caries afflux of blood and redness mark its commencement; softening follows: to these pain and tumefaction may be added, and we have, with the exception of heat, the ordinary characters of inflammation; lastly, the production of pus, common in inflammation, is almost always met with in caries. But although these analogies exist, there are very decided differences; among these is the progressive destruction and loss of substance—inflammation rarely destroys a whole organ, while a short bone often disappears completely under caries; again, in the course of caries left to itself, the disease increases indefinitely: this invading tendency is not the character of inflammation. Therefore, I think, caries cannot be likened to necrosis, nor to an ulcer of the soft parts, nor even to inflammation. Still its nature is as well determined as that of most other affections, for we know that it consists in changes in the osseous tissues; that the investigations

of surgeons and chemists have pointed out, and to which we have sufficiently alluded.

All bones are exposed to caries, but their spongy portion suffers more frequently than the compact, probably because it is more vascular; thus it is that the bones of the carpus, the tarsus, the spine, the sternum, the sacrum, the thicker portion of the iliac bones, the scapula, and the extremities of long bones, suffer most frequently.

Children suffer more frequently than adults or aged persons, and in them its progress is more rapid.

Causes.—The causes of caries are external, or local, and internal, or general; causes which act mechanically on bones are capable of exciting it; it often follows contusions, sprains, &c. Abscesses of the soft parts produce it less frequently than was supposed when pus was conceived to be a corrosive fluid, capable of destroying the periosteum. The greater number of the cases of caries are produced by internal causes; of these syphilis holds a prominent place, but, certainly, many cases of what is termed syphilitic caries are necrosis. Scrofula is probably a more frequent cause than syphilis; it attacks, especially, lymphatic children, before the age of puberty. Scorbutus not very unfrequently produces caries of the jaw, the sternum, the pelvis, the spine, the hand, and the foot. Rheumatism and gout are not very unfrequent causes of caries.

It is rare that the progress of caries is rapid; the inflammation which precedes and accompanies it excites, at the affected point, a fixed, permanent pain, which, when the disease is syphilitic, becomes more intense during the night. If a joint be the seat of the affection, it is not moved without pain and difficulty. If it affect a superficial bone, a circumscribed tumor is presented; it is painful on pressure, but, at first, the colour of the skin is not changed; sometimes there is fluctuation; at others, some time elapses before it softens. The adjoining soft parts are inflamed and tumid, the tumor is raised, softens towards the centre, where it reddens, ulcerates, and purulent matter escapes; this purulent fluid is a greyish, thin sanies, containing flakes of albumen, or portions of bony matter; its smell is sickly and fetid. After opening, the tumor does not entirely subside, unless it be far removed from the carious point, and a sinus is formed, extending to the diseased bone, when this purulent fluid often becomes brownish or dark; but although the dressing would occasionally indicate that it became blackish, this is sometimes owing to the dressing containing lead in some form. Around the fistulous opening, fungous granulations are often seen, which bleed

very easily. If we pass a probe into the sanies, it soon comes into contact with a hard rugous surface, and if we press upon it, the probe easily makes its way through it, and gives the sensation of a crepitus; this is a consequence of the breaking down of the lamellæ of the diseased bone. At other times there is no crepitation, the sensation being as if the probe passed into lard. These investigations are rarely painful, but they are often followed by a considerable effusion of venous blood. If the bone be deep, the symptoms are not always so evident; then there is a fixed pain over a bone whose structure is favourable to caries. Abscess may be formed at a greater or less distance from the point, as in psoas and lumbar abscesses. If they give way, or are opened by incision, the pus becomes changed, the system suffers, and hectic may follow: this change has been attributed by some to the entrance of air, but as we considered this point when speaking of abscess, we will not return to it here. Caries may affect several points at the same time, especially when it is of rheumatic origin: we have a patient in the St. Marylebone Infirmary, in whom ten or eleven sinuses exist, communicating with carious bones, and she bears up under it extremely well.

Prognosis.—From what has been said, it must be evident to you that caries is a very serious disease, that it rarely gets well of itself; but it is less dangerous in children than in after life, because, in them, the constitution makes more successful efforts to cure it. When it depends upon physical injury it is often most manageable; when it is too deep seated to admit of direct treatment, furnishes an abundant suppuration, which exhausts the patient, affects the articular extremities of long bones, and affects, at the same time, several bones, it is a very dangerous, and often mortal disease—at least if amputation be not performed; but when it is superficial, not yielding much pus, and affecting the middle portion of long bones, the general health being good, the prognosis is, of course, less unfavourable.

Treatment.—The preceding history of caries affords a very clear indication that, in the treatment, two broad principles are to be kept in view: to destroy the general cause, if it be known, and to act directly upon the affected bone. If the disease depends upon syphilis, scorbutus, scrofula, &c., the internal treatment must be directed to cure them, and the local disease will then occasionally cure itself; but usually it is not so; the exciting cause may be removed, but the local disease may persist, and local treatment may be necessary.

Some years ago Dr. Robert Williams called the attention of the profession to

the hydriodate of potash, as a means of curing caries, whether produced by syphilis or other cause. To a certain extent caries is, no doubt, an evidence of a deteriorated constitution, and probably, when once produced, the state of the bone is very similar, whatever be the cause. In the exhibition of the hydriodate, small doses are useless; for some time I was accustomed to give two or three grain doses, and my opinion of its value was unfavourable; but in doses varying from five to eight grains, three times daily, it will be found in many cases to exercise a very beneficial influence over the disease; I am not, however, prepared to say that the extent of benefit is much greater than we have been accustomed to obtain from sarsaparilla. A combination of both, however, will be found more effective, in a majority of cases, than either separately.

The local treatment must vary with the extent, the situation, and the nature of the disease. If it commence with a hard, deep, inflammatory tumor, antiphlogistics, narcotics, and emollients, are necessary to lessen irritation and pain; poultices and poppy fomentations are often very serviceable for this purpose. When those means have lessened pain and tumefaction, we may apply counter-irritation upon neighbouring parts. When the tumor enlarges, and fluctuation is felt, it must be opened early, to prevent burrowing; an incision should be made on the most projecting point of the tumor; emollients must be applied until the irritation is lessened, and the tumefaction subsides. The opening becomes fistulous, and the sanio-purulent discharge continues. The carious surface cannot cicatrise until it has undergone such a change as will restore to it its ordinary vital properties; this may require destruction of the part, or the substitution of an irritation more easy to cure. Powerful irritants commonly best accomplish this object; how they act it is not easy to explain. In children, when the caries is superficial, good effects are often obtained from baths, to which carbonate of soda, or potash, is added so gradually as not to excite local irritation. Tincture of myrrh, of benzoin, of aloes, camphorated spirit, applied by means of lint, directly upon the diseased surface, often do good. If the disease be deep seated, these means will rarely succeed, and recourse must be had to such energetic means as will destroy the diseased surface, and excite in the adjoining bone healthy action; in fact, convert caries into necrosis. Formerly, for this purpose, mineral acids and caustic substances were applied, and renewed as often as was necessary to destroy the affected portion; but the application of these sub-

stances was found to be uncertain; it was difficult to limit their action to the diseased part; it was impracticable when the bone was deep seated, and particularly when it yielded a large quantity of sanies, which enfeebled the action of these substances. It was, therefore, found necessary to carry out the same principle in a different way—to use the actual cautery, the surest, most expeditious, and most energetic of all the means employed against caries. It acts by destroying the carious surface, and exciting, in the adjoining parts, the action necessary to throw off the sequestrum; the application may be repeated as often as is deemed necessary. When the iron is applied, the bone must be fairly exposed. The cauteries should be of different forms, and should be heated to whiteness; the hotter they are, the more rapid is their action, the less severe the pain: before it is applied, the parts should be made as dry as possible, and the soft parts must be protected. It is usually necessary to employ more than one at a time, because the temperature of the first is depressed by the fungous granulations and fluids with which it comes in contact; and the application should be continued until the diseased surface is black and charred. The action of the cautery upon the affected bone is not very painful. If, after some days, no inflammatory symptoms are manifested at the diseased point—if the fungous granulations are pale and soft—the first application of the cautery was insufficient, and it must be renewed.

When the disease affects a joint, it is hardly possible to determine its extent, and the actual cautery cannot be used, because the consequences of its application would be too serious, and its effects too uncertain. If caries extend deeply into a bone, the diseased portion has been scooped out by a gouge or a trepan, and the cautery has afterwards been applied.

When the disease remains for some time almost stationary, the constitution not suffering, it is often prudent to limit ourselves to absolute rest of the part, cleanliness, and tonics internally; because sometimes, after a while, nature undertakes the cure. When caries affects a joint, the limb should be placed in such a position that if ankylosis occur the limb may be useful. If, on the contrary, the powers of life are suffering, the suppuration becoming more abundant and fetid, hectic symptoms becoming developed, and the loss of life imminent, amputation must be practised as a last resource. Amputation, by removing the source of irritation and suppuration by which the patient is broken down, will frequently, weak though he be, be followed by rapid amendment.

NECROSIS.

We apply the term necrosis to the mortification of the bony tissues: to this condition the term dry caries was formerly applied. Necrosis may result from the spontaneous or mechanical separation of the periosteum from the bone—from a similar separation of the medullary membrane—from death of the osseous tissue itself, or from a combination of all.

It is easy to understand how the destruction of the internal or external periosteum occasions necrosis: the bone receives no vessels except through the agency of these membranes, and the vessels by which the bones are supplied with blood are of great tenuity. When, therefore, by any cause, the separation or destruction of these membranes takes place, the supply of blood to the corresponding portion of bone is cut off, and mortification of an equal quantity of bone follows: to what depth the mortification extends we shall see immediately. The power of nutrition possessed by one and the other of these membranes, is not the same: a much larger quantity of blood is supplied by the medullary than the periosteal membrane. If the periosteum be destroyed, only the more superficial layers of bone are necrosed, while a much greater thickness is destroyed if the medullary membrane suffer; sometimes, indeed, it destroys the whole thickness. Cases do happen where necrosis occurs whilst the internal and external periosteum are intact; from syphilis, scrofula, and other internal causes. How this happens I cannot explain. These several causes act together under particular circumstances. This may happen in a severe burn, under the influence of extreme cold, in gangrene from certain causes, in the fragments of certain fractures.

The appearance of a necrosed bone varies with the circumstances under which it has occurred: if it be a spicula detached in a fracture, it closely resembles a healthy portion, except in colour, which, in place of being a very faint rose, is a dull white. If it follow a separation or destruction of the periosteum to a certain point, it will be similar; but as it often happens that the periosteum has been previously inflamed, if the periosteum has been exposed by one or both surfaces to the contact of pus or granulations, the bone will be sensibly changed in form and polish. Sometimes it is in thin laminae, sometimes in angular fragments; its surface is rough, unequal, and grooved, as if there had been partial absorption. Whether all disorganized parts are capable of being absorbed may be a doubtful question; certainly the appearances may be explained by the mechanical action of the granulations and the sparingly solvent ac-

tion of pus: this would not be absorption, but destruction; and Jobert strongly maintains that in this way the necrosed shaft of the femur may be reduced to the thinness of writing paper. Whatever may be the cause, the sequestrum certainly loses bulk and weight. With regard to colour, it is always duller than the healthy bone, but it may suffer other modifications. Wilson says, necrosed bones are white, if furnished by compact tissues; yellow-brown or black if spongy. Weidmann thought the black colour was owing to the contact of air. A sequestrum will sometimes present an earthy appearance, like that of a long buried bone; but although we may point out the variations in colour, it is impossible to offer any satisfactory explanation of them.

If we subject a portion of necrosed bone to the action of a feeble acid, a soft mass formed of gelatine is the result, whilst the earthy part has been dissolved by the acid.

When a bone has been necrosed in part, or sometimes even in its whole thickness, nature employs several means of cure: she seeks to eliminate the mortified bone, and she rapidly produces a new ossification to supply the loss. These two phenomena we shall examine separately.

The removal of the sequestrum differs with the particular form of the necrosis: if it be superficial, the periosteum having been removed or destroyed, there is no new ossification; or, the periosteum being intact, new bone is secreted, and the old bone is imprisoned, or the periosteum being destroyed, and the medullary membrane having formed new bone, the new bone is incarcerated by the old; but this is a very rare circumstance. If it be superficial, if the periosteum be destroyed, and has not secreted new bone, the removal is very simple: it is often separated in thin laminae; hence the term exfoliation. As soon as a portion of bone is mortified, new activity is developed in the action of the surrounding healthy parts; inflammation, or a state closely bordering upon it, is developed; suppuration takes place in the course of a line which separates the dead from the living bone, and a distinct separation then takes place. When this separation is complete, the dead part constitutes a sequestrum, which is gradually pushed off by the granulations which are developed. In the next case, the periosteum being intact, and having secreted new bone, the sequestrum is imprisoned. The production of the sequestrum is the same as before, but the process for removing it is very different and very wonderful, as shewing the extent of the resources of nature. The sequestrum bathed in pus, pressed upon on the one hand by granulations which constantly

irritated, constantly increase, on the other by new bone, its texture gives way, and certain portions of it are carried away by suppuration. Whether the work of absorption have any thing to do with the process or not, the sequestrum does diminish in bulk and weight, and is loosened in the containing cavity. Arrived at this condition, if the new bone did not prevent, it would, no doubt, be soon expelled: left to itself, however, it may remain a very long time in this state, and profuse suppuration may destroy the life of the patient. In more fortunate cases we find the sequestrum reduced into fragments, which escape through holes in the new bone. Under rare circumstances it is brought about in a remarkable manner, pointed out by Weidmann: the new bone, as yet too feeble to resist the muscles, flexes under their action, and the axis of the holes by which it is pierced is changed, so as to dispose them favourably to receive the extremity of a sequestrum. He saw, in this way, the greater portion of the body of the humerus escape spontaneously; the new bone had been caused by the action of the deltoid.

In a third case, Troja has seen (so has Cruveilhier) the medullary membrane form a bone, which is imprisoned within the old one, the periosteum being destroyed. If similar cases are presented in practice, we are bound to suppose that the old bone is thrown off in fragments; but as I know no certain case of the kind, I cannot say whether matters pass in this way or not.

Every case of necrosis is not necessarily accompanied by the formation of new bone; cases of exfoliation, the periosteum being destroyed, are in point; but if the mortification extend deeply, the periosteum being preserved, as the line of separation is in process of being established, the periosteum begins to be detached; it is red and vascular, it secretes a lymph, which is poured out between the membrane and the sequestrum; this is gradually transformed into bone, which adheres to the healthy bone, at the limits of the sequestrum, which it contains. This tube of bone is never absolutely complete; it contains many holes along its whole extent, which Weidmann termed cloaca. These openings constitute a salutary means of escape for the pus and osseous particles, or even for the sequestrum, when not too large. How they are formed is a debated question; some persons attribute them to the corrosive action of pus upon the periosteum at the commencement of the disease, or at a later period, upon the newly formed bone. Troja thought they were owing to a want of ossification at the points. Others have referred them to suppuration

at certain highly-inflamed points of the periosteum. However formed, they vary in number, in form, and in seat; if the sequestrum be small, there may be only one, if larger, there may be several. Weidmann has never seen more than five, nor Troja more than eight; Berard has seen twelve. They are usually situated towards the inferior, rarely at the superior extremity of the cavity, and their direction is obliquely outwards; they are sometimes round, sometimes oval, and about the size of a common quill. When once the sequestrum is removed, these holes generally disappear.

This invagination may occur in flat bones; they are invested with periosteum on either side, which may secrete bone, and thus imprison the old bone. At Alfort Museum there are three scapulæ in this condition.

I have said the medullary membrane may secrete bone, because Troja and Cruveilhier had seen cases where the periosteum was destroyed, and the medullary membrane had formed a cylinder of bone within the old bone. Mr. Stanley and others deny the possibility; they have destroyed the periosteum, and have never seen the medullary membrane form a new bone. This is no doubt true, and we are bound to believe the positive testimony of Troja and Cruveilhier, which must prevail against negative evidence. Besides, Duhamel, Villerme, and Breschet observed, what succeeding observation has confirmed, the existence of an internal osseous plug in the process of consolidating fracture, which can only be formed by the medullary membrane. I am, therefore, of opinion, that the medullary membrane is capable of taking part in the process of forming new bone.

Causes.—Necrosis may be caused by external or internal agency; it may be spontaneous or traumatic. Among the latter we may place all lesions capable of detaching the periosteum; wounds, contusions, fractures, heat, cold, caustics, and gangrene. In all these cases, it is easy to understand how the effect is produced; the bone is either at once deprived of life, or the vascular connection is cut off. It is not so easy to understand how internal or spontaneous causes act: it is difficult to explain why the same cause, syphilis, for instance, in one case will produce caries, in another necrosis. Again, a wound, with destruction of the periosteum, in a young person, may produce caries, in an adult may determine necrosis. In whatever way they act, the action of internal causes is admitted to be real; syphilis, scrofula, arthritis, and rheumatism, seem to be capable of producing this disease. Again, suppurative periostitis, denudation of the bone by the action of a bad saw, the introduction of a

probe into the medullary canal of a stump, or profuse salivation, may induce necrosis.

Long bones, in the order of the frequency of their suffering from necrosis, may be classed as follows:—the tibia, the femur, the humerus, the lower jaw, the bones of the forearm, the clavicle, the fibula, the metatarsus, and the metacarpus.

Symptoms.—In an early period of its course necrosis may be accompanied by inflammation, which may disorganize the periosteum. Usually the first symptom is a dull pain at a particular point, increased at night if it be syphilitic, or by atmospheric changes if rheumatic. After some time a flat doughy tumor is raised at the point, without any change in the colour of the skin: for some time the evidence of fluctuation is doubtful, but, at last, it becomes very manifest; the skin reddens, inflames, ulcerates, and pus, carrying with it debris of the periosteum, and bone, escapes. If the necrosis be superficial, and there be no obstacle to the expulsion of the sequestrum, it is carried away, granulations are developed, pus lessens, and ultimately the fistulous opening closes. If the necrosis extend deeper, the periosteum being preserved, the progress of the disease will be slower, the symptoms more urgent, the pain will have continued long before any other local symptom will be manifested. An ill circumscribed tumor is ultimately formed, sometimes extending along the whole length and circumference of the limb; it is hard, unequal, doughy, and livid; pressure upon it gives pain, and the bone is evidently much enlarged. Some points redden, ulcerate, and pus escapes; if through one of these openings a probe be passed, it gets into a bony canal; these openings all become fistulous; they are surrounded by fungous granulations, which bleed on the slightest violence; for a time they may close and cicatrize, but easily re-open, close anew, to open again, sometimes after months; the cause being, the irritation of the sequestrum. At the same time the power of the limb is lessened, it cannot be used without greatly increasing suffering. Sometimes the symptoms are slow in their progress and not very pressing, but at others the pain is very distressing, the suppuration is abundant, digestion suffers, the system sympathises, hectic supervenes, and death may follow. The symptoms are much less serious, where the necrosis is a mere exfoliation, than when the old bone is incarcerated; but the violent pain, thirst, sleeplessness, occasional delirium, and almost always abundant perspirations of the latter, are owing to the efforts which nature makes to throw off the dead bone; the irritation, as we have already shewn, being kept up by the dead part being placed between two inflamed surfaces, which it constantly excites.

When by the efforts of nature, or the assistance of art, the sequestrum is thrown off, the new bone is perfectly capable of replacing the other, it receives the insertions of the same muscles, and is moved by them like its predecessor, but at first it is less regular, and what is remarkable, larger in all its dimensions, especially in young subjects; so that the articular extremities are farther apart than they were in the old bone. In a boy of thirteen, the left leg, necrosed, was nearly double the size, and an inch and a half longer, than the right, although previous to the disease of the left, they had the same proportion.

Diagnosis.—It is not difficult to detect necrosis: the heavy fixed pain in the course of a bone, the many small abscesses, succeeded by fistulae, the abundant suppuration, the immature age at which it is often seen, are usually sufficient to enable the surgeon to distinguish between caries, cancer, and necrosis: yet these data are not always enough. A probe passed through one of the fistulous opening, will give to the hand the sensation of contact with a hard, rough body; solid and resistant, if it be necrosis; irregular, soft, and easily perforated, if it be caries: add to this that a sequestrum struck, gives a sharp sound, while, in caries, scarcely any will be elicited. We should not only ascertain if there be a sequestrum, but whether it be invaginated, moveable, in one or many fragments, its depth, its extent. In making this examination, two probes are often useful, for the purpose of moving the sequestrum, which we shall sometimes fail in doing with one: we choose two fistulous openings, at a distance from one another; a probe is passed into one, while percussion is practised with the other. If the disease have existed long, the general disturbance being severe, the local symptoms pressing, the limb large and deformed, the probe, when introduced, penetrating into a rough cavity, where it is as it were imprisoned, it is probable the necrosis is deep seated: as to the extent, it is easily made out by the probe, when superficial; but when deep, we must estimate it by the number and position of the fistulous openings, the distance between them, and the extent of the tumefaction; but all these things will only enable us to guess.

Prognosis.—Of course the prognosis must depend upon the extent, the seat, and the greater or less depth of the disease; its cause, the age of the patient, and his general health. It is seldom of itself a mortal disease; if it be confined to exfoliation, it is not a serious disease; but when deep seated, extensive, occurring in a scrofulous or aged person, it may either primarily or secondarily bring about the death of the patient, by the intensity of the inflammatory action, or by exhausting suppuration; if it extend to a joint, it is a disease of

great severity, because to the necrosis itself articular disease will be added.

Treatment.—There is no disease in which nature has more clearly indicated the means of cure than necrosis: to separate the sequestrum, and, in many cases, to wait until the dead bone is thrown off, is the proper course of treatment. In the last century, the simple, the only remedy for necrosis, affecting the long bones of the limbs, was amputation. We shall soon see that the proper treatment is much more simple; and that amputation should be reserved for extreme cases. In the first place, we should endeavour to neutralize or remove the cause; but, before we exhibit internal remedies, to act upon this cause, it is prudent, in many cases, to subdue inflammatory action at the part. The local indications are, to arrest mortification, if it be possible; if not, to limit it, and favour the removal of the sequestrum. When by a wound a bone has been exposed, the soft parts should be immediately reapplied: if, as a consequence of contusion, blood be extravasated between the periosteum and the bone, or if pus be collected there, so as to separate that membrane from the bone, an incision should be made, to evacuate it, and the lips of the wound carefully brought together; in this way we sometimes prevent necrosis; but if it be established, and an abscess be formed, it should be opened as soon as it is fairly distinguishable; if not, the skin is disorganized, and a good cicatrix is not formed. Usually the opening has not much tendency to close; but sometimes it is necessary to use proper means for keeping it open. When the sequestrum is not thrown off, or when it has kept up such irritation as keeps up profuse suppuration, and endangers life, the indication is, to extract it. At all periods of the disease, antiphlogistics may be necessary, locally, with absolute rest; especially so when it extends to the neighbourhood of a joint, and the patient is threatened with ankylosis. In some vigorous subjects the inflammation is so intense, and the general reaction so great, that general as well as local bleeding becomes necessary; but it must be always borne in mind, that we should do nothing wantonly to lessen the vital powers, which will be sorely pressed when suppuration sets in: if the sequestrum be small and superficial, on the cranium, for instance, it should be extracted as soon as it is sufficiently moveable; it should be frequently moved, by tugging at it gently until it give way. Formerly it was the custom to apply styptics, but in the present day they are discontinued. However, it is always desirable to remove it as soon as possible, because the duration of the disease is lessened, and a cause of irritation and sup-

uration is removed. But when the sequestrum is imprisoned, the case is different; then it is not only necessary to wait until the sequestrum is loose, but until the new bone has solidity enough to resist muscular action, and if it be the leg, to sustain the weight of the body. This does not happen soon; the surgeon should therefore wait, so long as the patient's health does not suffer by the delay: by this course two important objects are obtained; the sequestrum is more moveable, and the cloaca enlarge, or are more numerous. The time, however, comes, when the new bone has acquired the necessary power, the sequestrum is moveable, and it may be proper to take measures for its removal, in preference to abandoning the patient to the inconvenience of an interminable suppuration. If the sequestrum be not sufficiently moveable, we may seek to make it so by traction; when the operation is decided we ascertain the state of the sequestrum, as well as the position of the cloaca; and we begin our operation upon the largest opening which may be nearest one of the extremities of the bone. The part being placed in a convenient position, some persons make a single incision down upon the bone; others make two semi-elliptical ones, which include the line of tissue diseased by fistulous canals; others make a crucial or T incision; the object in each being to expose the bone, so as to ascertain whether the opening in the new bone be large enough to receive forceps, and to allow of the extraction of the sequestrum; if it be not, it must be enlarged by a trepan, a cutting forceps, a strong scalpel, or a saw; even when the opening is sufficiently large, the extraction is often difficult, because of the incarceration, and the irregular shape of the sequestrum, and because its position is unfavourable for making traction upon it. Traction should not, however, be violent, because it may injure the new bone, or break off a fragment, which may be inaccessible, and keep up the irritation. Neither should we remove too much of the new bone; this may be easily done, because its power of resisting traction is often not great. We may, when the opening does not correspond to an extremity of the sequestrum, with a sharp forceps cut through it, so as to facilitate removal. We do not always succeed in removing every fragment at a single sitting; one may be loose, the other adherent; but the removal of one will sometimes free the patient from irritation for years.

Suppuration usually continues for some time after operation; it unloads the neighbouring tissues, and brings away small particles of bone which have been left. The suppuration gradually lessens; the wound is covered with granulations, and a de-

pressed cicatrix follows; this cicatrix corresponds to the point where the new bone was destroyed, and where there is usually no reproduction. The limb must be kept quiet for some time, to acquire the necessary solidity to support the weight of the body, if it be the leg; if this be not attended to, the bones may be curved at the point. Cases will occur where there is profuse suppuration, a bad constitution, and great feebleness, whilst the sequestrum is so firmly fixed as not to allow of our attempting extraction; it is necessary then to look to the strength of the patient; to determine the moment when further delay would be fatal, and decide between it and amputation; and here much experience and sagacity are necessary.

TUBERCLES IN BONE.

That a tubercular condition may be developed in bone was a fact known to Galen (*Nonnulli aut existimant spinam in posteriorem partem perverti ubi in eâ fuerint eruda tubercula, &c.*, *De articularis*) to Marcus Aurelius Severinus (*sed spectatis causis alii gibbi ex casu, alii ex tuberculo &c.*; *De gibbis*, Cap. 2.) to Gerber, who, in a dissertation, published in 1735, shews that their existence was generally known, and considered as the cause of curvatures; to Platner, who, in 1745, published a work (*"Deiis qui a tuberculis gibberosii fiunt."*) How comes it then that ideas so precise as several of these persons possessed on this subject should have been so long lost? It is, I apprehend, because all facts of the science do not, at the same time, make the same progress; the interest of particular questions absorbs at particular times all attention, and other questions are lost sight of; so has it been with tubercles in bone, they have been lost sight of for a century. In 1816, Delpech raised the question, which he conceived to be new; and attention was directed to it; Serres, and Nichet, of Lyons, his pupil, pursued the subject; and the latter, in 1835, published a very important Memoir, founded on seventeen cases of Pott's disease which he refers to the deposition of tubercular matter in the vertebræ. So far as I know, up to the publication of the Essay of Nelaton, tubercles had scarcely been considered in any other light than as occasioning gibbosities; but this is much too narrow a field. In the bone, as in the lung, tubercular matter may be presented under two forms; it may be encysted, or it may be infiltrated; and with respect to bone, at least, this is a point of great importance.

When we examine a fully developed encysted tubercle of bone, we find in the centre of the osseous tissue a cavity, often shut in on all sides, containing an opaque yellowish white matter, inelastic, and pre-

sented no osseous particles; it does not form concentric circles; it is miscible, but not soluble in water; whether this matter be exactly similar to tubercular matter existing in the lungs or the brain, or whether it contains a large portion of phosphate of lime, is yet undecided. This matter is contained in a cyst, which lines the cavity; this cyst is not thick; it is at first gelatinous, transparent, but ultimately acquires considerable power of resistance; its external surface is vascular, and its vessels communicate with the surrounding bone; the internal surface is white and tomentous. The excavation thus formed in the bone may present appendices or openings of communication with other cavities; the osseous tissue which limits these cavities has suffered no very obvious change; the cavity enlarges during the evolution of the tubercle; and if cartilaginous or fibrous matter be met with in its progress, it usually gives way; it often makes way through the intervertebral fibro-cartilage. These tubercular collections vary in extent, from two or three to fifteen or twenty lines in diameter.

When a tubercle is developed in bone, important changes are brought about in the superficial osseous layers, and in the periosteum: they become more vascular in a point corresponding to the deposition, and new bony matter is deposited there; it is in this way that the extremities of long bones often enlarge in white swelling. These tubercles cannot of course be followed, or discovered in their rudimentary state, with the same facility as in the soft tissue of the lungs; it is therefore necessary, if you suspect a bone to contain tubercles, to remove the periosteum, and carefully examine whether the surface contain any vascular points or irregularities; if it do, the compact tissue should be removed with a saw, and the cellular structure cut away with a scalpel; in this way tubercles may be discovered at an early stage of their development. When the tubercles, in the natural course of development, make their way to the surface of the soft parts, the matter is evacuated, and a fistulous communication remains, the fundus of which corresponds to the tubercular excavation in the bony tissue: the parietes of this cavity cannot fall in like those of an abscess in the soft parts, and this disposition tends to keep up the discharge; but gradually the parietes may thicken until they fill up (Nelaton); this is a desirable but not the common termination.

When the tubercular matter is infiltrated through the bony tissue, like water in a sponge, it may be found alone or accompanied by the encysted form; it may be in the form of a semi-transparent deposition in the osseous cells, which a stream

of water does not wash out : these depositions examined through a lens seem to have very delicate vessels ramifying through them. The infiltrated matter may be purulent ; this is distinguished from the former by its dull yellow colour, and by the absence of blood vessels ; this yellow matter is at first firm, gradually softens, and becomes fluid and puriform ; a current of water at this time directed upon it, washes it out of the cells. The absence of vessels is a fact which it is important to note, because it serves to explain certain circumstances in the history of tubercular affection of bones. In the first period of the affection the texture of the bone undergoes little change, but when the puriform condition arrives, the cells are completely obliterated by hypertrophy, under which the part may acquire the hardness of ivory.

All bones or parts of bone are not affected by this disease with equal frequency ; the spongy portions usually suffer. In children, when the difference between one bone and another is not so decided as it is in after life, the bones of the limbs suffer almost as frequently as those of the trunk ; in after life it is rarely seen except in the bones of the trunk. In the long bones the extremities usually suffer ; in the femur the inferior extremity suffers more frequently than the superior ; the contrary happens in the tibia ; in the humerus and the bones of the forearm, the cubital extremity is most frequently affected.

Nelaton classes the bones, as to frequency, in the following order :—vertebræ, tibia, femur, humerus, (in children—phalangeal, metacarpal, and metatarsal bones,) sternum, ribs, and iliac bone, petrous portion of temporal, short bones of carpus and tarsus.

It is most commonly seen in the early periods of life ; Nelaton saw it once in a person of fifty-five.

Both of these forms of disease may be seen in the vertebræ, but the infiltrated more frequently than the encysted ; they may be developed in the bodies or the apophyses, but the first is incomparably the most common. The body of a vertebra may thus be reduced to a shell ; it can no longer sustain the weight of the body, it gives way, and the vertebræ above and below come into more or less complete contact, and a gibbous condition is immediately produced ; union may then take place, and the disease be cured. New tubercular cavities may, however, be formed, and new union may result. A remarkable example of this occurs in the tenth case of Nichet, where the bodies of eight dorsal vertebræ had entirely disappeared ; the second and eleventh vertebræ, which formed the limits of the disease, were united. How, says Nichet, was this brought about ?

I apprehend by a cavity hollowed in a vertebra, being extended in all directions, destroying the fibro-cartilages, and extending to the succeeding vertebræ. Sometimes a hard portion of a vertebra will resist destruction, and keep the parts separated : some persons regard this as a favourable circumstance, whilst in reality it is a serious obstacle to cure : in fact, in these cases, all attempts to oppose gibbosity are decidedly irrational. All our efforts should tend, not to prevent gibbosity, but to suspend the tubercular secretion, the source of all the evil. It is singular, but a happy provision, that the anterior spinal ligament in these cases often becomes ossified, and prevents compression of the spinal cord.

The extremities of long bones may be affected by tubercular disease, constituting, as I conceive, a frequent cause of white swelling ; but the disease may present either of the two forms we have considered. At this time we shall not consider the subject generally, but confine ourselves to the progress of tubercle. When developed in the extremity of a long bone, it is seated not far from the joint, it enlarges and approaches the surface, may perforate the diarthrodial cartilage, may empty itself into the joint, or into the adjoining tissue ; in the former case, acute inflammation may be at once set up in the articulation. In these cases we may see a perforation of the cartilage, without any sensible modification in the cartilage around the opening. Tubercular infiltration may exist in the extremity of a long bone, without affecting the articular surface, but it may be extended to the surface of bone under the articular cartilages. Cartilage disappears by a mechanism probably similar to that of the destruction of intervertebral cartilage. It is evident that there is a striking similarity between the pulmonary tubercular disease and the one we are considering, as respects perforation in the lung : tubercles will perforate the pleura, and produce acute pleurisy ; in the extremity of a long bone it will perforate the joint, and excite acute inflammation there. I shall at present say no more on the subject, but I hope, before long, to shew that tubercular disease of bone is a frequent cause of disease of the spine and of the joints.

EXOSTOSIS.

Under the term exostosis I propose to consider three distinct conditions of bone ; in the first, there is an increase of bulk or density ; in the second, the density is lessened ; in the third, there is at the same time increase of volume. These diseases may affect the whole or only a portion of the thickness of a bone. In the first, be-

sides increase of bulk, there is increase of density, the bone becomes more compact and heavier than in its natural state; this increase may affect not only the spongy but the compact substance; when it affects the compact portion, it is often irregular and tumor-like; when it affects the spongy portion it is more equal. In both cases the periosteum is thickened and injected. We can set no limit to the extent of increase in bulk and density, when the cranium is the seat of the disease. Sandifort describes a curious cranium of this kind in the museum at Leyden. Ribell describes one, which weighed eight pounds and a quarter, the ordinary weight being a pound and a quarter to two pounds; the inferior maxilla alone weighed three pounds and a half. Jadelot found buried at Rheims, a cranium weighing eight pounds, its thickness varying between nine and eighteen lines. Ilg described the head of a young woman who died at the age of 27, which without the lower jaw weighed 120 ounces. All the foramina through which nerves pass were greatly contracted. When cylindrical bones are thus affected, the bones acquire a great increase of solidity. Ruysch speaks of bones becoming solid enough for scalpel handles. Bonn speaks of a femur entirely converted into a solid cylinder. The increase of density in these cases is usually greater than that of bulk. Lobstein took two portions of femur of equal length, and not very different in bulk; one weighed four ounces and a half, the other two ounces. Sancerotte published a case where the increase was general; it was that of a man of 39, who in 1768 weighed 119 pounds; in 1772, although the soft parts did not at all participate in the increase, he weighed 178 pounds. The urine of this man was several times examined, and found not to contain the earthy salts which belong to it.

The new matter, whether developed in the medullary canal or under the periosteum, whether of the size of a pea or that of a human head, sometimes assumes a styloid, a reticular, or a radiated appearance; sometimes it is rough, stalactitic, or cauliflower-like, sometimes it presents areola like the maddrepore, sometimes it is in needle-like points, and sometimes it is smooth. The colour is usually like that of the bone. Lobstein has seen it completely black. It may be developed on any bone, but those of the cranium, the long bones, especially those superficially placed, as the clavicle, the tibia, the lower jaw, the sternum, and ribs, are most frequently affected. In some cases many bones, or even almost all the bones of the skeleton, are affected at the same times. Many examples of this kind are given by Sir A. Cooper and Lobstein.

Both sexes seem equally to suffer; and in each it may be produced by two dis-

tinct orders of causes, internal and external. Van-der-Haar and many others are of opinion, that of these causes syphilis is by far the most frequent; it is in that case a symptom not of primary but constitutional syphilis; gout, as well as scrofula, seem to stand in the relation of causes. It is not very clear that scorbutus or rheumatism has any tendency to excite it; of 500 cases of scorbutus seen by Petit, 100 had caries, but in only four were there exostoses, and of these, three affected the lower jaw. Age seems to have an influence in producing it; it may follow a contusion; but then it is said there must be a tendency to it. Abernethy mentions the case of a young man in whom the tendency was so strong, that the slightest contusion produced it. In such cases, at least, irritation of the periosteum is the immediate cause.

Symptoms.—The symptoms of exostosis vary with the cause. If it be venereal, it is preceded by pain, which at first extends along the whole length of the bone, and is more severe during the night than the day, especially when the patient gets warm in bed; the pain, at last, gets fixed at a point, and there a tumor is developed. When it succeeds to scrofula or contusion, the pain is much less severe; in fact, in many of these cases, the tumor is felt before the pain. The progress of the tumor is very variable; if rapid, the pain is very severe, and can only be calmed by large doses of opium; if slow, the pain may be very trifling. Exostosis may be inconvenient from its size, from its pushing aside, or compressing, neighbouring organs, and, in certain situations, even without great bulk, it may occasion serious functional disturbance; in the vertebral column, it may press upon nerves, so as to occasion paraplegia, or other disease; may press upon, and obliterate arteries, the subclavian, for instance, (Cooper) may press upon the epiglottis, and produce suffocation. (Cooper.)

Diagnosis.—The diagnosis is usually not difficult, when the disease is external and superficial. It is then a hard, inelastic tumor, variable in form and bulk, indolent, not painful, and firmly adherent to the bones; the skin over it, unless much distended, does not change colour. These characters usually serve to distinguish it from periostitis, in which the tumor is commonly pasty, and more or less compressible; still you must be on your guard, for exostosis of the clavicle has been mistaken for a steatomatous tumor; the ligaments and tendons tumefied after a fall, or a luxation, have caused similar error; amputation of the thigh has been performed for a supposed exostosis of the femur, which was aneurism in process of cure. The diagnosis is very important with reference to treatment: we cannot rely on

exostosis being syphilitic, unless it has been some time preceded by primary syphilis, and coincides with other signs of general infection. Some persons, in such cases, refer it to the abuse of mercury. The scrofulous diathesis will equally serve to characterise scrofulous exostosis. Osseous tumors are always comparatively slow in their growth, though in this respect there is a great difference; in one case eight or ten years may be necessary for the tumor to attain great size; in other cases, manifestly syphilitic, in a few months the tumor may acquire its greatest development.

Some persons believe the matter of exostosis to be inorganic, formed by a simple deposit of phosphate of lime, and that, therefore, it cannot be removed; but then every surgeon has known such tumors to be much reduced, if not entirely removed; whether this happens before ossification is completed in them, or not, I cannot say. The osseous tumor may be necrosed, and detached, by a process similar to that of the separation of a sequestrum. (Delpech and Boyer.)

Prognosis.—Left to itself, the prognosis is not very serious, unless it should interfere with important functions. As to treatment, little success can be expected, unless the cause be known, and can be energetically attacked; in syphilitic cases, we have a well-determined means, but even here we often do little more than arrest the further development. It is seldom that it takes a retrograde course; as to ablation, it has succeeded, but we must always apprehend reproduction; a second operation may be followed by a second tumor, (Cooper) or, if the diathesis continue, we may get bone developed in internal organs. (Baillie.)

Treatment.—We must therefore consider the treatment under two different points of view—surgical and medical: the latter must be composed of general remedies, directed against the suspected cause, and topical means to induce resolution. Internal remedies are mercurial, or other anti-syphilitic, antiscrofulous, or antiscorbutic remedies, according to the indication. Where the indications are not clear, we must take the most probable. Sir A. Cooper recommends sudorifics and small alterative doses of mercury, where syphilis is not suspected. Mr. Skey mentioned a case where the tumor lessened during the administration of mercury, the urine being largely impregnated with phosphate of lime. Abernethy tried lemonade acidulated with nitric and muriatic acid, under an idea that he might thus dissolve the phosphate of lime of the exostosis. I know no cases which support this opinion. In the present day, when the disposition to localize the causes of disease is so strong,

there are not found wanting persons who maintain that the cause of exostosis is always local, and therefore limit their means to the local treatment. In cases where the affection evidently succeeds to a cause capable of developing inflammation, as a blow—where the inflammation is manifested by acute pain and tumefaction—it is certainly proper to leech, to cup, and to apply emollients, but you cannot greatly rely on these things; in many cases they only produce a slight alleviation in the symptoms. When the tumor is indolent from the first, or when the pains have diminished under treatment, whatever may be the cause or nature of the affection, recourse must be had to resolvent agents—mercurials, camphor liniments, sulphur or alkaline baths; which, in young scrofulous cases, often succeed well. Cooper recommends blisters, which should be kept open by applying upon them equal parts of mercurial and savine ointment; but their application should be preceded by antiphlogistic means. These local and general means rarely answer the end for which they were employed. Still, until such means have been tried, we do not recur to surgical treatment. If the tumor be indolent, and if it cause no deformity, no operation should be had recourse to; because, when the disease is stationary, it is less serious than the operation necessary for its removal. If it cause pain or derangement in the general health, make rapid progress, or affect a large portion of a limb, amputation or other operation may be necessary. If it be deep seated, palliating means alone can be used. Some persons have attempted to destroy exostosis with caustics or cauteries, but these are dangerous applications, which may substitute necrosis for exostosis. Still, after the removal of such tumors, the actual cautery has been used, to prevent repullulation. Cooper and Wilson give cases of the kind. If the tumor have a small base, the pedicle may be separated by a saw; the soft parts being attached by two semi-elliptical or a crucial incision. As to saws, we must use those which we find most convenient in a given case. After the removal of a tumor, the soft parts are brought together so as to obtain union by first intention.

APOPLEXY (MENINGEAL HÆMORRHAGE) OF NEW-BORN INFANTS.

BY THOMAS H. BURGESS, M.D.

[For the Medical Gazette.]

THERE are two diseases of vital importance to which the new-born infant is peculiarly liable—apoplexy and asphyxia. It would appear, from the re-

cords of medicine, that mistakes relative to these complaints are of frequent occurrence; that apoplexy has been confounded with asphyxia, and asphyxia with apoplexy; and further, that in fatal cases of either, death is often attributed to some vague unmeaning causes, as "feebleness," "congenital weakness," &c. &c.

I have chosen for the subject of this paper Apoplexy, which appears to me to be the most important of the two; and although we might suppose, were we to judge from the scanty records furnished by our own medical writers, that it is of exceedingly rare occurrence in this country, nevertheless, the experience of every intelligent practitioner of midwifery must teach him the reverse. M. Cruveilhier states, he has ascertained, from personal observation, that more than one-third of the infants who die during the act of birth, at the Maternité of Paris, fall victims to apoplexy; and he regards this disease as the most frequent cause of death in all cases of infants who die, either during the process of delivery or within the first few days of their existence*. Some English physicians, however, deny its existence altogether, on no other ground than that of its being (to use their own phraseology) "*quite French*." With such individuals it would be useless to argue. Others, with more liberal feelings, and possessing, perhaps, a greater share of information, as well as of common sense, admit the existence of the morbid condition, and object merely to the *name*. In this objection we partly coincide; but as terms much more dangerous than *apoplexy* have been applied to the disease, in the hope, we presume, of more clearly and accurately expressing its real nature, and as, however loose the term may be, it would be difficult to substitute one more suitable, we have retained it in this paper.

In the eighth edition of Underwood on the "Diseases of Children," we find, at the bottom of page 117, a note by the editor (Dr. Merriman) on the "*Discoloration of new-born infants*." This writer says, "When the *discoloration* is observed before the pulsation has ceased in the umbilical vessels, it *may be useful* to divide the funis, so that the blood passing through the umbilical arteries may be received in a cup

to the amount of two ounces. This, and immersing the child in warm water, offer the most probable means of relief, whenever the *discoloration* arises from a permanent or temporary cause."

When a practitioner of such respectable standing as Dr. Merriman makes use of a term so vague as that quoted in the foregoing paragraph, to particularize an important morbid state, frequently terminating in meningeal and cerebral hæmorrhage, is it to be wondered at that many of our pathological definitions are the *ludibria* of our professional brethren on the other side of the channel? Independent of its vagueness, the name "*discoloration*," as applied to the disease under consideration, is exceedingly dangerous, owing to the fallacious security implied by that term: for instance, in those cases where the disease occurs a few hours after birth, when the infant is in the hands of the nurse. This personage being familiar with the above definition, and interpreting it in its true or literal signification, looks upon the first appearance and gradual progress of the apoplectic hue as circumstances of but little moment: at all events, the "*discoloration*," in her opinion, does not go deeper than the skin, nor does it involve other tissues, and can be removed by heat and friction. Stertorous breathing, frothing at the mouth, prominent eyes, convulsions, and perhaps a trickling of blood from the nostrils, are the first symptoms that awaken her to a sense of danger, and indicate, when too late, the necessity of seeking medical advice!

Before concluding these prefatory remarks, I may mention another pathological condition of great interest, incidental to the same periods of existence as apoplexy and asphyxia. This disease was first described by Zeller* and Michaelis, under the expressive appellation "*Cephalæmatoma*†;" and Val-leix‡ and Burchard§ have recently investigated the subject more fully. Cephalæmatoma has some relationship with the disease under consideration, inasmuch as the origin and development of the one, in many instances, bears considerable analogy to those of the

other. According to M. Valleix, the production of cephalæmatomata depends principally upon pressure of the neck of the uterus acting in a certain direction on the foetal head, during its transit from the womb; and Desormeaux is of opinion that the cervix uteri, pressing upon the neck of the infant during the act of birth, is by far the most frequent cause of apoplexy. From these statements it would appear that the compressing agent is exactly the same in both cases. With this inference we must, for the present, rest satisfied, but with the hope of pursuing the inquiry further at a future period; and now we shall proceed to the following case:—

History.—Mrs. A—, having gone a fortnight beyond her time, was safely delivered of a female infant on the 29th of November, at 9 A.M. The labour continued between three and four hours, during which period the pains were severe, and the intervals between each of short duration. An hour elapsed from the dilatation of the os uteri to the birth of the child, and the waters were discharged at least half an hour before that event took place. The head of the infant presented in the way common to natural labour, and descended as far as the cavity of the pelvis, apparently without meeting any interruption in its progress; it was here, however, detained for about fifteen minutes (the pains in the meantime increasing in severity), and was then expelled in the natural way, and without the assistance of the attendant. Immediately on the expulsion of the head from the vagina the infant cried loudly, and continued crying for some moments. A short interval of repose supervened on this stage of the delivery, at the end of which the pains resumed their former severity; and after the lapse of about a minute and a half, or less, from the expulsion of the head, and during the third pain from that period, the body was expelled, and the second stage of labour completed.

The umbilical cord was not entwined around the neck of the child during the process of labour; its position seemed to be perfectly normal; and after the birth of the infant the circulation of the blood through it was found to be carried on without any interruption. About half a minute was allowed to elapse between the birth and the division of the cord; and as the child continued crying during that time, and no untoward

symptoms appearing, it was accordingly deemed advisable to divide the cord without further delay. Immediately after birth a considerable quantity of yellowish ropy mucosity passed from the infant's mouth, and about fifteen minutes afterwards a copious discharge of dark green excrementitious matter, the meconium, came from the bowels; this took place before the child had either taken food or medicine. Within the first hour of the new-born's existence the feet and hands were observed to assume a sort of light slaty colour, which at first sight had more the appearance of the mottled hue of health than that of an abnormal coloration. The colour did not become in the slightest degree darker for at least one hour from the time when it was first noticed, and the child in the meantime appeared lively, partook of its food, and, with the exception of an occasional discharge of mucosity from the mouth, seemed to be going on fairly and well.

After this period the colour of the extremities became gradually darker, the loud cries of the infant already noticed, were now replaced by low and continued moanings, and the mucosities flowed abundantly from the mouth. The nurse administered half a tea-spoonful of castor oil immediately, and had recourse to friction and the warm bath, in order to dispel those gloomy symptoms; but not finding any of the remedies of much avail, and being now apprehensive of danger, she sent forthwith for me. When I saw the infant, the colour of the body throughout was that of a deep blue, with the single exception of the nose, which was remarkably pale and cold. The mucous membrane of the lips and gums partook of the same hue, the mouth was drawn to one side, the eyelids were swollen, the fingers and thumbs were bent inwards towards the palms of the hands, and the little sufferer was moaning deeply.

Judging, from the symptoms now described, that the infant was in an apoplectic fit, I immediately divided the cord and allowed it to bleed. In order to accelerate the flow of blood the child was put into a warm bath, which the nurse kept in readiness by her side. The eyes of the infant were closed, and it appeared quite comatose during the whole of these proceedings; towards the close of them a soft gurgling sound was heard in the throat, for the first time. About

three dessert spoonfuls of blood were drawn from the cord, and as the last was still flowing, a small stream of florid coloured blood appeared trickling down from the right nostril on the upper lip. This was the immediate harbinger of death; for the next moment a convulsive paroxysm ensued, and the infant expired in the nurse's arms.

I may state here, that immediately after death took place, the body became remarkably pale, and the paleness continued for about three or four hours, at the end of which it resumed its former blue colour.

Post-mortem examination 43 hours after death.—External appearances.—Body well developed, and above the ordinary size of new-born infants; embonpoint considerable; colour, dark-blue throughout; mucous membrane covering lips, gums, and mouth, pale blue; nose much paler than the rest of the body; nostrils tinged with blood; superior extremities relaxed; fingers bent firmly inwards towards the palms; chest full; lower extremities slightly rigid; mouth and nares perfectly free from mucosities.

Brain. — Head well formed. On dissecting the scalp from the skull, a large quantity of blood, dark coloured, issued apparently from an emissary vein of the superior longitudinal sinus. Internal surface of scalp emphysematous, highly injected with venous blood (venous injection of an arborescent appearance), and a considerable quantity of serous infiltration was observed between the scalp and pericranium. The pericranium itself was perfectly healthy. The cellular tissue here interposed was also emphysematous: the emphysema appeared in distinct patches, and not throughout. The fontanelles were not prominent*. On dividing the bones, the surface of the brain appeared highly injected with florid blood. The veins took a zig-zag course, and were engorged with dark blood. At the junction of the

anterior and middle lobes (left side), on the external inferior aspect of the brain, a large bleb-like patch was observed, about the size of a five-shilling piece, of serum and dark coloured blood, immediately under the arachnoid membrane, and extending down to the nerves going to the orbit. The membranes were here easily separated from the brain; latter softer in this place than elsewhere; substance of left hemisphere, generally speaking, of the natural consistence; white substance injected throughout, of a sort of palish purple or slaty colour. Left ventricle contained little or no serum, and was slightly injected. Choroid plexus of same side very firm, owing, apparently, to the great engorgement of its veins with dark venous blood.

In the *right* hemisphere and middle lobe a patch was observed beneath the arachnoid of a dark sero-sanguineous appearance, and similar to that noticed in left hemisphere, but extending much deeper into the skull than the former, and passing close by the side of the sella-turcica, instead of going only to the nerves, as that on left side. Right ventricle, much more injected than left, contained no serum. Choroid plexus on right side not so much injected as left, but, at the same time, very dark coloured. Cerebellum highly injected on its surface; of a slaty hue when cut into; firm. Pons varolii healthy and firm. Tubercula quadrigemina *idem*. There was no sanguineous effusion of any importance observed at the base of the brain.

Spinal marrow. — The vertebral canal being laid open from the atlas to the lumbar vertebræ, the spinal marrow was examined *in situ*. Size and consistence normal; a very considerable quantity of dark-coloured effused blood was seen extending from about the second to the sixth dorsal vertebra on the left side, and altogether external to the membranes; the latter were healthy. Right side perfectly free from effusion, and but very slightly injected. The cord was now removed from the vertebral canal, together with the medulla oblongata and inferior part of cerebellum. There was no effusion whatever beneath the cord, and the theca of the canal was not injected; it was shining, and of a light bluish tint. Nothing particular was noticed on making sections of the parts removed: in short, the spinal

* A peculiarity of the cranium of infants, first described by Haller, and recently brought into play by M. Valleix, in his ingenious theory of the origin and mode of production of cephalæmatomata, was here well illustrated. On removing the pericranium from the *parietal* bones, and then gently compressing the latter, minute drops of blood oozed forth by innumerable orifices, diverging in radii from a centre, and finally formed by their union a layer of sanguineous fluid on the surface. Continued pressure of the cervix uteri on the head, will, according to M. V., produce a cephalæmatoma, and the foregoing peculiarity may be regarded as a predisposing cause to that disease.

marrow appeared healthy and firm throughout. The exact quantity of the cephalo-rhachidian fluid was not ascertained, but it appeared, however, to be small. *Chest*: on cutting into the thorax, a layer of fat, more than a quarter of an inch in thickness, was observed between the muscles and skin. Muscles firm and healthy; a large quantity of serum was effused into the cavity of the chest. The lungs contained no more blood than could be accounted for on the principle of gravitation; they were remarkably healthy. The heart and pericardium were also perfectly normal; former contained no blood. Thymus gland healthy. The abdomen was not examined.

OBSERVATIONS.—On reviewing the history of the foregoing case, and the morbid appearances discovered at the autopsy, one or two points in particular appear to me of sufficient interest to merit a few moments' consideration. In the first place, what was the cause of the apoplexy in that instance? secondly, did the post-mortem lesions above noted resemble those usually met with in similar cases? and, lastly, a few remarks regarding the treatment recommended in general in infantile apoplexy.

I. It will be remembered that nothing untoward occurred in the case during parturition by which we might account for the apoplexy; for although the pains were severe, the labour was natural and comparatively of short duration; also that the infant cried loudly on the head being expelled, and again on the expulsion of the body, and before the cord was divided, and finally that the blue or apoplectic hue did not appear for a considerable period after birth. The causes commonly assigned for infantile apoplexy are as follows: Long and laborious labour, especially when the infant is large and plethoric; compression of the head in the passage; compression of the neck by the umbilical cord; employment of the forceps in extricating the head; compression of the neck and cord by the mouth of the womb, or by the external parts; preternatural presentations; premature discharge of the waters of the amnion, &c. Such are the opinions of MM. Lullier Vinslow*, Chambon†, Courant‡, d'Angers, Capuron§,

Desormeaux*, Velpeau†, Billard‡, Valliex, Davies§, and Kennedy||. Two of the principal of the above-mentioned causes, however, are denied by MM. Gardien¶ and Cruveilhier** ; the former will not admit that compression of the cord, however severe, can produce the apoplectic state, and the latter, instead of allowing that the application of the forceps produces the disease, states it as his firm conviction that it is the means of preventing infantile apoplexy from occurring in numerous instances. I confess that I find some difficulty in attributing the apoplexy, in the case just related, to any of the above-mentioned causes. It is true the head of the infant was detained for some short period in the cavity of the pelvis, before it was expelled; but this does not appear to be the cause; and M. Cruveilhier†† observes that although he has seen infants in an apoplectic state at the termination of an ordinary, or even a speedy labour, he has, on the other hand, witnessed cases where the head was retained in the cavity of the pelvis, for twenty-four and forty-eight hours, and even longer, without occasioning any disease‡‡. The same author remarks that in a great number of cases it is impossible to determine the cause of apoplexy occurring in infants during the progress of parturition. In some such instances, (he further observes) perhaps after the discharge of the waters, the uterine contractions keep up a fatal compression on the umbilical cord still contained within the cavity of the womb. This latter, I am inclined

‡‡ Desormeaux asserts, that the apoplectic state is often renewed, or even developed for the first time, after respiration is fully established; and that he has seen the disease occur without any appreciable cause the day after birth. Vide Dictionnaire de Médecine, vol. xv. p. 153.

Dr. Kennedy ascribes the frequency of apoplexy in the new-born infant to the suddenly altered circulation, together with the loss of balance between several of the most important of the vital organs consequent upon that change.

to believe, was the most probable cause of the apoplexy in the case I have related; and it is hardly worth mentioning, that the ropy mucosities observed in the mouth, &c., if sufficiently abundant, would produce a very different, though important, morbid condition—*asphyxia**.

II. The emphysematous appearance of the internal part of the scalp, and of the cellular tissue immediately beneath it, as already noticed, is not usually met with in cases of infantile apoplexy, and I certainly think it was not a post-mortem effect in this instance. The most constant anatomical character of this disease, occurring in new-born infants, is, according to M. Cruveilhier, an effusion of liquid blood into the cavity of the arachnoid†. The effusion is most commonly confined around the cerebellum and posterior lobes of the brain; it rarely occupies the cavities of the ventricles. M. C., however, met with three cases in which he found clots of blood in the ventricles‡, and he has given a very instructive illustration of the disease, in which are represented the scalp and subjacent cellular tissue highly injected; the cerebellum, and posterior lobes of the cerebrum, surrounded with clots; portions of the dura mater ecchymosed; the bones of the cranium intensely injected; and liquid blood surrounding the spinal marrow, down to the lumbar vertebra. In the case I have related all the lesions were not so strongly marked as in this, although one or two of them were still more so; and, with regard to the effusion into the arachnoid, M. Velpeau observes§, although it is of frequent occurrence, nevertheless, in the majority of instances, the blood either does not

escape from the vessels, or forms but slight ecchymoses. Désormeaux* states that in cases of death from apoplexy of new-born infants, the vessels of the encephalon are gorged with blood; sometimes this fluid is effused on the surface of the meninges, or even into the substance of the brain itself; the lungs are also engorged with blood." The latter lesion, it would appear, is not of constant occurrence, and in the foregoing case the lungs were remarkably free from engorgement; M. Gardien†, however, who says but little regarding the pathology of the complaint, states, in a general way, "that the head and chest are always loaded with blood, and that after death there are frequently found effusions into the skull (*des épanchemens dans le crâne*), as we find in the cases of adults who die of apoplexy." This view of thoracic engorgement he carries into his observations on the treatment of the disease, as we shall presently see. The organic lesions, met with after death in this disease, as mentioned by Dr. D. D. Davis, in his elaborate work‡, differ materially from some of the foregoing, especially from those of Cruveilhier. Having mentioned several of the leading symptoms of a well-marked case of infantile apoplexy, Dr. Davis goes on to say that in such instances we find the vessels of the head exceedingly turgid, and many of them ruptured, and their contents effused into the ventricles, and into different parts of the brain, forming cysts, containing deposits of coagulated blood." Dr. D. does not mention thoracic engorgement as an anatomical character of the complaint.

From the foregoing details, it results, that the principal difference between the lesions just quoted, and those of the preceding case, consists more in locality than in magnitude; as, for instance, none of the authors cited mention the sanguineous effusion having taken place *beneath* the arachnoid, or the engorgement of the choroid plexus, both of which conditions obtained, in this in-

M. Valleix draws a decided distinction between the apoplexy that occurs in the act of birth, or a few hours subsequent to that event, and that which takes place several days after delivery. Of the latter he gives three instructive cases; but, with regard to the former, he says little, and excuses himself on the score of his not having had an opportunity of seeing any other infants than those that were several days old; "conséquently (adds M. V.) I have but rarely observed the form of the disease described by M. Cruveilhier and others." M. Valleix does not clearly define what he means by a new-born infant. See his "Clinique des Maladies des Enfants nouveaux nés," 1835.

* Dictionnaire de Médecine, vol. xv. p. 154.

† Traité d'Accouchemens, vol. iii. p. 139.

‡ Principles and Practice of Obstetric Medicine, vol. ii. p. 1214.

Billard states, that injection of the meninges, and of the substance of the brain, is so common an occurrence in the new-born infant, that it appears to him more proper to regard them as natural than pathological conditions. See his Traité des Maladies des Enfants nouveaux nés, et à la mamelle. Paris, 1828.

tance, to a remarkable degree; and, on the other hand, the extensive effusion (externally) from the superior longitudinal sinus, must have materially prevented that which took place within the cranium from being so great as it otherwise would have been; thus, as it were, counterbalancing the more loaded, ecchymosed, and injected state of the brain and its membranes, together with the greater effusion into the vertebral canal, noticed by some of the other writers.

III. Whatever discrepancy of opinion may exist between authors, with regard to the causes and morbid appearances of infantile apoplexy, all agree on one most essential point—its treatment; the principal feature of which consists in prompt and speedy blood-letting. M. Savary* thinks it proper to caution the physician from confounding this complaint with asphyxia: he says, “It is very important to distinguish the asphyxia from the apoplexy of new-born infants, as the treatment of one is directly opposite to that of the other;” but I am inclined to think, with M. Gardien†, that the aspect or appearance of the infant will, in general, readily point out the real nature of the disease; for in the latter, to use the expression of the celebrated Baudelocque, “the infant comes into the world *ex sanguine*,” the colour of the body is pale instead of blue. There is another affection—the “blue disease,”—which, in my opinion, is much more likely to be confounded with this form of apoplexy than the foregoing; but the comparative rarity of its occurrence subtracts, in a great measure, from the baneful results that would otherwise accrue from such a contingency.

Notwithstanding the above statements, we have the high authority of M. Cruveilhier that mistakes relative to the identity of those two diseases are of very frequent recurrence. He states, “that in almost all the cases of death at the Maternité, commonly attributed to *asphyxia*, or to *congenital feebleness*, he found the lesions of infantile apoplexy‡.” Suffice it to say, there is but one inference to be drawn from all such mistakes on the part of the attendant—inevitable death to the infant. In the one case (apoplexy), our only chance

of success depends on the immediate extraction of blood; in the other (asphyxia), notwithstanding the assertion of M. Chaussier to the contrary, such a remedy would not only be useless, but according to many would be highly injurious. M. Gardien recommends*, in all cases of apoplexy of new-born infants, immediate section of the cord, or of the ligature, in case it should be tied, as by this means, he says, “you unload the brain and chest, which are gorged with blood;” also leeches behind the ears, gentle compression of the abdomen, and the warm bath, containing a little wine, brandy, or vinegar. Desormaux states†, that in consequence of the torpidity of the circulation in the umbilical arteries, during the apoplectic state, it is with difficulty the blood can be extracted after dividing the cord. In such instances he recommends the patient to be put into a warm bath, and, while in it, the funis is to be constantly expressed from its insertion to where it was divided; and if these means fail, a single leech placed behind each ear will in general suffice: he is likewise of opinion that compression of the abdomen is both useless and inconvenient. M. Velpeau says‡, that section of the cord is the first and principal remedy to be had recourse to, and agrees with Desormaux in stating, that as it is impossible from the outward signs of the apoplectic infant to distinguish, *à priori*, simple congestion from encephalic hæmorrhage, the accoucheur is bound to render the same care and attention to *all* cases, as if they were the worst or most dangerous forms of the complaint. In order to encourage the flow of blood, M. Velpeau recommends, on the authority of M. Champion§, resection of the umbilical cord from time to time, as an adjuvant of much utility. M. Cruveilhier regards all cases of infantile apoplexy as the effects of *mechanical* causes||; and is of opinion that the disease may be prevented in numerous instances by a timely termination of the labour. His remarks on the treatment are entirely prophylactic. He states, that he has seen retropulsion of the cord frequently practised with success at the Maternité, when there was

danger from pressure on this part. In cases of the presentation of the feet, he says the application of the forceps, after the body is expelled, will frequently prevent death from taking place. Dr. Davis alleges that *two ounces* of blood is the *maximum* quantity to be drawn from the divided cord in this disease*. Dr. Kennedy† recommends leeches to the *fontanelles*, if the funis will not give sufficient blood.

REPORTS OF CASES, &c.

By H. M. HUGHES, M.D.,

Physician to the Surrey Dispensary.

RENAL DROPSY.—ALBUMINURIA.

So much has of late been written upon this affection, that, although it abounds with unexplained difficulties, and therefore offers a fruitful field for pathological investigation, I feel that the observations of one whose attention has not been especially directed to the subject are not likely to present matter either of novelty or of interest; my general remarks, therefore, will be few.

It is now several years since Dr. Osborne asserted it was probable that upon no question connected with pathology had so much and such decisive evidence, direct and confirmatory, been adduced, as upon the general connection of the secretion of albuminous urine with peculiar derangement of the kidney. Since that time this evidence has been immensely increased, both by the original discoverer, Dr. Bright, and by other labourers in the same field, who have recently presented the results of their observation to the profession. Notwithstanding the vast and daily increasing amount of facts adduced in proof, or in support of this connection, there are some who continue to express doubt upon the subject; if they do not as heretofore ridicule the notion of dropsy being connected with, and principally dependent on, disease of the kidneys. Such persons advance, in justification of their incredulity, the fact recognised and acknowledged by all, that albumen occasionally appears in the urine under circumstances in which it seems impossible to believe

that there can exist any permanent derangement of these organs, and a few solitary cases in which after the continued secretion of albuminous urine the kidneys have been found healthy. This and much more may be granted without, I think, affecting the correctness of the deductions, or the truth of the opinions, originally advanced and still maintained by Dr. Bright. The care, indeed, with which the facts and observations were in the first place collected, and the caution with which the opinions founded on them were primarily introduced to public notice, are very obviously evinced by the circumstance that little or nothing, propounded more than twelve years ago in reference to a new and important discovery, now requires alteration or material modification. That albuminous urine may exist without *permanent* derangement of the kidney, is clear from its frequent appearance after scarlatina, and the recovery of persons in whom it occurs. That it may sometimes arise from the morbid state of the circulating fluid itself, appears probable from the escape of various constituents of the blood in sea scurvy, purpura, and other similar diseases. If, indeed, the presence of albumen in the urine may (as in the early stages, at least of Bright's disease, and after scarlatina I imagine it may,) be supposed to depend upon the escape of the serum of the blood from the vessels of the kidney, if it may in some cases be considered to arise from the congestion, dilatation, and consequent thinning of the coats of the vessels of the secreting portion of the organ, it appears at least not improbable that, the state of the vessels being natural, it may also sometimes result from an altered condition, or tenuity of the blood itself—that under some circumstances it may proceed from a change in the fluid *from* which, and in others from a change in the fluid *by* which, the urine is secreted. That albumen may also temporarily exist in the urine under certain conditions of the system, and from causes not ascertained, as in some cases of pregnancy, in persons suffering from salivation, and some acute diseases, without important, or permanent derangement of the kidneys, is not, and has never been, I believe, denied. But that when the urine for a considerable time remains constantly coagulable by heat and nitric acid, when there exists no evidence of disease of the bladder, ureter, or prostate,

* Principles and Practice of Obstet. Medicine, vol. ii. p. 1214.

† See Dub. Journ. vol. x. 1837.

and particularly when the coagulable urine is, or has been, conjoined with a light specific gravity of the fluid, with anasarca and other symptoms of the morbus Brightii, there is abundant cause for believing that the person in whom it occurs labours under some serious functional disorder, if not organic disease, of the kidney, has been proved by observations so numerous as not to admit of doubt in the mind of any whose opinions are founded upon the facts collected by the inspection of the dead, and are not influenced by old prejudices and scholastic prepossessions.

The weight of the immense amount of evidence bearing upon this subject, already collected, is but little affected by the few solitary cases that have been published by Dr. Darwall, Professor Forget, M. Solon, Dr. Morrison, and others, in which "perfect soundness" of the kidneys was found, though albuminous urine had been secreted for some time, and in one case occasionally for *five years*, before death. Such cases merely prove that coagulable urine *may* exist without disease, or such derangement of the kidney as is cognizable by the senses, or at most that it is not universally dependent upon an abnormal condition of these organs.

The advantage of acting on the skin in the treatment of this disease was originally pointed out by Dr. Bright himself, and was subsequently more particularly insisted on by Dr. Osborne. This physician has even stated that when he has been able to produce a healthy action of the surface, he has had little difficulty in removing the complaint, and evidently believes that the disease of the kidney is essentially connected with suppressed function of the skin. Dr. Bright, in a paper contained in the 1st vol. of the *Guy's Hospital Reports*, says, "In almost every case, the first impression that brings on the anasarca is suppression of perspiration; but it is almost as constantly the fact that the kidneys have undergone some previous irritation, and, very likely, that the albuminous urine, in most cases, existed previously to the occurrence of those symptoms, by which it has been recognised, more particularly previously to the anasarca." In the same paper, he says, "The only organ, except the kidney, which I think, on taking a review of the history of this disease, might probably act as a primary cause, is the skin, and this is so closely

connected, in its derangements, with the kidney, that the relations of their lesions, as regards cause and effect, become equivocal." But he afterwards adds, and herein differs from Dr. Osborne, that "we often establish, for many months, the secretion of the skin, while the urine remains albuminous." My own comparatively very limited experience accords generally with that of Dr. Bright. That the suppression of the natural functions of the skin is frequently the cause of the anasarca, I have no doubt. My conviction arises not simply from the fact mentioned by Dr. Bright, but from its reappearance after removal, in consequence of the application of cold; from its cure by diaphoretic medicines, and such other measures as tend to restore a perspirable state of the surface; and from its co-existence with the harsh and dry skin after scarlatina, to which, in a former paper, I have already referred. Cases have, however, occasionally occurred to myself, in which I was unable to detect any other cause for the complicated disease than such as acted on the external surface of the body, and in which the complaint could certainly not be attributed to habitual indulgence in spirituous or fermented liquors, and I have seen a few, though very few instances, in which the coagulability of the urine, together with the anasarca and other symptoms, have ceased when a free perspiration has been established. Whether, in such cases, the disease is cured, or only temporarily suspended, will probably hereafter appear. A principal cause of the generally unmanageable and incurable nature of the complaint, probably consists in the, usually, extremely insidious character of its first stages. Patients, particularly those of the lower order, do not apply for medical advice, till the dropsy, one of the symptoms, and sometimes, by no means an early symptom of the disease, attracts their attention, and till there is often good reason for believing that the affection of the kidney has already existed for several months, or even years. When we are fortunate enough to discover the complaint in its early stages, and when active means are adopted for its removal, I trust there are sufficient grounds for entertaining the hope that it may be arrested in its progress, if not entirely cured.

Of the five cases of which I have some

notes, as occurring under my care, during the past year, two were males, aged 40 and 43, and three females, of the respective ages of 27, 28, and 35. All, with one doubtful exception, had been habitual spirit drinkers at an earlier period of life, though all asserted that they had, for some years, discontinued the practice. The anasarca in four followed, and appeared to have first been produced, by exposure to cold; in the fifth, it succeeded to scarlatina. In two, it was accompanied with hydrothorax; in two, with bronchitis; and in one, with acute dysentery. Three went into hospitals, or passed into other hands, and two died under my care. The history of the two fatal cases is, briefly, as follows.

William Hawkins, aged 40, came under my notice, as a patient of the Surrey Dispensary, Oct. 31st, 1839. He was a steady man, the father of a family, and cook of a Boulogne steam vessel, in which capacity he had, some years ago, drank a great deal of French brandy; but, according to his own and his wife's account, had latterly been tolerably temperate. Six years before, he had fever in India, but was not afterwards troubled with any complaint, till about six weeks previously to his last illness, when he was injured in the back by a fall, the consequences of which confined him to bed for a fortnight; after this, he regained his accustomed health. He had never suffered from cough or dropsy. Three weeks before I saw him he had been confined with scarlatina; the rash was bright and general, but he had little or no affection of the throat. After his partial recovery, he went a voyage to Boulogne, and upon his return was affected with œdema of the face and feet. This was not more than two or three days before he came to the dispensary: general anasarca then existed; the face and surface were pale, the skin hot and dry, without exfoliation; he complained of pain, and tenderness on pressure in the loins; his urine was small in quantity, clear and pale, but strongly coagulable by heat and nitric acid. He had some cough, and complained of tightness of the chest, which, on percussion and auscultation, afforded the physical signs of bronchitis.

Ordered to be cupped in loins to ʒxvj .
and to take Antim. Potassio tart.
gt. 1-3rd, Liq. Am. Acetat. Aq. fontan.

aa. ʒvj . 6tis. horis, et Pulv. Jalap. C.
ʒij. quotidie mane, and to be clothed
in flannel.

He was afterwards bled twice, and diaphoretics, with hydragogues, were continued without benefit. Inf. Digitalis, and other diuretics, were prescribed, and Elaterium administered without effect; and though he was kept in bed with a large poultice on his loins, the skin remained dry, the œdema rather increased, the urine remained coagulable, and the cough and dyspnoea became more troublesome. After six weeks' ineffectual treatment his head became affected; he rambled in his sleep, appeared heavy, and partially comatose; he was capable of being roused, and of answering questions put to him, but soon relapsed into his former lethargic condition, and died, without any decided fit, Dec. 15th. Being myself engaged, the inspection was performed by Mr. Nettlefold, forty-eight hours after death. I was favoured by that gentleman with the following particulars, and an opportunity of myself examining the kidneys. The head was not opened. *Chest*: The right pleura was firmly and universally adherent, and at the lower part the lung beneath it was converted into a firm grey substance, about half a line thick; in the centre of the upper lobe of this lung was an irregular, but defined, hardened mass, of a dark purple colour, as large as a hen's egg (probably pulmonary apoplexy.) It was contained in a cavity with soft, and almost diffuent parietes, which contained no fluid, and appeared not to communicate with any bronchial tube: the other portion of the lung was very œdematous. The left pleura was only partially adherent, but the lung contained a similar dark purple mass, and was, at other parts, œdematous as that of the right side. The pericardium was healthy, the heart large and flabby. The inner membrane of the stomach was dark from congestion, and the liver very large, but not unhealthy in structure. The kidneys were rather large, their tunics strongly adherent, and their surface, besides two or three urinary cysts, presented a very marked granulation, depending upon small rounded whitish masses, about the size of pearl sago. On section, the cortical structure was found thin, irregular from partial contraction, and universally granular;

the tubular portion large, and the parts of which it is composed increased both in size and distinctness.

I have only to remark upon the preceding case, that from the advanced state of the disease in the kidneys, and the usually slow and insidious progress of the complaint, I think there can be no doubt that these organs had been deranged for some months, at least, before the attack of scarlatina.

George Edwards, a large stout man, aged 43, became a patient of the Surrey Dispensary, January 11, 1840. He had, previously to this illness, enjoyed good health, had been occupied as a carter, and accustomed to drink freely, though not frequently so as to produce intoxication. When I first saw him, he had already been confined to his bed for several days with catarrh, the result of cold and wet, to which he was much exposed in his occupation. On my first visit he appeared to be suffering from bronchitis, with some, and not very extensive, œdema of the lungs. There was nothing, however, in the general features of his complaint indicative of more than the ordinary interest of such cases, except the pale and bloated appearance of the face. He complained of cough, and great oppression at the scrob. cordis, and some head-ache. His skin was dry, but not hot; his respiration difficult, and his pulse full and soft. Auscultation and percussion indicated pulmonary congestion, œdema, and bronchitis. The urine was to be saved for examination.

Ordered C. C. Scrob. Cord. ad ʒviii.; Pulv. Jalap. C. ʒss. st. et quotidie mane sumend. Ext. Conii, gr. iv.; Sodæ Sesquicarb. gr. x.; Antim. Potassio Tart. gr. ʒ; Aq. ʒiiss. 6tishoris sumend.

14th. — Oppression of chest much relieved; bowels freely opened; complained, on examination, of tenderness on pressure in the lumbar regions. Skin dry, not hot; urine coagulable by heat and nitric acid; had but little sleep.

C. C. Lumbis ad ʒxij.; Opii, gr. ss.; Antim. Potassio Tartat. gr. ʒ, ft. Pil. hora somni sumend. Rep. Mist. et Pulv.

16th. — Pain of loins on pressure entirely removed. Had no cough, and but little oppression at the chest; urine still coagulable. Ordered to keep his

bed, and to continue his mixture and powder.

He afterwards took a variety of diaphoretic medicines, with hydragogue cathartics, and small doses of tr. digitalis. He was then ordered the less stimulating diuretics, and again returned to the diaphoretics, with a large linseed poultice on the loins, without producing any effect upon the urine. He had been taking antimony and Dover's powder during the day, and gamboge and compound jalap powder every morning, had little or no anasarca, and complained of some sickness from his medicine, but was, in other respects, little changed from his ordinary condition for several days past; when, after the omission of his aperient powder on the preceding morning, and his bowels being in consequence more confined than usual, his fears having been excited the night before, in reference to his children, who had gone to see an illumination, and some anxiety existing in his mind about his club, he was, at 9 A.M. February 11th, attacked with tremors, headache, heat of skin, and "pain of the inside." When seen about 1 P.M. the face was pale, the head and skin hot, the pupils rather dilated and sluggish, the pulse was feeble, frequent, and sharp. He was exceedingly restless, and complained of intense pain of the forehead.

C. C. Nuchæ ad ʒx.; Lotio evaporans fronti appl.; Haust. Cathart. st.; et rep. 6tis hor. ad plen. alv. solutio.

Feb. 12th. — The cupping and cold almost entirely removed the pain of the forehead, and the bowels were freely moved by the aperient medicine, and he appeared as well as usual afterwards; but in the evening he was suddenly attacked with dyspnœa, and afterwards became much excited and very restless, wandering much, and frequently getting out of bed; so that it became necessary to restrain him by force. When visited early in the morning, he was perfectly sensible, complained of no pain in the head, and answered questions directly and distinctly. There was no unnatural heat of the forehead, but the pupils were as the day before, and he was in a state of constant restlessness and agitation, continually changing his position from the erect to the semirecumbent, from the semirecumbent to the erect, or from one side to the other. He complained of

some pain in his left side, but of scarcely any tenderness on pressure; his tongue was pale and moist, his respiration was 60, without perceptible rattle, and his pulse scarcely perceptible. On examination, the whole chest was resonant on percussion, not excepting that part in which he experienced pain. Throughout the entire chest, also, the respiratory murmur was heard pure and distinct; more loud, indeed, than in the healthy adult thorax, and of puerile intensity. No unusual dulness was perceptible in the præcordial region, but the sounds and rhythm of the heart were not distinguishable, in consequence of the frequency and violence of the inspiratory movements, and the patient's great agitation and constant motion. The extremities were cool, the countenance sunk and anxious, but not hippocratic.

Haut. Ammon. c. Sp. Æther. Sulph. C. ʒss. st. sumend. et 3tiis horis repetend.; App. Sinapismus Scrob. Cord. et lateri sinistro.

7 P.M.—He was much the same; perfectly sensible, but still excessively restless and anxious. He had removed from his bed, and sat in a chair by the fire, but had the street-door locked, lest I should find him in that situation. A blister was ordered, and other stimulant medicines were prescribed, but he died an hour after, before either could be obtained.

To what these unusual and suddenly supervening symptoms were attributable, could not unfortunately be decided, as he left a dying request that no examination should be permitted. I have occasionally seen similar results produced equally suddenly by œdema of the lungs, but the existence of this condition was disproved by the auscultation and percussion. Might the symptoms arise from a defined local *phrenic* pleurisy, or were they produced by a fibrous concretion in the heart?

I had intended to have added another case of acute anasarca, accompanied with coagulable urine and acute dysentery; but my notes of the case are not at present by me: I shall, therefore, defer noticing it till I add a few remarks to those I have already made* on the disease last mentioned.

* MEDICAL GAZETTE, December 20th.

MR. OWEN AND MR. NASMYTH ON THE TEETH.

To the Editor of the Medical Gazette.

SIR,

I ESTEEM it a fortunate circumstance to have seen your journal of Saturday last in time to put a stop to some proceedings, of which you will understand the nature from the subjoined letter, which I have addressed to the Secretary of the British Association, relative to the charge of plagiarism which you have preferred against me in your review of my work entitled "*Odontography*," &c.

London, June 10th, 1840.

My Dear Phillips,

It has been more than once objected to the publications of the British Association, that the communications, of which abstracts are given in the annual volume of Transactions, are not always remarkable for novelty; nay, that sometimes injustice has been done to able foreign Scavans by the silence with which their discoveries, broached at our Sections as novelties, are passed over. I do not write to call your attention, on this account, to Mr. Nasmyth's able memoir on the Cellular Structure of the Ivory, Enamel, and Pulp, of the Teeth, communicated to the Medical Section, (August 29th, 1839); but pray compare what he now proposes to print in the forthcoming volume of the Transactions, as the memoir communicated by him in August last, with the abstracts of that memoir printed in the *Athenæum* (No. 620, Sept. 14th, 1839), and *Literary Gazette* (Sept. 21st, 1839). I was, unfortunately, unable, as you are aware, to attend the Medical Section when the paper was read, and am, therefore, acquainted with the discoveries and opinions it contained only by the abstracts above quoted.

I subsequently communicated to the French Institute a memoir on the Development of Teeth, of which an abstract was published in the "*Comptes Rendus*," for December 16th, 1839, and a succeeding number. I have been charged by the Editors of the *MEDICAL GAZETTE* and *Lancet* with having plagiarized my theory of dental development, and the facts on which it rests, from Mr. Nasmyth's memoir read at Birmingham in August last; and this accusation, besides deriving plausibility

from the stale trick of passages parallelized by means of mutilation, is likewise, and mainly, supported by quotations from Mr. Nasmyth's memoir, in the eighth volume of the Transactions of the British Association!

I would suggest that when an author has not, at the period of reading his memoir at a sectional meeting, deposited the same, as read, in the Archives of the Association, the secretary should exercise a discretionary power, with respect to the admittance into the Transactions of a memoir or abstract, which may materially differ from the original communication, or its abstract printed in the *Athenæum*, *Literary Gazette*, or other journals which report the proceedings of the Association; otherwise a grievous injustice may be done to other inquirers, whose works may appear between the periods of the meeting of the British Association and of the publication of the volume of the Transactions of that meeting, by an apparent anticipation of their discoveries; and an envious or malicious person may add to that injustice a plausible but false accusation of plagiarism.

I have not seen the memoir or abstract which Mr. Nasmyth has transmitted for publication in the forthcoming volume of the Transactions; but the attack to which I have alluded, and the mode in which it is supported, lead me to anticipate a difference between it and his memoir of August, which, while doubtless originating in a natural desire on the part of the author to render his memoir, as printed in the forthcoming Transactions, not below the present state of science, has given occasion to its being made an instrument of attack on the real author of its improved condition.

To defend myself, therefore, from the imputations of the editors of the London weekly medical journals, I am obliged to request that you will direct Messrs. Taylor to send me a proof of Mr. Nasmyth's memoir, as now prepared for publication, in order that I may be able to point out the interpolations, additions, or omissions, which may convert the differences between Mr. Nasmyth's August communication and my December memoir into correspondences.

To give you an idea how easily, though doubtless unintentionally on Mr. N.'s part, this may be effected, I shall observe that my observations on dental development, and the theory

founded thereon, while they indicated the amount of analogy and the characteristic differences between the modes of formation of ivory and bone, were subversive of the prevalent doctrine, that the ossific matter of the tooth was deposited in thin layers on the surface of the pulp, a doctrine based upon the well-known facility with which these layers can be detached. Indeed, I expressly deny that the surface of the pulp is formative, in the sense of producing the ivory which is in apposition to it.

Pray observe, therefore, whether Mr. Nasmyth retains in his memoir (quoted by my accusers from the *Transact.* of the Brit. Assoc. vol. viii.) the following passages, which you will find in the abstracts thereof furnished by him to the *Literary Gazette* (Sept. 21st, 1839,) and *Athenæum* (Sept. 14th, 1839.)

"When merely a thin layer of ossific matter has been deposited on its (the pulp's) surface, it may, with great facility, be drawn off entire."—*Lit. Gaz.* p. 578.

"The formative surface of the pulp, which is in apposition to the ivory, and by which the latter is produced, he described as presenting a general cellular arrangement, which he denominated reticular, resembling a series of skeletons of a desiccated leaf."—*Athenæum*, p. 707. It might be contended—for it must be confessed that the cuttle-fish scarce more effectually conceals its body, by scattering abroad its ink, than does Mr. Nasmyth his meaning by a similar process—that the mode of production here meant by Mr. Nasmyth, was that which I subsequently described in December, viz. by *conversion of the pre-existing and pre-arranged cells in the substance of the pulp*, instead of by evolution from its reticular surface. See, therefore, whether he still retains the following statement, which expresses his notion, in August last, of the mode of formation in question. "Mr. Nasmyth is of opinion that, from the spirally fibrous frame-work of the reticulations are evolved the spiral fibres of the tooth."—*Athenæum*, p. 707. Again if the passage—"A comparison between the superincumbent perfect ivory, and the formative surface of the pulp beneath, is always easy"—*Lit. Gaz.* p. 599—be retained in the memoir, as it is about to appear; observe whether the word *formative*, as applied to the surface of the pulp, be now omitted in that passage: because, in order to make Mr. N.'s me-

moir 'on the Cellular Structure of the Teeth,' as read in August last, consistent, as regards the theory of the formation of ivory, with mine 'on the Development of the Teeth,' as published in December last, as well as with itself, as improved by the new paragraphs, quoted by my accusers, to support their charge of plagiarism—the statements in the original memoir, to which I have drawn your attention, upholding the old doctrine of dental development by thin layers of ossific matter, successively *evolved from, or deposited on the formative surface of* the pulp, and those other statements which expressly deny, or imply the negation of, the formation of ivory by ossification of the pulp, and indeed the whole, or nearly the whole, of the speculations on dental development, contained in the first and second columns of the Literary Gazette, p. 598, must be omitted, and other statements substituted.

Not, however, to tax your patience with more of these physiological subtleties, I may simply state that the aim of my researches, communicated to the Institute, was so far different from those I am accused of plagiarising, that whereas it was neither to controvert nor confirm the cellular structure of the ivory, as described by Retzius,* it bore directly on the establishment of a true theory of its development, and this theory my observations enabled me to propose with confidence. Now the main object of Mr. Nasmyth's investigations on the microscopic structure of the

teeth, communicated to the British Association in August last, was to prove the cellular structure of the ivory; with regard to its mode of development he expressly states, "that the researches which he has made on this point are, as yet, imperfect."—Lit. Gaz. Sept. 21, p. 597. And the Athenæum reports, "that with respect to the formation of the ivory, Mr. Nasmyth stated that he was not prepared with a satisfactory theory." (No. 620, Sept. 14, 1839.) It is in accordance with these admissions, and with the evidence of Mr. Nasmyth's leaning to the old doctrine of the deposition of the ivory in thin ossific layers, or any other form, upon the formative surface of the pulp, contained in the passages which I presume may be possibly omitted in his forthcoming memoir, that the accomplished translator of Müller's Physiology (loc. cit. p. 431)—when he states that "The observations of Purkinje, Raschkow, and Schwann, respecting the mode of formation of the proper dental substance, have not yet completely elucidated the subject"—does not refer to any subsequent discovery, in Mr. Nasmyth's communication to the Brit. Association in August, 1839, tending to such desirable additional elucidation; whereas that communication, if it had anticipated, as the editors of the Gazette and Lancet affirm, all that I claim as original in my December memoir, would unquestionably have afforded important additional, if not complete elucidation, of the nature of that interesting process."

And here, Mr. Editor, allow me to suggest to such of your readers as may not be disposed, either through your, or my equally strenuous recommendation, to compare the abstract of my memoir in the Comptes Rendus, with that of Mr. Nasmyth, in the Athenæum and Literary Gazette, in quest of scientific analogies or otherwise, to turn to Pt. I. of Dr. Baly's Müller, 2d edit. pp. 427-431, published in October, 1839: this excellent work I presume to be in the libraries of most, if not all of your readers; and, with the evidence they will there find of the disposition, on the part of the learned translator, to do justice to the discoveries of his countrymen, I would ask, if they can conceive it possible that Dr. Baly would omit all notice of the laborious and ingenious microscopic observations, of the apt selection of appropriate subjects for yielding the required results, which convert a previous probability of

* "In our best English work on Physiology you will find the following passage: 'M. Retzius has discovered that the tubes in their course from the cavity of the tooth to the external surface of the ivory, branch by dichotomous division, and give off numerous side twigs, which ramify in the intertubular spaces. Some of these twigs terminate in small cells filled with calcareous matter, and very similar to the corpuscles of bone. In the human teeth these cells are very minute, and difficult to discover; but they are distinct in many mammalia, as, for example, in the horse (fig. 41.)' Baly's Translation of Müller's Physiology, 2nd Ed. Part I. p. 427. Dr. Baly adds, 'In the Report of the meeting of the British Association in the Athenæum, No. 620, Mr. Nasmyth is represented as stating that the intertubular substance of the ivory is not structureless, but distinctly cellular.' And he might have added, that Mr. Nasmyth, instead of citing Retzius' beautiful observations, anticipating his alleged discovery, likewise asserted 'that the interfibrinous substance of the teeth had been improperly described by modern anatomists as presenting no traces of peculiar conformation.'—Lit. Gaz. p. 601.

"If this statement be retained in the account of the alleged discovery of the cellular structure of the intertubular substance transmitted for publication in the forthcoming volume, it ought, in justice to Retzius, to be omitted."

the development of ivory, by intus-susception, or conversion of pre-existing and pre-arranged pulp-cells, into certainty? And that he should have passed over, in silence, a theory which, while it enunciates the resemblance between dentification and ossification, at the same time defines the nature and amount of the differences in these processes? Yet such must have been the flagrant injustice committed by Dr. Baily on Mr. Nasmyth, if the memoir from which the translator of Müller quotes Mr. N.'s alleged discovery of the cellular structure of the intertubular substance of the ivory, likewise anticipated, as you assert, "all that Mr. Owen claims as original," or "contained," as the editor of the *Lancet* affirms, "*every fact which Mr. Owen announced to the Institute of France, as his own discovery!*" That Mr. Nasmyth's memoir, when it is published, may contain any or every discovery in dental anatomy, which I have made, and made public, would not surprise me; their adoption by careful and industrious investigators will be my best reward. But to return to the letter, by which I trust to prevent this being done for the purpose to which you have applied it. "Since, however, the editors of the *Medical Gazette* and *Lancet* avail themselves of the version of Mr. Nasmyth's memoir of August last, as it is designed to appear in the 8th volume of the *Transactions of the British Association*,—nay, even quote that volume, in order to brand me plagiarist, as if such a work were in existence—it seems to me to be not an unreasonable request that you will restore in the memoir, of which you superintend the publication, those passages, the omission of which would enable the editors of the *Lancet* and *Gazette* to give a colour to their accusation.

"But, as you may anticipate, some interpolations, as well as omissions, in the memoir in question, are necessary to establish the alleged conformity between it and mine. Take a sample: Mr. Nasmyth is reported in the *Literary Gazette* (loc. cit. p. 598) to have said in August last, "Schwann regards the dental substance as the ossified pulp, whilst Mr. Nasmyth's observations lead him to conclude that the cells of the ivory are altogether a distinct formation."

The observations subsequently published by me have, as I believe, fully established that which Schwann's re-

searches left as a matter of probability only, and which Mr. Nasmyth's researches, up to August last, lead him to deny. But the Editor of the *MEDICAL GAZETTE*, to prove the theft, for which I should have richly merited the characteristic blackguardism heaped by his brother editor of the *Lancet* upon the hypothetical plagiarist, quotes the following passage from the new memoir:—"In Mr. N.'s own report, given in the *Transactions of the Association*, which has been printed separately, and a copy of which is now before us, we find it stated, 'that the ivory is neither more nor less than the ossified pulp, and that it can in no wise be regarded as an unorganized body.'"

The reader is left to draw one inference from this statement, which I wish, for your sake, were true, viz., that a copy of the *Transactions of the Association*, vol. viii. were in any body's hands; but I fear that some time must still elapse before you can have the pleasure of announcing its publication.

I am, sir,
Your obedient servant,
RICH. OWEN.

To Prof. Phillips, F.G.S.
Sec. Brit. Association, &c. &c.

Having, Mr. Editor, in the preceding letter, disposed of the evidence which you adduce from Mr. Nasmyth's Memoir, in an unpublished volume of the *Transactions of the British Association*, in proof of my plagiarism of his Memoir of August last, I next proceed to prove that the charge of injustice to recent writers, which you rest upon paragraphs of my own works, can be supported only by wilful mutilation of such paragraphs, accompanied by a false statement, which the part suppressed would have exposed.

The false statement is, that Mr. Owen claims to have 'discovered the organic nature of the ivory:' * the proof that your statement is false is afforded by the portion of the paragraph of my memoir following 'membrane glandulaire,' which you have, therefore, purposely omitted; this omission I now supply. After the word 'glandulaire,' I proceed to say, "Telle est la théorie proposée par Cuvier, et par ses savants continuateurs, dans la seconde édition des *Leçons d'Anatomie Comparée*. (Tome iv. 1re partie, p. 197). La même opinion se trouve reproduite tout récemment par M. de Blainville, dans sa magnifique *Ostéographie*; et le profes-

* MED. GAZETTE, No. 37, p. 438.

seur Müller, tout en reconnaissant, avec la profondeur de science et la perspicacité qui la distinguent, la nature plus compliquée de la substance dentaire, telle que l'ont démontrée les recherches de Purkinje, de Fraenkel, et de Retzius, regarde pourtant encore les dents comme formées, ainsi que les poils et les ongles, par une exsudation progressive de couches fournies par un bulbe sécréteur." — *Comptes Rendus*, Dec. 16th, 1839, p. 784.

Now every anatomist knows that Purkinje discovered the fibrous texture of the ivory; that Müller proved the fibres to be tubes, as Leeuwenhoek had originally stated them to be; and that Retzius detected the cells of the inter-tubular substance.

Those recent authors alone, therefore, *who have enuniated in general propositions the results of observations extended over all the vertebrate classes*, as Cuvier, De Blainville, and I might have added Wagner, Carus, Della Chiaje, &c., were said by me to have described the ivory as inorganic, in the sense you use that word, viz., as being devoid of a cellular, fibrous, or tubular structure. In order to prove this statement of mine to be inaccurate, you resort 'to the simple method of juxta-position;' and again quote from my Memoir in the *Comptes Rendus*; but you quote (at p. 439) the same passage which you quoted before (at p. 438)—with a difference; *then* the last half was truncated, *now* the editorial shears excise my specific character of the latest authors who have described the teeth as inorganic; and you pass from 'développement des dents,' to 'les ont décrits,' &c., as if they were continuous in the original; omitting the intervening sentence, beginning with 'et qu'ont resumé,' and ending with 'mammifères.' Is it thus that you aim at persuading your readers that I have unjustly suppressed all mention of the estimable authors, as Retzius and Mr. Nasmyth, who have described the cellular structure of the teeth, in order to appropriate to myself the credit of this discovery? You are, doubtless, well aware of the meaning attached to the word 'organic' by many physiologists, especially of the French and German schools:—many mineral bodies are cellular, some, as asbestos, are fibrous, a few are tubular: these modifications do not necessarily, therefore, prove a body to be organized. The profound Müller uses the term 'unorganized'

as applied to the teeth, in the sense of their being developed by a process of excretion or evolution from the formative surface of a pulp, of their being simply in apposition with that surface, and of their being incapable of a growth when once formed. Now I have shewn that, if any theory of the formation of ivory can be gathered from the observations in the *Literary Gazette* and *Athenæum* of Sept. 21 and 15, it is essentially the old theory mentioned by Müller;—whether the ivory be evolved from the formative surface of the pulp, and be in simple apposition thereto, in the form of 'thin ossific layers,' 'spiral fibres,' or cells,' does not signify.

My theory maintains that the strata of tubes and cells, successively developed in the formation of ivory, are due to a conversion, according to certain laws, of the substance itself of the pulp, and that each new-formed stratum is not merely in apposition to, but in organic connection with, the uncalcified pulp. In August last, (according to the *Lit. Gaz.* l. c. p. 598) Mr. Nasmyth denies that the dental substance is the ossified pulp; in the report published in your journal a contrary opinion is put forth. Permit me to add to your reference to that report, (at p. 439 of No. 37) an element not usually omitted in quotations made with a view to a charge of plagiarism, viz. the date: it is not every reader who would intuitively calculate that your p. 538 of vol. xxv., was published January 3rd, 1840, just in time to admit of my memoir of December 12th, 1839, being carefully read and digested. When the difference between the theory of January, 1840, "that the dental substance is the ossified portion of the pulp" (*Med. Gaz.* l. c. p. 541) and the emphatic statement of September, 1839, "that so far from being the ossified pulp, it was altogether a distinct formation," (*Lit. Gaz.* p. 598,) was pointed out to me by a friend—whose disposition is the very antipodes of impudence and duplicity—and who, suggesting the possible source of the striking change in Mr. N.'s sentiments on this subject, was indignant at the effrontery of the statement that the abstracts of September 21st, 1839, and of January 3rd, 1840, maintaining theories diametrically opposed to each other, were abstracts of one and the same memoir, read August 26th, at Birmingham,—I replied that, so far from being annoyed, I felt gratified at

having been able so to state my case, and expound my evidence, as to have produced such a complete and sudden conversion in the sentiments of any physiologist; that I thought it a most singular example of plasticity of mind, and uncommon power of rejecting preconceived notions, this sudden change of Mr. Nasmyth's; and that as he had done me the honour to adopt my theory, it was so far his own, and he was welcome to it.

With respect to a satisfactory theory of dental development, the observations made by Purkinje, Raschkow, and Schwann, had not yielded the desired elucidation; nor is it to be wondered at, when they were confined to the teeth of the mammalia. My habitual studies in comparative anatomy enable me, after many abortive attempts to detect the mode of development of the ivory in the higher class, to select a fitter subject, perhaps the most appropriate, for these delicate and difficult investigations. The teeth of the foetal shark (*carcharias*) are flat, and so thin as to allow sufficient light to pass through them to demonstrate their structure under very high magnifying powers: their beautifully gradational development in each row, from the primitive papilla to the completely calcified pulp, offers to the observer all the requisite stages of the process; the great number of these vertical rows, exceeding a hundred in each jaw, yields him abundant opportunities of repeating and varying the mode of his investigations.

You will have observed, Mr. Editor, in the number of the 'Comptes Rendus' from which you quote, in your review of my Odontography, that only the chief results or conclusions of my investigations are there printed; but I can assure you, and I think your readers will credit me, that none of the numerous details, there omitted, of the difficulties as they arose, and the processes by which they were met and surmounted, in the course of my inquiries, were plagiarized, any more than the theory they substantiated, from any previous publication.

And, finally, Mr. Editor, with respect to your assertion that my Treatise on the Comparative Anatomy of the Teeth "differs from the ordinary run of books"—as you elegantly express it—inasmuch as it is a Descriptive Catalogue of the Hunterian Collection.

I trust that the five quarto volumes

of that Catalogue, which I have had the honour to complete, 'do differ from the ordinary run of books;' and that the same may be said of the Descriptive Catalogue of Osteological and Dental Preparations, which was entrusted to an officer of the College of Surgeons, now, alas! no more. But I should allow a great injustice to be done to the learned directors and curators of the Museums of Paris, Leyden, Utrecht, and Frankfurt, and of the London Zoological Society, were I not, after such an assertion, to anticipate so much of the general Introduction to my Odontography, as to acknowledge that by far the greatest part of the dental organs of the rare fishes described in the published portion of my work, was liberally submitted to my examination and my draughtsman by those gentlemen during my visits for that purpose to their respective collections.

The skeletons and dental preparations of fishes in the Hunterian Museum, are, as yet, few, in comparison with the vast collections of them for zoological purposes in the museums above mentioned: but they have been systematically arranged, openly displayed, and described in a published catalogue, ever since the College Collection was in its present edifice. With respect to the few dental specimens therein contained, which I have found requisite to describe and figure, as, *e. g.* those of the *Diodon*, the most liberal permission was granted to me for that purpose by the Museum Committee. These, and all similar aids and facilities afforded me in the course of my work, which my spirited Publisher has enabled me to bring out, will be, not less than the discoveries of my predecessors, duly acknowledged in the proper place.

I am, sir,

Your obedient servant,

RICHARD OWEN.

June 12, 1840.

[Our giving immediate insertion to Mr. Owen's communication (which we have done at some inconvenience) will, we trust, be received as proof of our wish to do him justice by letting both sides be heard. As to the rest, we leave it for our reviewer to speak for himself in reply, when he has seen Mr. Owen's answer, and which he will do only in common with others, when it meets the public eye.—Ed. Gaz.]

CARTILAGINOUS TUMOR.

To the Editor of the Medical Gazette.

SIR,

IN a report of the pathological department of the Medico-Chirurgical Society, in your number for June 5th, Mr. Charles Hawkins is said to have described a cartilaginous tumor, which was found lying loose in the peritoneal cavity. I have no doubt of the correctness of his conjecture, with regard to its origin, that it had, at first, been a growth from the inner surface of the abdomen, which subsequently became detached. I believe that such tumors originate in the subserous cellular tissue, that then the serous membrane gradually becomes elongated, and at length gives way, so that the tumor becomes loose. Of course those formed in serous and synovial cavities must be of the same nature, and formed in the same way; we have so many proofs of the near relationship of these two kinds of sacs.

Mr. Syme, in his *Surgery*, states, as the most probable account of their origin in the knee, that they are growths, broken off from the edges of the semilunar cartilages. Those which have been found in the ankle, the shoulder, the elbow, and the twenty met with by Haller, in the articulation of the lower jaw, could not have had such an origin, because, in the first three joints, there are no moveable cartilages, and in the last they were collectively larger than the whole interarticular cartilage. We must, I think, believe that they are formed in the same manner as the intra-peritoneal cartilages.

I have, in my museum, a preparation of a testicle, which strengthens this view of their origin. Under the tunica vaginalis testis, and in the thickness of the tunica albuginea, is a small, hard, cartilaginous growth, about the size of a millet-seed; another, about the size of a grain of barley, was lying, quite loose and unattached, in the cavity of the tunica vaginalis. There was no thickening, or other alteration, of this tunic, or of any other part of the testicle, and no collection of fluid in the serous bag. The preparation is worth keeping, because it shows the two cartilages in two different states, attached and loose, the one being the antecedent of the other.

This accidental formation appears to

be rare in the testicle, as no mention is made of it in Cooper's Dictionary; the only ossifications mentioned there are those in the form of bony plates. Are not the phlebolithes described by the French pathologists, of which I have met with several specimens in the interior of hypogastric veins, formed in the same way, by the ossification of portions of lymph, either attached inside the venous membrane from the first, or first outside of it, and afterwards elongating and rupturing it?—I am, sir,

Your obedient servant,

JAMES DOUGLAS,

Lecturer on Anatomy.

235, George Street, Glasgow.

ON

CONGENITAL PECULIARITY IN
THE STRUCTURE OF THE HEART.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the accompanying hints worthy a place in your interesting GAZETTE, I shall feel obliged by their insertion.—I am, sir,

Your most obedient servant,

C. M. DURRANT, M.D.

Ipswich, June 10, 1840.

In attending to diseases of the heart, whether organic or merely functional, the fact that the changes arising from natural structural peculiarity may, and often do, produce many of the physical signs of real disease of the organ, cannot be too strongly impressed on the attention of the observer; since an error thus made in the diagnosis tends to throw discredit on auscultation, and is one indeed into which professed and practised stethoscopists have not unfrequently fallen.

This condition simulating disease may arise either from the natural conformation of the individual, or from the normal peculiarity in the structure of the heart itself.

With the first may be included sex, age, and the formation of the thoracic parietes as regards development. On these points it is sufficient to premise, that the sphere of sound is naturally much more extended in young persons, and females, especially if the latter be

lean, have small breasts, and narrow meagre chests; in such, the apex of the heart often strikes with force against the parietes of the chest, and is productive of an unpleasant jerking sensation, often causing great, although happily groundless alarm, in the minds both of patient and friends.

In examining, pathologically, the hearts of women and children, the parietes will be found thinner, and the cavities more capacious, in proportion to the size of the body, than in adults of the male sex. Again, in those with a large thoracic cavity, having thick muscular or fat parietes, the extent of sound is much diminished, often heard indistinctly, even within the prescribed limits. It will not be foreign here to remark that the average extent of dull sound, elicited by percussion, over a well-proportioned heart, varies from one and a half to two and a half square inches, the remainder of the organ being covered by lung.

The natural thickness of the cardiac parietes, as well as its tonicity of fibre, varies considerably in different individuals; the strength of the heart's impulse being in direct ratio to the same. The heart is generally naturally large in those with capacious chests, especially in males with great muscular development; the contrary is usually the case in lean individuals, with a weak and flabby state of the muscular system; in the former, the impulse will be considerable, but the sound limited, while the reverse will occur in the latter peculiarity. When the parietes of the heart are naturally thick, the impulse will be found prolonged and sluggish; on the contrary, when the walls are normally thin, and the general capacity of the organ diminished, the stroke will be rapid and abrupt.

In cases of precocious puberty, especially if connected with early excesses, particularly in reference to the generative function, the heart is extremely liable to become enlarged to a certain extent, and thus remain, without farther increase, and unproductive of serious consequences, provided the exciting causes be abandoned. The above excesses are a far more fruitful source of enlarged heart, in both sexes, than is generally supposed, and if persisted in, organic disease of the viscus will be the inevitable termination.

Cases in which the heart is naturally

large in proportion to the body, at the same time free from disease, are of more frequent occurrence than those presenting a diminished size of the organ, in the average ratio of about eight of the former to five of the latter.

The following case of chlorosis is merely interesting as illustrative of a well-marked instance of a congenital small heart, with symptoms purely functional.

Aun Eaton, æt. 19, a dress-maker, states that she has enjoyed uniform good health up to the present period of attack, but for some weeks past has suffered from constant pain in the left side, not increased on pressure, with uneasy "falling" sensations in the regions of heart, some cough without expectoration, and general uneasiness at epigastrium. Tongue moist, but coated at edges; bowels usually costive; catamenia irregular; pulse small, quick, feeble; chest narrow and contracted, yielding a clear sound on percussion over entire surface; the usual dull space over region of heart much limited; breasts small and imperfectly developed; respiratory murmur healthy; both sounds of heart much louder, clearer, and more abrupt than natural, and audible over entire chest; impulse very feeble, apex imperceptible, slight bruit de soufflet with first sound, and loud bruit de diable over right carotid; no pulsation at epigastrium; abdomen tympanitic; urine scanty, with an occasional sediment; ankles swelled and puffy.

A mustard poultice was applied to the side, and under the continued use of warm stimulating purgatives, together with the iodide of iron, and temporary relaxation from the accustomed sedentary occupation, the patient completely recovered; both bruits entirely disappeared; catamenia became regular; every abnormal symptom vanished; the direct physical signs of naturally small size of heart alone remaining.

The figure of the above patient was tall, and, with the exception of the chest, well formed.

I have selected this case from others, simply because it indicates so distinctly the points to be attended to in the diagnosis of the structural peculiarities under consideration.

The diagnosis of cases presenting the above peculiarities in development is not unfrequently attended with considerable ambiguity, especially if com-

plicated with symptoms consequent on functional derangement.

It is principally by the absence of positive evidence in reference to cardiac disease that we are enabled to arrive at just and correct conclusions. Thus, as previously stated, we may have extended dulness on percussion, the apex of heart may be felt striking the parietes so low even as between the seventh and eighth intercostal space; nevertheless, the organ itself, naturally large, may be entirely free from disease. In these instances, although the pulse be strong, yet it is not the full, regular, vibrating pulse of hypertrophy. Again, there may be dyspnœa, arising probably from many causes, yet not the constant suffocating dyspnœa of pure cardiac affections. The absence also of venous congestions, bloated countenance, turgid and pulsating jugulars, and dropsical effusions, will materially aid us in our examination.

It is by negative signs also that we must, in a great measure, be guided, in cases where the heart is normally small.

By attending minutely to the general history of the case, by present symptoms, and by the absence of the usual sympathetic phenomena attendant on organic cardiac disease, we in general shall be enabled, without difficulty, to arrive at a just and satisfactory result.

The practice of daily and carefully examining cases of this description by the combined aid of inspection, palpation, percussion, and auscultation, cannot be too strongly insisted on; for by this alone can we form a correct diagnosis, and permanently remove the anxiety of the patient and his friends, at the same time prevent most serious errors in the treatment.

CASE OF GLANDERS.

To the Editor of the Medical Gazette.

SIR,

THE effects of the poison of glanders on the human constitution have now been observed and recorded in a good many instances, but the resulting disease is still sufficiently new to the annals of medicine, and important in itself, to make it desirable that every case in which it occurs should be presented in some detail to the profession, whose

interest in the subject may, perhaps, be in some measure enhanced by their constant demand on the services of the noble animal in whose frame the poison in question is first generated. These reasons will, I trust, warrant the request of a portion of your space for the following case, though it was seen by me at too late a period to allow of a thorough investigation of its course, and was not elucidated by post-mortem examination.

I was called, on the 3d of April last, to visit (in conjunction with Mr. Ferris, an experienced surgeon of this town) a young man, named Joseph Pascoe, of the age of 22, and of tolerably robust constitution. I found him in the following state:—

His face was bloated and swollen, with a blush of dusky red on the right side. The right eyelids (the upper especially) were very much swollen, infiltrated with serum, and of a rather livid hue. Punctures had been made in the upper and outer portion of this swelling, and in these points small ulcers, discharging a sanious pus, were formed. The eye was, in consequence, entirely closed, and a thick mucopurulent discharge exuded from within the lids. On the left side the swelling was less. A gluey semi-transparent secretion presented itself at the left nostril, but did not escape in any considerable quantity. The voice was thick and hoarse, and the throat sore, so that deglutition was painful. Bright erythematous patches appeared, with diffused swelling, in several spots, the largest being above the right knee (which had been very painful, and was still painful on pressure), and on each instep. No portion of these patches was hardened or circumscribed; their surface was rather glossy, and the redness was readily dispelled by the touch, to reappear as quickly on its removal. No other form of cutaneous eruption was visible. The patient was capable, on being roused, of answering questions collectedly, but speedily relapsed into a state of sopor, with muttering delirium. In this state he generally lay, and his sensibility to pain was, no doubt, much blunted, and the particulars of his suffering not very clearly to be ascertained at this stage of his disease. Paroxysms of excitement now and then occurred, during which he endeavoured to leave his bed. He did not complain of pain

in the head. The breathing was oppressed and hurried, with mucous rhonchus at times. The abdomen was very tympanitic; the bowels rather confined.

Turpentine was administered by the mouth, and in enema; and copious, dark, offensive dejections, with free discharge of urine, took place. The tympanites subsided in great measure, and the patient subsequently took several doses of a mixture containing creosote. His state, however, became gradually worse. The delirium was, in the course of the night, more violent, so that he was kept in bed with difficulty; and on the following morning (April 4th) the swelling had extended to the left eyelids, and on the right side it had assumed a dark livid hue, in parts nearly black. The discharge from the left nostril was slightly tinged with blood. The delirium was much the same in character and degree as yesterday. I observed, that in his mutterings he made frequent reference to horses. In the course of the day the coma became more complete, and he died in the evening, about thirty hours after my first visit, without any further change of symptoms.

It appeared that he had been affected, for about a fortnight, with pain in the loins, lassitude, chills, and other feverish symptoms, which were referred to a mild form of "influenza" then prevalent. The subsequent sore throat, and erysipelatous inflammation of the eyelids, were not sufficiently peculiar to have excited much attention.

The *ensemble* of his appearance and symptoms led me, immediately on my first seeing him, though knowing at the time nothing of his history or occupation, to suspect the influence of some animal poison on the system; and as the contagion of glanders was that to which he might most probably have been exposed, I directed my inquiries in the first place to this point. I then found that he had been employed as driver of a van, and that one of his horses had been for many months diseased, and affected with a discharge from the nostril, and that he had attended the horse closely, and had been in the habit of wiping away the discharge. Before his death, I was informed by his father that he had seen the horse snort out a quantity of this secretion into the middle of his son's face. I examined the horse, which was stated to have been latterly

improving in health. It was not much out of condition, but had still a discharge from one nostril, and also some small tumors inside the lower jaw. It was considered by the farrier to have been for a long time decidedly affected with glanders.

The young man had complained since Christmas of lassitude and pain in the back and limbs, which he attributed to exposure to cold and wet. His voice likewise had been rather husky, and there had been some discharge from the nose, giving him what he called "the snuffles."

It seems probable that the disease was communicated through the schneiderian membrane, perhaps through the conjunctiva; no wound, abrasion, or local affection indicative of any other origin, having been noticed by the patient or his friends.

The discharge from the nostril, and the infiltration of the eyelids, together with the irritative fever, were common to this case with all the others to the records of which I am able to refer.

The absence of all pustular or tubercular affection of the skin is unusual, but analogous to what is commonly observed in the effects of wounds received in dissection.—I am, sir,

Your obedient servant,
CHAS. BARHAM, M.B., Cantab.
Physician to the Cornwall Infirmary.

P.S.—Incidentally to the above case, it may not be irrelevant to allude to what has long appeared to me to be one not improbable cause of a disease of not unfrequent occurrence, and of the utmost importance in its consequences, both direct and indirect—puerperal fever. The cause which I suspect is the introduction of animal matter from the parturient female into the system of another by the hand of the accoucheur. If we consider the exceeding subtlety of poisons of this nature, and the infinitesimally small quantity capable, when it does act, of producing the most disastrous effects, on the one hand; and on the other the difficulty of ridding the cuticle entirely of the animal fluid it has imbibed, a fact often disagreeably proved, after dissecting or examining bodies, by the tenacity with which the offensive smell clings to the hands, notwithstanding repeated washing, the probability that some animal particles may be introduced in the manner stated, and that in quantity

sufficient to affect the system of the recipient, appears very strong. Again, if we look to the pathology and morbid anatomy of this disease, in its worst forms, as exhibited by recent investigations, which show it to be intimately associated with uterine phlebitis, whilst its symptoms present many points of resemblance to those produced by dissection wounds, we are led to the inference that the causes of inflammation of the lining membrane of the vessels are, in both instances, similar in their nature, and in their mode of introduction into the system. The fact that this very fatal form of disease has often occurred in the practice of some one particular individual only, in a neighbourhood, has frequently attracted attention, and measures of caution have been consequently recommended; but these have, as far as I have seen, extended only to the dress. Now the supposition that effluvia, absorbed, and again given out by the dress, occasion the disease, involves these difficulties: First, the poison must be considered to be chiefly, if not exclusively, absorbed by the respiratory surfaces of the patient, surfaces which are known to be exposed to the most condensed emanations from animal matters, in that state in which inoculation with them is most dangerous, and yet no ill effects are produced. Secondly, the many females exposed to the same effluvia, from being about the person of the lying-in woman, neither take nor communicate the disease, as they would no doubt occasionally do, had their clothes imbibed a poison capable of acting in the way supposed. Besides, it is necessary, on this view, to imagine that, whilst the poison is introduced by the channel of one system of organs, it leaves this altogether intact, and its effects are produced on another system, remote from the first—an anomaly which occasions, in order to its explanation, the calling in of some mysterious susceptibilities of the patient.

On the other view the series of phenomena is perfectly intelligible, and in accordance with our knowledge. An animal fluid of deleterious quality, such as we know to exist frequently before as well as after death, is imbibed by the cuticle of the hand of the accoucheur; a portion of this is taken up by the uterine vessels of a puerperal patient, to which it is directly applied, and which are then in a condition most favourable to absorp-

tion; the system to which the poison is applied becomes first affected, and afterwards the well-known symptoms of irritative fever are developed.

The objection may perhaps be made, that the accoucheur's hand is, itself, seldom affected by this poison, which it is here considered to be the medium of conveying; but the relative conditions of the hand, covered with cuticle, and of the uterine surface, at parturition, will fully account for the difference of result; the former serving as an adequate protection in dissection, or only permitting, at most, a slight erythematous inflammation to take place, whilst a particle of the same fluid which it so innocuously imbibed, may, when introduced into a scratch, give rise to a train of symptoms similar to, and as deadly, as the worst form of puerperal fever.

It is probable that the views I have just explained have been stated and, no doubt, more ably, by others; but as they have not been noticed in any work which I have perused, I have thought it best to place them thus briefly upon record. Repetition, in regard to a disease so intensely interesting, is venial; it may even be desirable, if it leads to the adoption of those means of precaution, not certainly very generally used at present, which are suggested by the opinion itself, so obviously, that to detail them would be impertinent.

A LETTER FROM DR. MURPHY TO DR. ROBERT LEE,

RESPECTING THE SITUATION OF THE DECIDUA IN CASES OF EXTRA-UTERINE GESTATION.

[For the Medical Gazette.]

SIR,

HAVING just read some interesting observations of yours in the MEDICAL GAZETTE, "On the situation of the deciduous membrane in cases of extra-uterine gestation," in which you state that, "In all the cases of fallopian tube conception which have since been recorded, except those of Mr. Langstaff and M. Velpeau, a deciduous membrane has been described as present, lining the cavity of the uterus," I have taken the liberty of directing your attention to a case of extra-uterine conception which was detailed before the Dublin Obstetrical Society, and was subsequently

recorded in the 45th No. of the Dublin Journal (July, 1839.)

In this case I could find no trace whatever of decidua; the internal surface of the uterus was quite florid. Whether the decidua might have formed in the cyst I will not say, as the advanced stage of the pregnancy made it difficult to ascertain it.

Knowing that you can appreciate the value of every fact which bears upon your investigations, and the difficulty of gleanings them from the mass of medical records, I feel assured you will pardon this mode of calling your attention to (I believe) not an unimportant one.

I am, sir,

Your obedient servant,

EDWARD W. MURPHY.

12, Upper Temple Street,
Dublin, June 7, 1840.

MEDICAL GAZETTE.

lupanicum sit, dicendi periculum non recuso."

CICERO.

THEORY AND PRACTICE.

ALTHOUGH theory and practice ought to throw mutual light on each other, it too often happens that they are totally at variance; so that Pope's celebrated couplet—

For wit and judgment often are at strife,
Though meant each other aid, like man and wife—
might be applied, if slightly altered, to speculation and facts.

It too frequently happens that theory limps behind practice, and is merely able to explain the facts which its rival has ascertained; occasionally, but too seldom, practice is derived from speculation. Even that secondary kind of theory, however, which follows facts at a distance, is of use; for it is difficult to explain, without at the same time suggesting; and thus it is that even an imperfect theory is like a golden thread which binds together what would otherwise be scattered. It is the necessary

casket, without which some of the jewels would be lost.

In England, many practitioners are as ready to cry out "no theory!" as if all the facts of medicine could be collected and applied, singly, without any link to connect them.

In France, on the other hand, theory is triumphant, and the practice of physic is sadly neglected, as far as regards the discriminating use of medicines. Bleeding and leeches, indeed, are constantly employed, (contrary to the supposition of those English practitioners who do not read French books or journals); but the use of many common drugs is so neglected, that the registers of medicine which have now been kept for 2000 years, would seem to have been kept in vain for the French.

The reason of this is clear enough. Although in some instances the registers have been kept pretty diligently, in others they have been so negligently scribbled, that they confuse rather than instruct. Now, our neighbours over the water so passionately thirst for a lucid plainness in every branch of knowledge, that a dim theory, or a doubtful fact, is alike distasteful to them; and hence we may easily conceive the repugnance with which they must regard thousands of the so-called facts with which medical books abound. The virtues of drugs, say the French, are not to be believed on the unconfirmed evidence of old writers; *quære peregrinum*—you have taken us in too often. We have rejected marygold and yarrow from our list of drugs, and no longer ask—

Cur moriatur homo, cui salvia crescit in horto?

Why, then, should we trust in calumba, cascarilla, and cusparia?

There is no doubt, however, that many of the drugs now generally rejected throughout Europe, or banished to domestic practice, possess medicinal properties; and it is more than probable that they have fallen into undeserved

neglect from the extravagant praises once lavished on them. When a tradesman, says Chesterfield, asks us ridiculously much, we offer him ridiculously little; and when sage is extolled as an elixir vitæ, we lower it to form a *tisane*—to be, what Laennec calls, one of the “pretexts of the expectant method.” In fact, a medicine has often been despised because it was not on a level with its golden reputation, though it might have done good service in a humbler sphere. Such a rejection is far from judicious. When the Vicar of Wakefield’s wife is for throwing the plated spectacles into the fire, the Vicar says, “though they be copper, we will keep them by us, as copper spectacles, you know, are better than nothing.”

The French scepticism, however, concerning drugs, is far from being confined to those of secondary power. About five years ago we recollect reading, in the *Archives Médicales*, that Andral had been trying purgatives in diseases of the chest, and was much gratified by their efficacy. So exquisite a knowledge of pathology and the stethoscope on one side of the channel, and so much practical acquaintance with remedies on the other, might tempt a patient to proceed to Paris to learn the precise disease of his chest, and return to London to have it treated. But if such a man as Andral learned so well-known a fact at so late a period, what must be the ignorance of the mass of practitioners on this point!

But in other instances, as well as in purgatives, remedies seem to have been dismissed from practice, and to be known only by a faint tradition. French practitioners wish, accordingly, to recommence the doctrine of the *Materia Medica*, and ascertain by registered experiments the properties of drugs in ascending doses. Parent-Duchatelet, according to his biographer, never used the words *souvent*, *quelquefois*, in his

writings; his constant inquiry was, “how often?” “how many times?” The sulphate of copper, like other emetics, frequently purges, but how frequently? This question is answered by a writer in the *Gazette Médicale* of May 23.

Dr. Toulmouche, a professor in the School of Medicine at Rennes, lately determined to try the emetic powers of the sulphate of copper, from finding nothing satisfactory on the point in the books which he consulted. Thus, he tells us that Geoffroy, in his treatise on the *Materia Medica*, gives a long account of copper and its sulphuret, but does not mention the sulphate. Desbois of Rochefort, in his *Cours Élémentaire*, speaks of it only as an external caustic, and as a poison internally. He shows how the symptoms produced by the poison are to be treated, but does not mention the sulphate as an emetic.

Orfila is afraid of it; for in the second edition of the *Dictionnaire de Médecine* he says that the sulphate of copper ought not to be employed as an emetic; alleging that it is extremely poisonous even when a great part has been thrown off by vomiting. Nevertheless, in his treatise on poisons, he mentions it as an emetic in cases of narcotic poisoning. The dose, he says, should be from 15 to 20 centigrammes (3 to 4 grains), adding that in larger quantities it might cause death, by inflaming the intestinal canal. The only English book consulted by Dr. Toulmouche was Cullen’s *Materia Medica*, where, it seems, this remedy is not spoken of under the head of emetics. Three other English authorities are mentioned in M. Guersant’s article on copper in the first *Dictionnaire de Médecine*. M. Guersant observes that the physicians of the last century gave the sulphate as an emetic. Thomas Marryat gave two grains with the same quantity of tartar emetic. On referring, however, to Dr. T. Young’s treatise on

Consumption, we find that the prescription just quoted was only one of Marryat's methods of giving the sulphate of copper. If much diarrhœa was present, he gave a grain of sulphate of copper with four of ipecacuanha. When an ulcer was formed, besides giving copaiba, he sometimes ordered five grains of the sulphate of copper to be dissolved in an ounce of tincture of cantharides, and the dose of the solution to be gradually increased.

If Dr. Toulmouche had consulted more recent English works than Cullen's on *Materia Medica*, he would have found a solution of his question, though perhaps not a complete one. Thus, in Dr. A. T. Thomson's *Dispensatory*, the emetic dose of the sulphate of copper is stated to be from two to fifteen grains; in Dr. T. Young's *Medical Literature*, from five to fifteen; in Gray's *Supplement to the Pharmacopœia*, from two to ten; and in Brande's *Manual of Pharmacy*, we are directed, in cases of poisoning by opium, to dissolve half a drachm of the sulphate in six ounces of water, and give a third part every ten or fifteen minutes, till it operates.

As for Dr. Simmons' dose, which M. Toulmouche inquires after, we learn from Dr. Young's treatise, just quoted, that he gave "first half a pint of water, and then from two to twenty grains of the sulphate in a cup of water, and afterwards another half pint of water, as recommended by Dr. Brookes."

M. Toulmouche, not at all satisfied with the silence of some authors, and the vague information of others, tried the sulphate of copper as an emetic in 72 cases, and with very favourable results.

He gave it twelve times in the dose of two grains; and it caused vomiting in eleven of the patients, and purging in four. Thirty-six times he gave four grains to women; vomiting was produced thirty-two times, and from one to three stools twenty-three times. The patients had almost all had the influenza

(*grippe*). Five men took the same dose; all were vomited, and four were purged.

In doses of six and eight grains it always caused vomiting, and in the majority of cases purging also. In one case M. Toulmouche administered twelve grains, and no effect was produced. Colic pain occurred twenty-five times in the seventy-two cases. In about one-third of the whole number of cases purging was produced without vomiting. On the whole, the professor thinks the sulphate of copper as safe as tartar emetic, and asserts that the writers on the *Materia Medica* have exaggerated the danger of administering it.

In the *Gazette Médicale* of June 6th, M. Toulmouche gives us his experiments with the sulphate of zinc. Here, too, he is dissatisfied with the accounts given by the writers on the *Materia Medica*. Several of them do not mention the dose; in others the emetic dose is made to vary from 3 to 21 grains; and in the dictionary of the *Materia Medica*, by MM. Mérat and Lens, it is said that in England, Drs. G. R. Mittal and Row have given it in the dose of 40, 80, and even 120 grains, in cases of poisoning by opium. Had M. Toulmouche consulted our modern English works on the *Materia Medica*, he would have found more uniformity of opinion.

Thus in Dr. A. T. Thomson's *Dispensatory*, the emetic dose of sulphate of zinc is stated to be from 10 to 30 grains; in Dr. T. Young's *Medical Literature*, from 15 to 30 grains; in Gray's *Supplement* from 10 to 30; and in Brande's *Manual* the average dose is stated to be twenty grains.

Smaller doses were found effectual in the professor's practice. In the dose of two grains it failed five times out of seven; four grains failed five times out of nine; six grains succeeded seven times out of nine; eight grains succeeded six times out of seven; ten grains succeeded twenty-five times out of thirty-six;

twelve grains were given three times, and always succeeded; fifteen grains were given seven times, and succeeded only twice.

M. Toulmouche tried the sulphate of zinc as an emetic in 83 cases, and the result of his experiments is, that ten or twelve grains are the most eligible dose. He was afraid to go beyond 15 grains, and thinks that the very large doses sometimes given by English physicians were administered only in cases of poisoning by opium, where the stomach had become insensible to the stimulus. In a great number of the professor's experiments, the zinc acted as a purgative, and in rather more than one-third of the cases produced slight colic pains.

If we were asked our opinion as to the usual emetic dose of the sulphate of zinc in this country, we should say twenty grains. On the whole, we think that M. Toulmouche has produced a valuable contribution to some future treatise of unrivalled accuracy on the *Materia Medica*; and though some of our readers may be inclined to suppose these experiments unnecessary, much in our opinion yet remains to be ascertained concerning the powers of still commoner remedies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

June 9th, 1840.

SAMUEL MERRIMAN, M.D., in the Chair.

Some Observations on the Mode of Union of Fractured Bones. By R. H. MEADE, Esq., Lecturer at the Middlesex Hospital.

THIS paper, which is one of a series upon the subject intended by the author to be brought before the society, contains the details of several experiments conducted on rabbits and guinea-pigs, with a view of determining the precise mode of union in fractures of the flat bones, the scapula being here selected for the purpose as the most easily fractured. The animals chosen were of different ages, that it might be ascertained whether age exerted any material influence on the reparative pro-

cess, and care was taken to inflict as little injury as possible on the soft parts. Preparations and drawings of the parts were exhibited in illustration of the narrative. From these experiments (nine in number), and many others of a similar kind performed on the scapula, the author infers that union is accomplished in the thick part of the scapula exactly as it is in the cylindrical bones, viz., blood is effused into the different tissues surrounding the fractured part; that this blood is next absorbed, and coagulated lymph deposited in the substances of the muscles, and in the neighbouring cellular tissue, so as to form them into a solid gelatinous mass. The periosteum which has been ruptured is separated from the fractured edges, inflamed and thickened, and lymph is effused between the fragments themselves. At a later period the external mass decreases in size, the muscles return to their natural texture, and a firm layer of cartilaginous matter surrounds the fractured spot, with which the periosteum is so completely blended that it is difficult to say whether it is external to or beneath it. This callus adheres firmly to the surfaces of the bones, and dips down between the fragments. Ossification then takes place by the deposition of earthy particles in the cartilaginous matter, which particles are deposited irregularly through all parts of the provisional callus at the same time, and do not appear first at that part which is next to the surface of the bone.

The process of union of fractures in the flat part of the scapula differs somewhat from the process here described. In speaking of the part which the periosteum plays in the production of the callus, the author observes that where two fractured portions of a flat bone overlap each other, and the edges which are in contact are denuded of their periosteum, union takes place between the opposed surfaces through the medium of fibro-cartilaginous substance becoming osseous, which possesses all the characters of the common external or provisional callus. This matter must here arise from the surfaces of the bone itself; and this fact shews that the provisional callus may be generated independently of the periosteum.

The author denies, in opposition to the opinions of Macdonald and others, that the cartilaginous matter differs from true cartilage in becoming tinged red when the animal has been fed on madder.

Account of a Case of Aneurism, supposed to have opened into the Pericardium a considerable time before death. By THEOPHILUS THOMSON, M.D., Physician to the Northern Dispensary, London, &c.

About the middle of the year 1838

Richard Tofield, a blacksmith, of strong muscular frame, was seized with pain in the back and side, after which he continued to suffer from palpitation, and fainted occasionally at his work. From the beginning of June, 1839, he was several times visited by Mr. Bird, the house-surgeon of the Northern Dispensary, who found irregularity of the pulse, most observable in the right wrist, with prominence and pulsation of the right side of the chest. On July 21, 1839, Dr. Theophilus Thomson visited him, lying in bed, with his lips and ears livid, skin perspiring, and anxious countenance. The audible symptoms observed in the chest, which were remarkable, and the treatment, under which the patient sometimes walked a mile, are described. In September he became worse; and on the 19th was found again confined to his bed, with great lividity of countenance and rapid pulse. By change of treatment his pulse became regular, and the expression of his countenance cheerful. He continued better till the 29th of September, when, on getting up to relieve his bowels, he became suddenly worse, stared wildly for a moment, uttered an exclamation, and fell back dead.

On opening the body, the pericardium was found distended with a prodigious quantity of blood, so that the heart was not without difficulty discovered. It was enlarged, flaccid, and greatly displaced, so as to explain the peculiarity of the sound remarked before death, in different parts of the chest. The pericardium also presented great marks of disease, both ancient and recent. The aorta, near its origin, was dilated to more than twice its ordinary size, and, two or three inches above the aortic valves, was discovered an orifice by which the blood must have escaped into an orange-sized cavity from which it passed into the pericardial sac. The author then states his reasons for thinking that the rupture into the pericardium had taken place a considerable time previously to death, and refers to Laennec, as giving countenance to the opinion that life is not necessarily terminated immediately, by such an effusion.

Account of a Case of Spontaneous Rupture of the Heart into the Pericardial Sac, under which life continued for about ten hours.

By WILLIAM STROUD, M.D.

Frederick P., aged 29, after anxiety and vexation endured for a considerable time, and after having been liable to profuse bleeding of the nose, during the spring season, for many years, was, on the non-occurrence of this bleeding, subject for six weeks to a sense of fulness in the head, with lassitude and somnolency. On the morning of April 27, 1839, after having

returned from Covent Garden Market, he was seized with faintness, giddiness and vomiting, and insensibility. The pulse became imperceptible, and he was apparently in a dying state. He was promptly bled by Mr. Symes, to three pints, recovered a little, continued complaining of great tightness of the chest, and weight at the heart, but died the same evening.

The pericardium contained a quart of blood which had escaped through an opening in the right auricle just below the insertion of the vena cava superior, the edges of which were not attenuated or apparently ulcerated. The author accordingly suggests the prudence of relieving plethoric oppression, even where signs of structural disease in the sanguiferous system are not evident. In this patient the heart was large, and loaded with fat.

PATHOLOGICAL DEPARTMENT.

June 16, 1840.

DR. CLENDINNING IN THE CHAIR.

Gangrene of the lung.

DR. BOYD exhibited a preparation of gangrene affecting a small extent of the posterior portion of the left lung. The part affected was about an inch and a half square. An abscess of nearly the same size was situated in a corresponding part of the right lung. The most remarkable circumstance in the case was, that the patient had no cough or indication of pulmonary disease; and he had no sœtor of his breath. He was brought into the Marylebone Infirmary in a low, reduced condition, complaining principally of the state of his stomach, and of pains in his limbs. It was stated by his wife, who accompanied him, that he was accustomed to drink to great excess. It was necessary to give him stimulants to support him in his sinking condition; but he died in eleven days.

Series of four preparations of Aneurism of the Arteria Innominata.

Mr. Shaw had on the table four preparations of aneurism of the arteria innominata. Interesting observations, he remarked, might be made from the facts which had to be stated concerning these specimens on the table: but he would confine himself to giving a description of the principal morbid appearances exhibited in the preparations, and to mentioning the more important circumstances observed during life, in the different patients. He considered the subject of the effects of these aneurisms especially interesting, after having so lately had the remarkable case of operation upon the two branches of the innominata, for aneurism, laid before

the Society by Mr. Wickham, of Winchester.

Aneurism of the innominate of great size; orifice of the subclavian artery closed; obstruction of the veins; pressure on the axillary nerves, and on the trachea; absorption and disarticulation of the clavicle.

The first of the series was a dried preparation. The larger trunks of the arteries, veins, and nerves, together with the trachea, the clavicle, and portions of the sternum and ribs, were preserved in connection with the aneurismal tumor. Mr. Shaw stated that he was indebted to Professor Budd for the details of the symptoms of the patient during life, and for the opportunity of making the dissection; the patient having been under that gentleman's care, in the hospital-ship Dreadnought.

The tumor was of a very large size, extending obliquely to the length of about eight inches, from the root of the innominate, to within three inches of the acromial extremity of the clavicle; and reaching upwards about four inches above the level of the clavicle, and descending as many below that bone. One lobe of the tumor passed downwards, in the thorax, as far as to the level of the third rib. A smaller sacculated pouch projected backwards so as to press upon the trachea. Upon making an incision into the aneurism, it was found to be filled with dark and soft coagulated blood; some parts of its walls being lined with thin layers of fibrine. The coats of the tumor varied in thickness from about a quarter to half an inch: the inner surface was generally rough, irregular, and broken; the outer coat had different degrees of firmness in different parts, consisting in some places of dense fibrous membranes, in others of the surrounding textures more imperfectly changed by the compression of the tumor. The most remarkable appearance that offered itself, on making the section of the aneurism, was the condition of the clavicle. It was absorbed by the contact of the tumor to such a degree, at its sternal extremity, that it was perfectly detached, and moved freely in the centre of the tumor, surrounded by the coagulated blood. The whole extent of the bone involved in the aneurism was denuded of its periosteum, and rough in its surface, from the effects of the absorption; and small spiculæ or patches of ossific deposit were found upon the inner surface of the aneurismal sac, in those parts which it may be supposed were previously in contact with the clavicle. A portion of the first rib, and likewise a part of the sternum, were removed by absorption, leaving the surfaces in these parts rough, and exposed to the blood.

The arteries.—The aorta did not present

any particular morbid appearance; it had only a few small specks of calcareous concretions upon its inner surface. The innominate came off from the arch, of its normal size, and then its walls immediately expanded into the aneurism. It has to be noticed that a very small aneurismal pouch, that might contain a nutmeg, was formed in the arch of the aorta, immediately above and behind the orifice of the innominate; so that a part of the parietes of the innominate formed the septum between the greater aneurism, and this smaller one of the aorta. On looking for the orifice of the right carotid artery, it was seen, at its normal distance from the commencement of the innominate, opening obliquely into the sac. In regard, however, to the subclavian artery of the same side, its orifice was completely obliterated. Nothing but a slight depression in the surface of the sac could be seen to mark its former situation; the sides of the opening had contracted, and become closely adherent. On tracing this vessel in its course over the first rib, it was found descending behind, and to the side of the tumor. In the first part, where it emerged from the aneurism, it was greatly contracted in size, and was impervious for about half an inch; but when it reached the axilla, its calibre was of the usual dimensions. It was particularly noticed that the vertebral artery, the thyroid axis, and the mamma interna, were impervious at the point where they were given off from the subclavian artery.

Veins.—Looking to the veins of the right side, in the first place, no trace could be discovered of the right subclavian vein. The right axillary vein was found behind the tumor, diminished to the size of a crow-quill; and it was traced into the walls of the aneurism, so as to be seen entering them, and gradually lost in their substance. Turning next to the internal jugular vein of the right side, it was observed to pass behind the aneurism, and to be continuous with the right brachio-cephalic vein; but no vestige could be perceived of the remains of the right subclavian vein, to mark where that vein originally joined it. The jugular vein, and also the brachio-cephalic vein, were very remarkably contracted in their diameters; so that it was difficult to pass a small bougie through the narrowest part. The left brachio-cephalic vein encircled the fore part of the tumor, and was diminished so much in size that it only allowed a bougie of number ten to pass along it. It has to be observed that scarcely any thickening of the coats of the veins was perceived, and they were free from any deposit of lymph in their interior.

Nerves.—The axillary plexus of nerves was involved in the walls of the tumor, at

its back part. The cellular substance which surrounded the nerves had the appearance of being inflamed; it being infiltrated at that particular part with serum, and even partially broken down to form an abscess. The right par vagum was traced into the walls of the aneurism, until it could no longer be followed. The recurrent branch was seen spreading, at first, in a flattened form on the parietes; then it became involved in them, and could not be traced to any extent. From the difficulty of the dissection, it was left doubtful whether these nerves preserved their continuity to their destinations, or not.

The patient was a sailor, 50 years of age. He was admitted under Dr. Budd's care on the 9th of May, of last year; and was under his observation till he died, in the end of the following January. When he first presented himself, no tumor was apparent; but a pulsation was felt at the upper part of the sternum, and under the sternal end of the clavicle. Although there was no obvious tumor, the hollow space below the clavicle, and also the depression between the insertions of the sterno-cleido-mastoideus muscle, were more filled out than is natural, and there was considerable pain when these parts were pressed with the fingers. The superficial veins in front of the neck, on the right side, were preternaturally dilated. The pulse could not be felt in the right arm, either above the elbow or at the wrist; while in the left arm it was strong, and 76. The pulsation of the carotid and temporal arteries was equally strong on both sides. He suffered pain in the right side of the neck, to some distance upwards, and he had numbness in the right arm. His voice was hoarse, and he was troubled with a dry teasing cough. He had a slight difficulty in swallowing. He only experiences pain in the part where the pulsation is felt after exertion. He stated that he had been ill for four months, and that the pain, together with the hoarseness, came on suddenly.

In the course of two months from his admission, a swelling became apparent at the sternal extremity of the clavicle. This tumor first manifested itself by a gradual rising and thrusting forwards of the sternal head of that bone at the articulation. The swelling grew more and more distinct every succeeding week, sometimes making progress at one period more rapidly than at another, till in the beginning of Dec. it was found to be of very considerable size, and to beat with alarming violence. The tumor rose above the clavicle, and also descended below it; that bone forming a depression in its centre. At this time he suffered very greatly from dyspnœa, and could not lie flat on his back, from the

dread of suffocation. His voice was husky, and he could only speak in a whisper. A new symptom presented itself at this period. His right arm and hand became œdematous. Besides, the numbness in these parts was much increased, and he suffered acute pain in them. He also lost the power of motion in the arm. The report of the 4th Dec., states that both arms had become œdematous below the elbows, and that the face had a bloated appearance. Both temporal arteries continued to beat with equal strength. From this period all the symptoms became aggravated. That which drew the principal attention was the dreadful pain that the patient suffered in the arm; he continued to repeat, that the pain would drive him mad. He was obliged to be propped up in bed, on account of the difficulty of breathing. The œdema increased, but it was limited to the head, neck, and upper extremities. The tumor became larger, and the skin covering it red, so that, for several weeks, there was a constant dread of the sac suddenly bursting. He died on the 22nd Jan., exhausted from the long-continued pain in the arm, and laboriousness of respiration.

Aneurism of the Arteria Innominata—Obliteration of the adjoining Veins—Obstruction of the Thoracic Ducts.

The next preparation was also one of aneurism of the arteria innominata. The sac was of the size of two fists laid together. It communicated with the arch of the aorta by an opening which corresponded with the orifice of the innominata, enlarged to about twice its natural size. The walls were of irregular thickness, not exceeding, in most of their extent, that of the parietes of the aorta. The inner surface was in general rough and broken, and had here and there thin layers of fibrine deposited upon it; but in other parts it was smooth, and assumed the appearance of the natural internal coat of the arteries. From the continuity of the walls of the aneurism with the coats of the artery, the tumor had that appearance which might be supposed to mark that the aneurism was originally formed by the dilatation and expansion of the arteria innominata: the posterior part, however, of that artery was of its natural length, from the aorta to its bifurcation, not having undergone any dilatation or change.

The veins.—The venous trunks, which conduct the blood from the head and neck and upper extremities, were preserved in connection with the tumor, to exhibit the effects of the pressure of the aneurism upon them. All these vessels were found to be impervious. The internal jugular veins of both sides had their coats greatly thickened; and, near their junction with

the subclavian veins, their canals were completely closed by the adhesion of their coats. The subclavian veins preserved their natural structure, and were only obliterated at the point where they were joined by the jugular veins. Both brachio-cephalic veins, besides having their canals closed at their commencement, were entirely obliterated at the part where they unite to form the vena cava superior, so as to be lost in the parietes of the sac. On forcing a probe along the left brachio-cephalic vein, the coats of the vein were seen terminating on the internal surface of the aneurism, about two inches from the point where the vena-cava became distinct from the walls of the tumor. It was thus proved that a portion of this brachio-cephalic vein had undergone absorption from the pressure of the tumor. It has to be mentioned, that, in order to facilitate the examination of the vessels, the veins had been previously injected: it was found that the coats of the vena-cava were so thin, and the adhesion between them and the sac so weak, at the part where the vessel was involved in the parietes of the sac, that the side of the vein towards the aneurism became ruptured by the force of the injection, and the fluid escaped into the interior of the tumor.

Lymphatics.—The veins into which the trunks of the absorbents enter having been obliterated, it became interesting to examine the appearance of the absorbent vessels and glands. It was not, however, an easy task to follow the thoracic ducts by dissection, in consequence of the condensation of all the parts in the vicinity of the tumor. A part of the right thoracic duct, about three inches in length, was preserved in the preparation, to shew that it was obstructed at its termination, and ended in the closed brachio-cephalic vein. The coats of the duct were much thickened, and its interior was filled with a deposit of a firm nature, resembling coagulable lymph. The great thoracic duct had been injected in the abdomen previous to the dissection; but it could not be traced to its termination. It was followed along the posterior mediastinum as far as to the tumor, where it became so much involved in the dense textures situated there, that it was lost sight of. In this extent its appearance did not present any thing preternatural. The lymphatic glands, wherever they were examined, were found to be unusually large and congested. An unexpected number of these large glands was found studding the walls of the aneurism, and firmly adhering to them in every direction. Those of the neck had acquired such a size that they occasioned a perceptible fulness in the lower part of the neck during life. The glands of the

axilla, and those also of the groin, resembled the others in being greatly increased in size, and being, like them, of a purple colour, and gorged with bloody serum. The glands of the mesentery were enlarged, but not quite to the same degree as those which have been noticed.

For the account of the symptoms observed in the patient during life, Mr. Shaw expressed himself indebted to Dr. Watson, under whose care the patient had been, in the Middlesex Hospital.

James Buck, aged 33 years, was admitted in the beginning of March 1838. His countenance presented a peculiar appearance, being remarkably turgid, and the eyes projecting: the veins of the ears, the lips, and the nose, were also of a purplish colour. On uncovering his chest, the jugular veins were perceived to be unusually full, and numerous tortuous and prominent veins ramified upon the shoulders and whole front of his breast, as well as the abdomen. These varicose veins were especially numerous around the nipples, where they formed circles of inosculations or plexuses with each other. On each side, the veins on the breast communicated by five or six superficial trunks with the cephalic and thoracic veins: they also communicated above with the veins of the neck, and below with the superficial epigastric veins. The veins of the right side were more tortuous than those of the left; the epigastric veins pursued nearly a straight course. Independently of the fulness caused by the blood-vessels, there was a distinct tumid appearance in the neck, above both the clavicles, produced (as was afterwards found upon dissection) by an enlargement of the lymphatic glands situated there.

The pulse at the wrist was considerably smaller and weaker on the right than the left side. No external tumor, having any pulsation, could be perceived, although the most careful examination was made. But an interesting circumstance was observed: the heart's action could be heard and felt at its proper place beneath the left nipple, strong and heaving. It was also found, that, about the middle of the upper portion of the sternum, the ear, at each systole of the heart, was distinctly jarred, though with less force than in the præcordial region; but in the space intermediate between these two points, no similar jarring sensation was perceived: nevertheless, the heart could be heard beating at this part, with a slight bellows-sound. It was considered, by Dr. Watson, that the jar communicated to the ear at the upper part of the sternum, indicated the swelling out of an aneurismal pouch in that situation, when the sac was filled by the contraction of the heart.

The patient lived to the end of July of

the same year. The treatment consisted principally in abstracting blood at frequent periods, by cupping, and in administering drastic purges. By following this plan, the patient was so much relieved at different times, as to leave the hospital and become an out-patient. For the last three or four days he suffered under the symptoms of acute pericarditis, by which he was carried off. It has to be added to the account of the dissection, that, on a large extent of the surface of the heart, a layer of reticulated lymph was found; and the pericardium contained a quantity of reddish-brown fluid.

Aneurism of the innominata: œdema of the head and neck and upper extremities.

Mr. Shaw next drew the attention of the society to another specimen of aneurism of the arteria innominata. In the preparation the aneurismal tumor was seen, with a portion of the arch of the aorta and its branches, together with the venous trunks which form the vena cava superior. The aneurism arose from the innominata midway between its origin and its bifurcation: it was of an oblong shape, measuring in its greatest length, which was in the direction upwards, about five inches, and in its transverse direction, three inches and a half: it was filled to four-fifths of its extent with concentric layers of fibrine, which gave to the whole tumor a hard and solid feel. Mr. Shaw mentioned that in making the post-mortem examination the tumor was found to reach upwards along the side of the trachea, so as to overlay the lower part of the thyroid gland; it had also caused partial absorption of the right clavicle, and of the upper part of the sternum. The orifice of the innominata, where it arises from the aorta, was nearly of its natural size, being dilated only to a slight degree: the openings of the right carotid and subclavian arteries were likewise of their usual diameters: the tumor rising from one side of the artery in such a manner as not to involve these orifices, but to form a distinct pouch or diverticulum, communicating with the vessel.

The veins.—The left subclavian and internal jugular veins had their coats greatly thickened, and were closed by a firm deposit of fibrine within them. The brachiocephalic vein also of this side was completely obstructed. It was with difficulty, Mr. Shaw observed, that this vessel could be found in making the dissection, owing to its being involved in the dense textures external to the aneurism, and to its size, as well as the structure of its coats, being so much changed. It was perceived in the preparation winding round the lower part or neck of the tumor in front. It was diminished to the size of a quill; its coats

were thick and fibrous, and the interior was occupied with fibrine. The right subclavian and internal jugular veins were seen adhering at the point where they coalesce to the lateral part of the aneurism; their coats were not so much changed as those of the corresponding veins of the left side, yet they were increased in their thickness to a certain degree. The brachiocephalic vein, however, formed by the union of these two veins, was more changed; it was contracted in its diameter, and contained a firm plug of fibrine, which obstructed it completely. Below the point where the two brachiocephalic veins join each other, the vena cava presented a natural appearance.

Adhesions were found between the pericardium and heart, and a clear whey-coloured fluid. The size of the heart, with its valves and cavities, seemed natural. The ascending aorta was very considerably dilated, and its lining membrane was marked with atheromatous deposits.

The face and superior extremities were œdematous, but the lower extremities were free from the slightest infiltration of fluid; nor did the abdomen contain any fluid.

The man from whom this preparation was taken was a patient of Dr. Wilson's; he was forty-four years of age: he was admitted into the Middlesex Hospital on the 1st of September, 1835, and died in the middle of the following October. He stated that he had been ill for two months, but had not been entirely free from pain for the last thirteen years. During the time he was in the hospital he suffered from difficulty of breathing, and could only speak hoarsely in a whisper; he had also difficulty of deglutition. The veins of the face and neck were turgid; and it was remarkable that the upper part of his body, including the head, neck, and superior extremities, became œdematous to a great degree, while no similar appearance was presented in the lower part of his body.

Aneurism of the innominata.

The last specimen was one with the history of which Mr. Shaw did not profess to be acquainted, having procured it at the sale of a museum, without any accompanying account of it. The preparation exhibited an aneurismal dilatation of the arteria innominata, and a portion of an aneurismal sac, which communicated with the dilated artery by a distinct circular orifice. The preparation, he remarked, was interesting, when taken along with the other specimens, as presenting a modification of the form of aneurisms in this situation.

Mr. Paget was induced to ask Mr. Shaw respecting the condition of the veins by

which the collateral circulation was carried on, by the belief that the enlargement of the cutaneous veins, to which it is commonly ascribed, is not nearly sufficient for the conveyance of so large a quantity of blood as is returned from the head and upper extremities. He had lately had an opportunity of examining a case in which the superior cava was almost completely obstructed, but in which the circulation was fully maintained. In Mr. Shaw's cases it seemed probable that much of the blood of the upper part of the body was returned to the heart through the vena azygos; here, however, that was impossible, for the vena azygos was obstructed with the superior cava. The current in the former must therefore have been a descending current; and he had no doubt that it was by the vena azygos and semi-azygos that a considerable portion of the blood from the head was conveyed to the inferior cava, through the medium of the numerous anastomoses of all the veins about the vertebral column above; and the anastomoses of the azygos and semi-azygos with the inferior renal or lumbar veins below. Another chief means by which the circulation in this case was carried on, was the enlarged left internal mammary vein, which was dilated to nearly the size of a swan quill; the right mammary vein on the contrary was of its usual size; its termination in the superior cava being obliterated, so as to render it useless for maintaining the circulation. The cutaneous veins of the chest and abdomen were also considerably enlarged, especially those in the left side, but evidently not to a degree sufficient to conduct away nearly all the blood from the upper part of the body. By them, however, and by the other enlarged veins already mentioned, the circulation was carried on very perfectly; and the man presented no sign of embarrassment from the peculiar condition in which he must have been placed, with a number of great currents of blood, all descending from the upper to the lower part of the body, and thence again ascending through the inferior cava; this latter vessel was dilated to fully double its usual size, and it was evident that all the blood of the great systemic circulation had been returned to the heart through it. Mr. Paget also stated that he had carefully examined the condition of these veins, in which the course of the blood had been contrary to that which it usually takes, for the purpose of determining what was the state of their valves; he had been unable to find any trace of them in any of the dilated cutaneous veins; the lining of those vessels was perfectly smooth and polished.

[To be concluded in our next.]

MEDICAL ASSOCIATION OF IRELAND.

[The following are the resolutions passed at the above meeting, as given in the Dublin Medical Press. Want of space obliges us to omit the speeches.]

The first anniversary meeting of the Association was held in Dublin, on Wednesday the 27th ultimo, and was very numerously attended by representatives of the various local medical associations, and by individual members from every part of Ireland. At one o'clock precisely the President, Richard Carmichael, Esq. took the chair, and addressed the Association at some length on the objects of their meeting. The Secretary then read the following report:—

Report of the Council of the Medical Association of Ireland, presented at the General Meeting held on the 27th of May, 1840.

Since the meeting of the Medical Congress, on the 29th of May last year, the Council have held sixty-three meetings for carrying into effect the wishes of the members of the association.

On the 15th of June they resolved to recommend the establishment, without delay, of district associations where they had not already been formed, and that such local associations should put themselves into communication with the Council, to secure unanimity and effectual co-operation.

On the 29th of June the Council communicated to the British Medical Association the intelligence of the establishment of the Medical Association of Ireland, at the same time suggesting that great advantages might be gained by the co-operation of the two bodies.

On the 13th of July the Council received a communication from Dr. Webster, the President of the British Medical Association, expressing the willingness of that body to co-operate with the Medical Association of Ireland, upon which the Council resolved to request that a deputation from that association should meet one from the Medical Association of Ireland, at Liverpool, during the meeting of the Provincial Medical Association of England.

On the 18th of July the Council resolved to publish an address to the members of the association, explaining the circumstances which necessarily led to an alteration in the plan originally contemplated for the union of the profession, and, at the same time, expressing a hope that this should not alter the views of the association respecting medical reform, or cause them to relax their efforts for the

attainment of the objects contemplated by them. They also made several suggestions as to the future organization of the general and local associations.

On the 25th of July, the deputations from the British and Irish Associations met in Liverpool, along with a committee appointed for that purpose by the Provincial Medical and Surgical Association of England, Dr. Barlow, of Bath, being in the chair, and the following gentlemen being present:—Dr. Webster, on the part of the British Medical Association; Dr. Forbes and Dr. Rumsey, on the part of the Provincial Medical Association; and Mr. Carmichael, Dr. Jacob, Mr. O'Beirne, Dr. Maunsell, and Dr. Macdonnell, on the part of the Medical Association of Ireland.

At this meeting it was resolved—That Drs. Barlow, Webster, and Maunsell, be respectively the organs of communication of the respective bodies which they represent, and that a free communication be forthwith commenced between those bodies for the purpose of drawing up a plan of general medical reform, in the shape of heads of a bill, to be considered by the several committees, and subsequently proposed to the associations; and that a communication be opened with the medical profession in Scotland, and the local associations in England and Ireland, as soon as possible; and that the members of this committee shall exert their influence to the same effect.

On the 12th of August the Council received a communication from Dr. Maffet, the Secretary of the County Monaghan Medico-Chirurgical Association, expressing their approval of the resolutions passed at the Congress, and declaring their determination to promote the objects contemplated; and "That they were willing to assist the Medical Reformers in Great Britain and Ireland in the adoption of such measures as are deemed expedient and necessary to protect the interests of our body, to correct existing abuses, and to promote that harmony of feeling which should exist among the members of a liberal and enlightened profession; and that while they conceived equal rights and privileges should be granted to all having sufficient qualification, and that the monopoly which impedes good feeling, and can only serve the interests of individuals, should be wiped away, they shall always labour to protect, for the honour of the profession, a high and elevated standard of education." On the same day a communication was received from Dr. Colvan, Treasurer of the Armagh Medical Association, enclosing six pounds, to be placed at the disposal of the Council, for carrying into effect the objects of the Association, and also from Mr. Cane, Secretary of the city and county of Kilkenny

Medical Association, enclosing £10 for the same purpose, and expressing the approval of that body of the "wise measures adopted by the Council in their address of the 20th," and stating that they felt grateful for the exertions, the talents, and the energy, which the friends of medical reform in Dublin have devoted to the interest of the profession, and that their humble aid shall be given to the Council in every measure necessary to the protection of our common interest.

On the 17th of July, petitions to both Houses of Parliament were agreed to, praying for a legislative enactment to secure a uniform system of instruction, and equality of qualifications and examinations; to confer equal rights and privileges on all members of the profession; and that one body should be appointed in each of the three kingdoms, to carry such a system into effect.

On the 7th of September, resolutions adopted by the County Cavan Medical Association, relative to the payment of medical witnesses at coroners' inquests, were received; and the Secretary was directed to acknowledge the receipt of the same, and to call the attention of that body to the address of the Council, published on the 24th of July.

On the 5th of December, a memorial address to the Secretary of State for the Home Department, was agreed to, and ordered to be transmitted; and a copy was laid before Lord Morpeth, the Chief Secretary for Ireland, by a deputation of Council. This memorial was subsequently published, with other documents of a similar nature, relative to Medical Reform, and freely circulated for the information of the members of the legislature, and the public generally.

On the 12th of December, a letter was received from Mr. Carter, Secretary to the North of England Medical Association, expressing the willingness of that body to co-operate with the Medical Association of Ireland, to obtain from Parliament the adoption of such measures as shall protect the interests of the medical profession, and place it under an efficient system of government; to which the Secretary was directed to reply, expressing the gratification felt at the information, and the wish of the Council to carry the proposed object into effect.

On the 26th of December, a deputation appointed to wait on Mr. Nicholls, the Poor Law Commissioner, to ascertain the truth of a prevalent rumour respecting the qualification required to be possessed by candidates for the situation of medical attendant to poor-houses, reported that they had seen that gentleman, who assured them that no determination had been come to on the subject, and that no step should be

taken likely to affect the medical profession, without due notice. It was then resolved that a case should be laid before the Attorney General, to ascertain whether the Apothecaries' Company possessed the power of inflicting a penalty on medical men who compound medicines for their own patients in public institutions. A communication having been received from the Armagh Medical Association, stating that the judge at assize had decided that cess-payers in presentment sessions had a right to reduce the fees awarded to medical men by coroners, it was ordered that the consideration of the matter should be referred to a sub-committee.

January the 9th, the case submitted to the Attorney General, relative to medical officers of charities compounding medicines, with his opinion thereon, was read and ordered to be published, from which it appears that the Apothecaries' Company have no power to prevent the physicians and surgeons of hospitals, dispensaries, or poor-houses, from compounding medicines for patients in these institutions.

On the 18th of January, the Council agreed to a petition to Parliament, praying that the subject of medical reform, and the consideration of the grievances under which the profession labours, should receive the attention of the legislature, and transmitted the same to Mr. Fitzstephen French, for presentation. This petition was published, with a recommendation that similar ones should be forwarded by the local associations.

On the 6th of February, a letter was read from Dr. Kingsley, of Roscrea, respecting the allocation of fines levied at petty sessions, in consequence of which, a deputation, composed of Drs. Jacob, Macdonnell, and Maunsell, had an interview with Mr. Hamilton, at the Chief Secretary's office, and ascertained that, in conformity with the statute, (1 and 2 Victoria, c. 99,) all fines must be paid into the office of the paymaster of civil services, and thence issued to charities in such proportions as the magistrates may award to each.

At a meeting of Council, held February the 27th, it was resolved—That a member of Council should attend the meeting of the Eastern and Western Medical Associations, to be held at Cork on the 12th of March, to ascertain the views and objects of the members of the profession in that part of Ireland, for the purpose of more effectually co-operating with them. Dr. Maunsell, the secretary, accordingly attended there, and assisted at the proceedings. At this meeting it was resolved, "that the Medical Association of Ireland is well calculated to form a rallying point for the profession in Ireland, and that the meeting was pledged to give it its support."

On the 19th of March, it was resolved, that the nature and objects of the association not being perfectly understood by the members of the profession in the provinces, it was desirable that a brief summary of them should forthwith be drawn up, and published, which was done accordingly.

March 26.—The president and secretary reported that they had had an interview with Mr. Drummond, at the chief secretary's office, and through him called the attention of government to the state of the medical charities, with the hope of obtaining for them some more permanent means of support than they at present enjoyed. They also suggested some alterations in the bill now in progress for the extension of vaccination; and reminded him, that through the Medical Association, the government could, at all times, ascertain the wishes of the profession in Ireland.

On the 2d of April, a letter from Dr. Jagoe, of Ballineen, having been read, stating that he had been summoned as a crown witness, to Cork, last assizes, and detained for eight days, for which a sum of four guineas was awarded to him, a deputation from the Council, headed by the president, waited on Mr. Drummond, at the chief secretary's office, in consequence, and represented the injustice and hardship of such proceedings, and earnestly requested the attention of government to the subject. Mr. Drummond recommended that remonstrances should be forwarded to the judges, urging the expediency and justice of suitably remunerating medical witnesses; and that petitions to parliament, praying for an alteration in the law, to enable assistant-barristers to afford such remuneration, should be forwarded. Attention having been drawn to the case of Dr. Edge, of Newtown, to whom seven guineas had been awarded, for five days' attendance at Maryborough assizes, an order was made to pay that gentleman ten guineas.

April 25.—A letter from Mr. Major, assistant-barrister of the county Clare, having been read, stating that he had taken off a fine imposed on Mr. John Wilkinson, of Limerick, for failing to attend at a petty sessions, the Council having applied to him on the subject, it was resolved that the thanks of the Council should be given to Mr. Major, for this and other marks of consideration shewn by him to members of the profession in his official capacity.

On the 9th of May, the Council prepared a series of propositions for the consideration of the present Congress, relative to the organization of the association, which have since been published, and to which the careful attention of the present meeting is requested.

On the 22d of May, Drs. Jacob and Maunsell waited on Mr. Hamilton at the

chief secretary's office, to ascertain the cause of the delay in advancing the amount of petty sessions fines, payable to the medical charities, when they learned that it has arisen from the imperfection of returns made respecting them, which must be amended, and that orders to obtain such amended returns are about to be issued, and payment may, therefore, be expected in less than a month.

In concluding this abstract of the labours of the Council for the past year, the members have to express their regret that it has not been in their power to do more towards forwarding the objects of the association. They, however, venture to hope, that when the difficulties they have had to encounter are taken into consideration, due allowance will be made for omissions. Sufficient, it is presumed, has been effected to prove that, with adequate support from the members of the profession, much may, in future, be done for the general good, by such exertions.

Dr. O'Beirne rose and moved the first resolution, viz.:—Resolved—That this Association, in its collective capacity, is unconnected with any College, Corporation, or Body, and that it is designed to advance the interests of no party whatsoever, but solely and singly to promote the welfare of the public and of the members of the medical profession, without any difference or distinction.

Dr. Jacob moved the second resolution, viz.:—Resolved—That the permanent continuance of a body capable of advising and protecting medical men in the discharge of their duties, and maintenance of their rights, suited to watch over professional interests, and to be the means of communicating between the profession and the government, is highly desirable.

Dr. Nugent, of Cork, moved the third resolution, viz.:—Resolved—That we constitute the Council of this Association as the organ of communication, on all matters concerning the interests of the medical profession, between its members and the government.

Dr. Kingsley, of Roscrea, moved the fourth resolution, viz.:—Resolved—That a General Meeting of the Association shall be held upon the last Wednesday in May, in each year, when a President, Secretary, Treasurer, and Council, shall be elected for the ensuing year.

That at every such Annual General Meeting, the name of a member shall be returned from the members of the Association in each country, or riding, or large town, to act as Secretary for such district, through whom the names and subscriptions of persons desirous of becoming Members of the Association shall be transmitted to the Central Council, and

whose duty it shall be to keep a list of the Members of the Association resident within his district, and to summon Meetings of said Members whenever directed by the Central Council, or required to do so by a Requisition signed by one-fourth of the whole number of such resident Members.

That such Secretaries of Districts shall be ex-officio Members of the Central Council.

Dr. G. W. O'Brien, of Ennis, moved the fifth resolution, viz.:—Resolved—That the objects of the Association are—

1. To form a society for the protection of Medical Practitioners in all their just and legal rights:

2. To seek for a Legislative enactment, giving a permanent constitution to the Profession, and directing a competent and uniform standard of Education, and an equality of privileges for all persons who shall, in future, be permitted to practise medicine throughout the Empire, and—

3. To secure for the public, in future, the services of a scientific Apothecary, who shall be protected in the exercise of his Profession, and not engage in the practice of Medicine.

Dr. Purcell, of Carrick-on-Suir, moved the sixth resolution, viz.:—Resolved—That the Council be directed to prepare a Petition to Parliament, for the enactment of a measure which shall provide for the regulation and control of the Medical Charities; also praying that adequate funds shall be provided for their support.

Dr. Jagoe, of Kinsale, moved the seventh resolution, viz.:—Resolved—That the Council be directed to prepare Petitions to Parliament for suitable remuneration to medical men, when called upon to perform public services in courts of justice.

Dr. Cranfield, of Enniscorthy, moved the eighth resolution, viz.:—Resolved—That the Council be instructed to prepare Petitions to Parliament, praying for attention to the neglected subject of Medical Police, and for encouragement to medical men disposed to engage in the investigation of all matters concerning the public health; and that copies of these different petitions shall be forwarded to each Local Secretary, in order to procure signatures in all parts of Ireland.

Dr. Cane, of Kilkenny, moved the ninth resolution, viz.:—Resolved—That the following plan of General Medical Reform shall be supported by this association:—

The establishment, by law, of one Faculty, having three branches, one in each of the capitals of the Empire; such Faculty to include all Practitioners in Medicine, both Physicians and Surgeons: each Branch to be governed by a Representative Council, elected periodically by and out of, the whole body of the Faculty

in each Kingdom. The Councils to have the power of making regulations for the government of the Profession, and also of admitting Members: no person being permitted to practise without being examined and licensed as a Member of the Faculty. The regulations of the three Councils to be similar and uniform, general conferences being, from time to time, held in order to preserve uniformity. This 'One Faculty' plan contemplates the establishment of a class of scientific Apothecaries to be examined and licensed as such under the direction of the Councils; also, that no Practitioner "shall be permitted to sell drugs, or to compound medicines, unless prescribed by himself, or by others in consultation with him, and for his own patients, except in rural districts, and by special license."

Mr. Donovan's proposal for establishing a College of Pharmacy, might, with some modifications, be made to coincide with this portion of the 'One Faculty' plan. Institutions for teaching not to be connected with the licensing body of the faculty.

Professor Williams moved the tenth resolution, viz.:—Resolved—That the Secretary, with Dr. Nugent, Dr. Healy, and Dr. Dunn, be a deputation to wait on Mr. Warburton, and other members of the legislature, to explain the views of this Association respecting Medical Reform.

Dr. Healy, of Ennis, moved the eleventh resolution, viz.:—Resolved—That Richard Carmichael, Esq., shall be President, that John Macdonnell, M.D., shall be Treasurer, and Henry Maunsell, M.D., Secretary for the ensuing year.

Dr. O'Reardon, of Tipperary, moved the twelfth resolution, viz.:—Resolved—That James O'Beirne, M.D., Arthur Jacob, M.D., Sir James Murray, M.D., Francis White, Esq., Professors Hargrave, Williams, Porter, and Benson, O'Bryen Bellingham, M.D., Hamilton Labatt, Esq., Richard Tuohill, M.D., S. Walker, M.D., Dundalk; Robert Barlow, M.D., Mullingar; John Morrison, M.D., Newry; John Colvan, M.D., Armagh; Henry M'Cormac, M.D., Belfast; Robert Cane, Esq., Kilkenny; Richard Maffett, M.D., Glasslough; Joseph Ferguson, M.D., Mullingar; Richard Cranfield, M.D., Ennis-corthy; J. Waters, M.D., Roscrea; M. D. Nugent, M.D. Cork; R. Corbett, M.D. Innishannon; Edward Jago, M.D., Kinsale; John Lynch, M.D., Charleville; John Purcell, M.D., Carrick-on Suir; John Wilkinson, Esq., Limerick; William Bell, M.D., Clonmel; John Jacob, M.D., Maryboro'; Dr. W. Murphy, Cork; together with the Local Secretaries, shall be Members of the Council for the ensuing year, with power to add to their numbers.

Sir James Murray moved the thirteenth resolution, viz.:—Resolved—That the marked thanks of the Association are due

to the President, R. Carmichael, for his fearless and independent advocacy of the rights of the profession during the past year.

It was then resolved that the thanks of the Association were due to the talented and fearless Editors of the MEDICAL PRESS, for their unceasing efforts to promote the welfare of the profession.

The business having been concluded, the meeting then separated.

To the above information we have to add that Mr. Carmichael has placed £500 at the disposal of the Council of the Medical Association of Ireland, for the purpose of aiding in carrying out a measure of medical reform.

SMALL-POX AND VACCINATION.

On the 17th, Sir James Graham moved, in the Commons, that the House do now resolve itself into a Committee on the "Vaccination Bill." Mr. Wakley moved, as an amendment, that the "Small-Pox Prevention Bill" be substituted in place of the above.

After some discussion the House divided, when there appeared for the motion 56; against it 39; majority for Sir James Graham's motion 17. The House then resolved itself into a Committee on the Vaccination Extension Bill.

On the 1st Clause, empowering poor-law guardians to contract with their medical officers for vaccination, being read, Mr. Wakley (after some discussion principally between him and Sir James Graham) proposed to leave out the words "medical officers appointed by the board of guardians," and to insert "medical practitioners, or any of them, within the several unions:" this was carried by 33 against 24.

The 2d Clause was postponed.

The 3d Clause provides that officers engaged in the administration of the poor-laws, should, for the purposes of the act, conform to the instructions of the poor-law commissioners. An amendment on this was moved by Sir B. Hall, and supported by Mr. Wakley, but the original clause was carried by a majority of 44, viz. 51 against 7.

Clauses 4, 5, and 6, were agreed to, without amendments; but on Clause 7 being proposed, which requires the guardians to transmit a copy of every contract to the poor-law commissioners, who may annul the same, Mr. Grimsditch and Mr. Wakley opposed the clause, moving an amendment, which, however, was negatived by 29; viz. 40 against 11.

Clauses 8 and 9 were agreed to.

Clause 10, prohibiting unqualified persons from inoculating. Mr. Wakley moved, as an amendment, that the following

words be introduced, viz: "That any person guilty of such misdemeanour shall be liable to be proceeded against, and convicted summarily before two or more justices of the peace, in petty sessions assembled, and committed for one month to hard labour." The Attorney-General suggested the omission of the words "hard labour," and the clause, thus amended, was agreed to. The remaining clauses were then agreed to, and the report ordered to be brought up next day.

ABORTION OF FIVE FÆTUSES IN THE THIRD MONTH.

DR. E. KENNEDY presented a specimen taken from a female who had borne five children at once, and had aborted in the third month of pregnancy. The specimen consisted of three distinct ova, with their appendages. Two of these were double, and contained twins, the third was single; each of the double ova were enveloped in a common membrane, and had a common placenta; the single ovum had its own placenta and membranes. Some persons were disposed to question the occurrence of these multiparian births, but there had been two or three well-authenticated instances of five children at a birth. One of these occurred lately at Naples, the other about twelve years ago in North America. It was a curious fact, that in the matter of multiparian births, Ireland preponderated. The proportion of twin cases in this country is one in sixty; in London it is one in ninety-one; in France, one in a hundred and forty; in America (where there is a large proportion of Irish settlers), it is one in seventy-five. It was also a curious fact, that the female who gave birth to the five children at once, in America, was an Irish emigrant. The female from whom the specimen was taken aborted with bearing-down pains about the third month of her pregnancy, most probably from over distension of the uterus. She had laboured under constant nausea, a symptom which appears to be one of the most ordinary signs of multiparian pregnancy. (Museum Lying-in Hospital.)—*Dublin Journal of Medical Science.*

PRIZES—COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,
THE members of the College of Surgeons must, I feel sure, be glad to observe the increased pecuniary value which the Council have added to the different prizes.

Permit me, however, to suggest that it is not the pecuniary value *alone* which is looked up to by the aspirants, but the honour and eclat attending the success, which is much more eagerly sought after.

Would it not, therefore, add to the inducement to compete for the Jacksonian or other prizes, if they were awarded in person by the President in Council to the successful candidates, instead of a simple notification being sent by post from the secretary, that the prize was awarded to Mr. —, and that he might get it any day by calling for it.

Another suggestion I would offer likewise is, that the testimonial should be such as the possessor of it would be proud to shew to his friends, with the College arms appended to it, instead of the written certificate of the secretary.

This might likewise be granted to the former prizemen, or at least to such as choose to apply for it, as, in contested elections, the possession of such a certificate might prove of infinite value.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF BONE, *continued*.—CYSTS—
SOFTENING—RICKETS—BRITTLINESS
—SPINA VENTOSA—OSTEO-SARCOMA.
Their Nature—Causes—Symptoms—Treat-
ment.

DISEASES OF THE ARTICULATING SYS-
TEM.—Sprains. *Their Nature and Treat-*
ment.

CYSTS IN BONE.

THE maxillary bones are the most frequent seat of cysts; but they have also been found in the long bones of the limbs, as well as in the bones of the vertebræ. According to Dupuytren, there is much variety in the contents of these cysts: they are either solid or fluid, but, most frequently, they are fibro-cellular masses; they may be like grains of rice; they may be hydatids.

Causes.—The causes which favour the development of these cysts are generally very obscure; they have been known to succeed to a blow—to incomplete extraction of a tooth. Their bulk is variable; it may be that of a musket-ball, or that of a hen's egg, or the fist: they occasion some pain, and interfere with the functions of the organ on which they are seated. The pain is sometimes heavy; sometimes acute; rarely lancinating. The tumefaction is a consequence of the increase of the cyst; the bony parietes are gradually thinned; they then yield to pressure almost like parchment. At first there is

danger of mistaking such a tumor for osteo-sarcoma; but you can scarcely fail from a single symptom in detecting the disease. Press upon it, it will yield, and again return upon itself just like parchment; but this is not the only guide; the adjoining tissues are not degenerated. If there be any doubt, an exploring puncture should be made; this, with the crepitation, can leave no doubt about the kind of disease with which we have to do. If doubts still exist, as to whether the affection be the one we are considering, or osteo-sarcoma, they should soon be dissipated, because from an early period osteo sarcoma is characterized by lancinating pains and varicose tumefaction, by change in the adjoining structures, and by its inequalities. In these cysts, on the contrary, the surrounding parts do not participate in the disease; their surface is smooth and equal, and they are more or less indolent; and the crepitation, such as I have described it, is not met with in osteo-sarcoma. This distinction is very important, because the two diseases differ essentially in their consequences. In the one case, the tumor may be removed, and the disease be cured; but in the other this rarely happens.

Prognosis.—The prognosis in these cases is favourable: they may be cured by operation: they may, it is true, repullulate when not completely removed; but this should not happen. If the tumor have caused considerable deformity, all traces of the disease may not be removed; but this is a trifling inconvenience, and cannot be compared to the consequences of the disease when left to take its course.

Treatment.—The nature of the disease being ascertained, the best means of cure is complete destruction. This should be done in the following manner:—An exploring puncture is first made, to ascertain the nature of the contents; an incision is then made along the tumor: when the inferior or superior maxilla is affected, this

incision may be made within the mouth. Arrived at the centre of the disease, it should be extirpated, and this is not difficult, for the affected bone readily yields before the knife: sometimes, when the cavity is exposed, a red-hot iron is applied over the surface to destroy it; or it may be stuffed with lint, so as to excite inflammation of those parietes, and destruction of the membrane by which they are invested, and in a reasonable time the cavity is filled up. Sometimes counter-openings are necessary. Before the diseased structure is removed or destroyed, we must endeavour to ascertain the cause of it, because these structures have a strong tendency to repullulate.

SOFTENING OF BONE.

It is to an Arab physician, Gschuzius, that we are indebted for the first observation of the disease termed Osteomalacia, or softening of the bones, as presented in adults: his patient was a man who was carried about on a palm mat, "because he had no bones, except those of the head, the neck, and the hands;" the other parts, from the clavicle to the feet, could be twisted like a garment; the tongue was the only part subject to the will. Since his time, a great number of cases have been published; among others, that of a woman, of twenty-one, who, after a fever, experienced great pain over the whole body; her limbs began to fail, and, in eighteen months, she lost a foot in height. Upon the inspection of her body after death, all the bones, except the teeth, were as soft as wax. The case of Madame Supiot is well known. She had borne four children; after each some accident happened; first lameness; then pain and swelling of the legs; lastly, paralysis of the legs, followed by involuntary contraction of the muscles of the lower extremities, which gradually brought the legs into such a position, that her head rested on her left foot as on a cushion; other parts of the body suffered, and ultimately the deformity became so excessive, that probably nothing like it has ever been seen. Many of the bones were softer than cartilage. The bones of the carpus alone preserved their figure and their situation, and were much less softened than other bones. At the commencement of the disease her urine was white, earthy, and presenting the characters of gypsum. Frank mentions the case of a woman of fifty-five, of high stature, who, in a few years, was reduced to that of a dwarf. Numerous examples might be given of women who, after parturition, have had the bones of the pelvis so disfigured as not to allow of the passage of the child. Although the greater number of cases on record refer to women, some have occurred in man: such was the

case of Gschuzius. In the Copenhagen Acts is the case of a man of thirty-two, who, at twenty-four, had severe pain in the limbs, followed by softening; the head became as round as a ball; the legs were scarcely six inches long. Another very singular case is related by Lobstein of an unmarried English lady, of thirty-five, in whom no osseous substance was found, except at the articular extremities of the long bones. The analysis made by Bostock (*Med.-Chir. Trans.* vol. iv. page 38) of softened bones shewed that the earthy portion did not exceed one-eighth of their weight, whilst, in healthy bones, it is more than a half.

Now is the softening of the bones, in after life, the same disease as the softening of childhood? Many authors have confounded them. John Hunter thought the analogy between them was very strong. He thought that in adults the softening proceeded to the greatest extent; that the bones became almost as flexible as tendons; whilst in children they always retain enough of calcareous matter to preserve their form and a portion of their solidity. P. Frank goes farther, and maintains that there is no difference; that the one is the rickets of childhood; the other of adult life. I confess my inability to agree with this opinion: the softening of adult life is a graver disease than rickets; it is produced by causes other than those which occasion rickets. Van-der-Haar speaks of a girl of fifteen who, after an exanthemic fever, had erysipelas of the right arm and left leg, which ended in suppuration; incisions were necessary; and it was discovered that there was not only tumefaction of the bone, with caries, but such a softening of the tibia and fibula, that if the leg were raised by supporting the heel, these bones bent. After an appropriate treatment they regained their solidity. Here was a case of acute softening succeeding to, or determined by, the exanthemic fever, producing in the bone a true chemical decomposition, which, in rickets, is the slow result of perverted nutrition.

It is scarcely necessary to insist further on the difference between these two affections. In rickets, do we find such a complete softening—such a commencement of dissolution of their substance? Does it attack children so suddenly? Does it succeed to such, apparently, slight causes? Still I do not think that in a pathologico-physiological point of view, there is an absolute disparity between the two diseases. In both there is a deranged nutrition; in both there is, probably, exaggerated action in the absorbents; the subtraction of phosphate of lime from the bones, and its presence in the urine, seems to prove this. Both occur at periods of life when a sort

of revolution is taking place. Thus, in rickets, the disease attacks the fœtus; from this results monstrosities and deformities, to which the bones of the head are subject, congenital deformities of the spine, twisting of the limbs; it attacks children at the epoch of dentition—a second period of excitement. It attacks adults, and generally succeeds to some acute disease—to rheumatism, to laborious parturition. The observations of Caspari show that women especially suffer; and this, as compared with men, in the proportion of ten to three. I admit, then, this kind of identity of cause; but I shall incline to the opinion that they are different diseases.

If the phenomena of this disease be curious, the restoration of the softened bone to their former state, and their new solidification, is not less worthy of attention. In the *Phil. Trans.* vol. xli. p. 616, is the case of a man of 60, in whom almost all the bones began to soften at 18. Now all these bones became solid anew; but all the joints were ankylosed. A second example, described by Pott, in the same volume, p. 816, is that of a young man, whose sternum, ribs, some of the vertebrae, the two femurs, and the iliac bones, after having been softened, recovered their original solidity.

The bones are too little accessible to the direct action of the therapeutical agents to be immediately the object of curative indications. Our attention should be directed to avoid all that is susceptible of increasing the curvatures which may already exist. When the tendency to soften is dissipated, mechanical means, methodically employed, and associated with hygienic or medicinal means, are frequently useful.

RICKETS.

Much difference of opinion exists among medical men as to what should be understood by the term rickets; the general symptoms of the affection, the nature and frequency of the deformities which characterise it, and upon the different alterations which it produces in the osseous system. In consequence of the etymology of the word, the term has been applied to deformities of the spine, whilst those deformities are rarely produced by the disease to which they are attributed. A great many authors have called all cases of softening of the bones in adults, rickets. The case of Madame Supiot, described by Morand, is in point. Again, it is not difficult to find persons who confound rickets with scrofula; and yet, of the twenty cases detailed by Ruzf, not one was affected with scrofula. In fact, neither the case of Supiot, nor a multitude of others, presented any evidence of this condition.

We apply the term, as it was done by Glisson, Mayon, and Petit; and for the purpose of making evident what we mean, it is necessary to refer to the external characters, the mode of attack, and of development of the disease; the age, the sex, the portions of the osseous system which it necessarily occupies; the general symptoms which precede and accompany its evolution—the changes of form and texture which it produces in the osseous tissues; the circumstances under which it is developed, and its presumed cause; the conditions of curability, and the means of treatment.

I hold, then, that rickets is a disease of childhood; of Ruzf's cases, thirteen were under two and a half, four under three, two under five, and one under eleven years; that it is caused or accompanied by a change in the plastic qualities of the blood; that it becomes more fluid, and upon this probably depends the suspension of the business of reparation; and, perhaps, the starting point is deranged nutrition, dependent upon bad or improper food, or depraved digestion.

The deformity of the osseous system is generally developed from below upwards, from the bones of the leg to that of the femur, from thence to the pelvis, and from the pelvis, simultaneously or successively, to the different parts of the upper extremities, the thorax, the vertebral column, and the cranium; yet the arms occasionally suffer first; and I apprehend this is principally owing to the habit of nurses taking children up by the arm. Ruzf believes the order of frequency to be different; he thinks the ribs suffer first, then the forearm, humerus, femur, leg, clavicle, and spine; and he may be right in those cases where children have not begun to walk.

The texture of rickety bones varies with the period of development of the disease: at first there is an effusion of sanguinolent matter in all the interstices of the osseous tissues, in the cells of the spongy tissue, in the medullary canal, between the periosteum and the bone, and in every part of the osseous tissue where nutritive vessels are distributed; the osseous cells are enlarged, the resistance is diminished, but the chemical composition is not changed. The second period is that of deformity: at the same time that the osseous frame-work loses consistency and softens, it becomes flexible. The matter deposited in the cells shews a tendency to become organised; the organised spongy matter is especially abundant between the periosteum and the external table of flat bones, as well as between their laminae. In the third period the newly organised tissue passes into the condition of a compact tissue; and this addition of new to the

old tissue increases the bulk of certain portions of the bone; but what is singular, we may see the mechanism employed by nature to cure the affection: in many cases we discover a new bone placed at the concavity of curvatures in the old one.

The period when children suffer from this disease is from six months to three years; it may not be presented before the second dentition, or even before puberty.

The long bones suffer most frequently: their extremities enlarge, their shafts are thinned and curved, either in their natural direction or in another. Most commonly the femur is arched inwards or backwards, so that in walking the legs are directed outwards, the knees inwards, the leg forming an angle with the thigh. The bones of the arm are also curved in two directions, inwards or forwards. These bones may not only be curved but flattened, and it has been remarked by Mr. Stanley, that what they gain in surface they lose in thickness.

When rickets affects young children, in whom the fontanels are still membranous, complete ossification of the bones of the cranium is retarded; the softest yield to the impulsion of the brain, which is singularly developed and hypertrophied; but this great increase of the brain and the cranium, in certain rickety children, is not always accompanied, as some persons have asserted, by a corresponding development of the intellectual faculties. If rickets be not manifested until after the ossification of the fontanels is complete, the volume of the head is not sensibly increased, but the cranial bones sometimes attain great thickness. The change in the pelvis is, in females, a matter of most serious consequence, especially as relates to the functions of the uterus; the deformity may be principally directed upon any diameter of the outlet.

Symptoms.—These changes are not brought about without much general disturbance. Rickety children are pale, thin, with little muscular development; the skin is flaccid, they perspire with little exertion; while asleep the head is generally covered with perspiration; their digestion is bad, and serous alvine evacuations are frequent; and if the thorax be much deformed, the respiration is impeded, and the circulation is quickened. Still, uncomplicated rickets is not a mortal disease, but as the particular conformation of the chest increases the gravity of all their diseases, they often die from diseases which in other persons might not have proved fatal. It is for this reason that so many rickety patients die in their infancy.

Causes.—Simple uncomplicated rickets is not so rare as many persons imagine, but most frequently it is preceded, or accom-

panied, by other diseases—bronchitis, enteritis, pneumonia, eruptive diseases, rheumatism, and so on. What the immediate cause of the disease may be I cannot say. Many causes have been given, such as change of blood, dentition, and so on; but it is hardly likely that rickets, a disease consisting in so evident a change, and which is always presented in the same way, should be the result of so many different causes. Certain it is that it is seen most frequently in families; for instance, all or nearly all the children of a family may suffer; it may be transmitted to a second generation; if there be the disposition, any of the so called causes may light it up. The disease is not unfrequent in Holland, the north of France, and England. So rife was it in England in the 16th century, that it was called the English disease; it is more frequent in large towns than elsewhere: insufficient or bad food certainly appears to contribute to its development.

Treatment.—In treating this disease, two points must be kept steadily in view; that the treatment must vary with the period of the disease, and that the same means are not applicable to the period of softening, and that when the ossification is taking place. In either case it is empirical; those who attribute it to the want of a calcareous secretion introduce it ready formed into the stomach; these will be found to disturb the stomach, and to do no good as a remedy for the softening: the same may be said of madder and antisyphilitics. Experience has shown that the powers of nature are sufficient, when the strength can be restored; therefore our object should be to endeavour to restore the power of vital organs. If the disease be complicated, the superadded disease should be remedied, bearing in mind that it is essential to keep up as much as possible the strength of the patient; tonics and excitants under all forms are most necessary; they should not be confined to the interior: sulphur or sea-bathing, and dry rubbing, with a dry bracing air, will materially assist internal means. It is essential to avoid milk, fruit, or farinaceous diet; if at the breast, the child must not be too long suckled; more animalized food than milk is required, such as eggs, animal jellies, and so on; if older, roast meat, with wine, answers well. As to the deformities, it is essential again to watch the two periods of the disease.

In the first, so long as the softening is not arrested, walking should be carefully avoided, because the weight of the body will only serve to increase the deformity; motion in the open air is essential, but not upon the legs. In the second period, when the progress of softening is arrested, and the phosphate of lime accumulates in great

quantity in the curvatures, so as to resist the weight of the body, walking may be allowed, but if of an age to take that exercise, none is so beneficial as swimming; and it will be found that the more exercise the child can take, the more promptly are the efforts to restore the bones set in action. With respect to machines, they have been condemned by very able surgeons; but it may be worth while to inquire whether they should be so absolutely proscribed as they advise. When the curvature of a long bone is not great, it may be quickly remedied as the child gains power, but where the tibia forms an angle with the femur, nature cannot remove it; and in such cases mechanical assistance will be found useful, though it will rarely remove a very decided curvature.

BRITTLENESS OR FRAGILITY.

In museums it is not at all uncommon to see bones of unusual lightness and fragility. In some cases so great is their fragility that if we press upon the extremity of a long bone it breaks down under moderate pressure between the fingers; the same thing may happen in the carpal, tarsal, or vertebral bones. The middle, compact portion of long bones, resists such pressure, but if an attempt be made to bend it, it may at once snap. If we examine a long bone in this state, we find the medullary cavity greatly enlarged at the expense of the compact portion; the parietes are extremely thin and brittle. The ribs often fracture with great facility; and when the cranium is similarly affected, the diploë seems to be entirely lost, and the two tables to be reduced to one.

This condition of the osseous system is particularly seen at the two extremities of life—infancy and old age, and it may be so decided that the slightest causes occasion fracture. Goodwin mentions the case of a woman who in the course of two years had no less than twenty-three fractures, without any other apparent predisposing cause than old age.

In this disease tumefaction of the bone is not seen, unless very near joints; and the periosteum is unchanged. Some persons have thought the condition depended on an unwonted activity in the absorbents, by which a certain portion of gelatine was removed; but Troja proved that the brittleness was neither dependent on a superabundance of phosphate of lime, nor a diminution of gelatine. The medulla does not preserve its ordinary consistency, but nothing proves that the change in the bone begins with this change in the medulla. After age, the other probable causes of this disease are cancer, scorbutus, arthritis, and rickets. There are on record many examples of the influence

of cancer in producing this condition. Hamilton mentions the case of a woman with mammary cancer, who fractured her thigh in rising from her chair. Strack observed a similar case in which, after operation, the patient fractured her thigh in bed, while sneezing. Many specimens of brittleness occurring in scorbutic patients are to be found in museums. Brittleness caused by arthritis is peculiar, its predilection for joints, and its complication with taphaceous concretions and ankylosis, are among its characteristics. If we examine the bones of persons who have suffered long from gout, we find them thin, light, and brittle, and false ankylosis usually exists at many joints. Saillant many years ago particularly directed attention to this.

Fracture is very common in rachitic children; fragility, therefore, may be associated with softening. It is probably often connected with organic changes: the celebrated case of the widow Melin is an illustration of that.

SPINA VENTOSA.

Although the disease to which the Arabs, Rhases and Avicenna, attached the term *Rihh Alschukhah*, and which has been rendered *spina ventosa*, be not very rare, yet much difference of opinion exists with regard to its nature. The name was criticised by Severinus, who, believing that the disease was exclusively proper to infants, and that it had always its seat around the joints, had termed it *pædarthroacis*: his disease was no doubt rickets. Boerhaave believed it to be a disease "when the corruption begins in the marrow, and extends from within outwards" Augustin defined it to be an internal inflammation, accompanied by total or partial intumescence of the bone, with severe pain and tumefaction of the soft parts, in which the bone, as well as the soft parts which cover it, constitute a hard, unequal, and sometimes monstrous mass, and in which the primary texture of the bone is completely altered. Voigtel's definition is very similar. Boyer's is simple: he says, it is an affection of cylindrical bones, in which the parietes of the medullary canal undergo a slow distension; sometimes to an enormous extent; at the same time, that they are greatly thinned, and even pierced at many points, as in the accompanying specimen from Liston's excellent treatise on Operative Surgery (fig. 1.). Sir A. Cooper considers *osteo-sarcoma* and *spina ventosa* as varieties of the same affection, to which he applies the term "fungous exostosis" of the medullary membrane. My own impression is, that it is a fungous transformation of the membrane which lines the interior of bones. At the point corresponding to the disease, the medullary

Fig. 1.

canal is enlarged like the globe at the end of the barometer tube, or like fig. 1. Mr. Gulliver has a beautiful specimen of the disease taken from a fox, in which the femurs are distended like bladders, the interior having been filled with a species of sero-sanguinolent matter. In all cases, this kind of fungous growth is seen, and as it can only result from changes brought about in the medullary membrane, I conclude that the canal is distended, as this fungus increases in bulk, the bone gives way before it, as the antrum often does before a fungus developed in that cavity.

The disease has usually been considered as peculiar to long cylindrical bones, such as the femur and tibia, and especially near the knee; the humerus, near the shoulder joint, and the bones of the forearm, near the elbow joint. Now though spina ventosa has a marked predilection for the long bones of the limbs, yet it does not exclusively belong to them; it may attack the maxilla, the ribs, the vertebræ, the cranial bones. It is frequently associated with caries. The soft parts which surround the diseased bone always participate in the disease when complicated with caries; they inflame and ulcerate, become fistulous, and yield a sanious pus. When it is not accompanied with caries, if the tumefaction be considerable, we find the muscles in a remarkable state of expansion and induration. If, for instance, the disease affects the femur, the cruræus, and

the vasti, the triceps and the short head of the biceps, are transformed into a semi-cartilaginous or lardaceous tumor. The semi-tendinosus, membranosus, gracilis, and sartorius, are strongly extended over the sides of the tumor, but preserve their natural structure. The inter-muscular cellular tissue, confounded with the muscles immediately surrounding the femur, is, like them, degenerated. The subcutaneous adipose tissue is changed; the skin is thinned and glistening. If the disease occupy the tibia, the skin adheres to it, and becomes brownish.

True spina ventosa is never congenital; but it attacks persons of all ages: in this respect, Boyer thought it presented a remarkable difference. Up to the age of puberty, it affects the metacarpal, metatarsal, and phalangeal bones. It depends at this time evidently on scrofula, is developed, and subsists long without pain, and frequently terminates in necrosis of the affected part; this is the first kind. The second, more rare, but more dangerous, especially affects adults, is generally developed near the extremities of long bones, the humerus, the femur, the bones of the forearm, those of the leg: it is often preceded by severe pain—often long continued, which the patient compares to a thorn piercing the marrow.

All that we know of the pathogenesis of spina ventosa is, that a morbid principle, syphilitic or cancerous it may be, impresses upon nutrition a vicious direction; that the osseous cells, as well as the canal, enlarge, so as to cause the bone to resemble a sponge. Why, in the different cases, is the pain so different; in one case so severe; in another so trifling? Because, I apprehend, the one affects more decidedly the centre of a canal than the other; in the former, the distention of the medullary canal is rapid, and the pain severe; physiologists are generally agreed, that the medullary apparatus is the most sensitive part of the bony tissue, and this is directly implicated. In the other, the bony tissue itself is more particularly affected, and the pain is less. But whichever part is affected, sooner or later, great disturbance is set up, low fever is developed, and the strength is exhausted.

Symptoms.—The first symptom, usually observed in spina ventosa, is a deep-seated severe pain; sometimes continuous; sometimes in paroxysms, which the patients liken to a thorn forced into the medulla. In other cases, though still deep-seated, it is so obtuse that the patient scarcely notices it; but whatever its character, it is often for a long time the only symptom by which the disease is manifested. Sooner or later tumefaction comes on, and the bone may acquire an enormous bulk.

The dilatation to which the bone is subject is peculiar, though very near the joint the articulating surfaces do not participate in it; and the tumefaction is so abruptly developed, that a little way above and below the point the shaft of the bone is natural: in fact, it seems as if distended by insuflation. At an early period of its development the bone is as uniform and as hard as the healthy portion, and the disease may at this period be suspended; but, in most cases, the consistency of the tumefied bone is changed, and by the touch we can distinguish softened points which give a sensation of fluctuation. The skin may inflame and ulcerate at these points, a more or less fetid sanies is discharged, and the openings are soon filled with fungous excrescences, which are usually painful, and bleed from slight causes. If we pass a probe through one of these openings, it gets at once to the centre of the bone, having with very little pressure got through the fungous mass.

Diagnosis.—The diagnosis of this disease is usually not difficult. The kind of pain which accompanies it enables us to distinguish it from exostosis: if, however, it be indolent, much difficulty will be experienced. Osteo-sarcoma bears some resemblance to it in form and seat; but the tumefaction of the former is more unequal and lobular, and its consistence, though firm, does not equal the hardness of bone. Again, the pain of osteo-sarcoma is lancinating, like cancer, and, in its progress, it is more rapid and acute than spina ventosa; add to which, the constitution gives way sooner, and assumes a cancerous diathesis. Spina ventosa is always a grave disease, because in the greater number of cases so much local and general disturbance is excited, that the death of the patient is the consequence.

Treatment.—As to treatment I have little to say: we have very little power of controlling the disease. All that we can do is to lessen pain by leeching, by fomentation, and by narcotics, externally and internally; but these means rarely stem its progress, it goes on until the existence of the patient is threatened. It is recommended that we should then cut down upon the part, open the cavity of the dilated bone, and destroy with the actual cautery the fungous mass it contains. Such an operation I do not advise you to undertake, because, if the patient get through the primary suffering, he may sink under the long and abundant suppuration necessary for removing the bone, which has been thus deprived of life; and there is no security that the disease will not be reproduced; and at last, supposing all these dangers to be avoided, it is evident that the patient will have a deformed

limb, which may be incapable of serving him. From all this it seems to me to result, that in all these cases amputation of the part is the only remedy which promises success.

OSTEO-SARCOMA.

Osteo-sarcoma, says Boyer, is an alteration of the osseous tissue, in which, after having experienced distension, it degenerates, and is transformed into a substance very variable in character, but more or less analogous to that of cancer of the soft parts, whilst the local and general symptoms present a still more striking resemblance with those of that disease. Sir A. Cooper termed it fungous exostosis of the medullary membrane, believing it to be primarily seated in that membrane. I have two objections to make to Boyer's definition: the increase of bulk does not constantly accompany nor precede this disease; the disease is not always and essentially cancerous.

All bones appear to be subject to this disease, yet we more frequently see it in the bones of the face, those of the base of the cranium, the long bones of the extremities, but above all the ossa innominata, which of all bones are the most frequently attacked.

There are two species of osteo-sarcoma: in the first the disease extends from the soft parts to the bone; this is commonly seen in the face, from fungous disease in the antrum; in the second the bone is the primary seat of the disease, and the soft parts suffer secondarily. When the disease has made much progress, the osseous tissue has more or less completely disappeared; in its stead we find a homogeneous, greyish, or yellowish, lardaceous substance, a section of which resembles the hard-boiled white of egg, or old cheese; its consistency, however, is very variable, soft in one part, hard in another, from that of cartilage to that of pap or jelly. The surrounding soft parts which have shared in the affection participate in the same alteration; muscles, tendons, ligaments, vessels, all are confounded in the same mass, all have suffered the same degeneration.

Causes.—Syphilis, scrofula, rheumatism, and even external violence, have been pointed out as causes of osteo-sarcoma. Now although these affections may complicate the disease, it is not proved that they can produce it. External violence, a fall or a blow, seems in many cases to be the exciting cause of its development. It seems to be a matter of doubt whether osteo-sarcoma ordinarily commences either in the medullary or periosteal membrane, or whether it arises in the bony tissue itself: cases may be adduced to favour one and the other of these opinions. To the

latter opinion Becker and Lobstein incline. They have seen osteo-sarcoma, by continuity of tissue, communicate the same change to the periosteum of an adjoining bone, without its undergoing any change. In a case of osteo-sarcoma of the tibia, the soft parts between the two bones of the leg were disorganised, as well as the periosteum of the fibula, whose substance, instead of being softened, was harder than natural.

Symptoms.—Very deep-seated continued obtuse pain, gradually becoming more acute and more severe, sometimes indicates the existence of the disease long before any increased bulk is apparent. In a short time these pains acquire characters which mark cancer, become, with irregular intervals, more intense, and as suddenly lacerating, as if produced by an electric shock. The constitution suffers, emaciation comes on, with a yellowish or leaden tint of the surface; the pulse is quick and small, with fever. The part becomes tumid; the tumor is immovable, adherent to the bone; compression produces no decrease in bulk, neither does it excite pain; the tumor is almost always irregular and lobular. At first the tissues move freely on its surface; but as it increases, they become adherent to and soon identified with it. As it approaches the surface the symptoms become more marked, the skin gives way, fungi sprout out, which ultimately form the fundus of a carcinomatous ulcer. The pain and general disturbance commonly keep pace with the tumefaction and destruction of adjoining parts, until at last even narcotics have little power to calm them; the patient gets no sleep, the appetite is lost, diarrhoea comes on, emaciation increases, and death follows. It is singular that the progress of osteo-sarcoma, or cancer of bones, is generally much more rapid, much more difficult to retard, than cancer of soft parts.

Diagnosis.—Cases have occurred where, from the vicinity of arteries, the disease has been mistaken for aneurism; in others, where a sensation of fluctuation has caused them to be mistaken for abscess; but a knowledge of all the circumstances of the case will usually prevent such mistakes.

I recollect a case where a young man, in apparently good health, fractured the inferior extremity of the femur: it was treated in the ordinary way. When the apparatus was removed, and he rested on the limb, he complained of pain at the injured point: it was soon evident that there was no union; the knee and the lower part of the thigh were largely tumefied, and the swelling gradually extended to the groin, and acquired an enormous bulk: it was hard, and not very sensible to

the touch; the subcutaneous veins were dilated; motion at the knee remained; but he could not walk without a stick, and then with difficulty: the tumor increased, the pain and sleeplessness kept pace with it. The limb was amputated at the upper fourth, the parts were brought together, and all pain immediately ceased. When the dressings were removed, union had partially taken place, and in about six weeks the whole was cicatrized. Fourteen years afterwards there was no return of the disease. The tumor weighed thirteen pounds; it was an enormous sac, with thick, sarcomatous, coriaceous parietes, with here and there osseous particles; the fluid it contained weighed five pounds and a half, was glutinous, like thick syrup, without smell or taste; in fact, bearing a strong resemblance to the *tissu colloide* of Laennec.

Prognosis.—The prognosis in this disease is always unfavourable. The disease will be fatal to the part itself, if not to life; and as the disease seems to have the fatal prerogative of rapidly changing the constitution, so as to render probable the reproduction of the disease even when it is removed, we cannot too soon take away the tissue it may have attacked, for each day's delay only increases the risk.

Treatment.—How can an organ, which has undergone an osteo-sarcomatous disorganization, be restored to its natural condition? No local means would, I apprehend, accomplish this object, because the source of the disease is not there, and the whole of the economy, it is probable, participates in it. If any good can be done, it must be by modifying the entire system. Some persons believe this possible; in the present state of our knowledge I do not. It has been suggested, that small doses of the oxymuriate of mercury might be found useful, either in or with decoction of sarsaparilla; but this will not cure osteo-sarcoma. Local means recommended consist in the application of leeches; if there be pain, of blisters, to be kept open by mercurial and savine ointment. The time, however, spent in using these means, often gives much reason for regret, because the disease has been advancing, and greater mutilation and chance of reproduction are the consequence. Sir A. Cooper and Lucas have tied arteries going to the part, but without success.

If a limb be affected, resection or amputation must be performed, and if the latter, the operation should have a joint between it and the disease. If either of the maxillæ suffers, it should be excised, as far as possible from the diseased point; in spite even of this precaution reproduction is frequent. But it not unfrequently happens that we are prevented from amputating

by finding lymphatic ganglia beyond the point diseased, resembling cancer, or fungus hæmatodes; or similar tumors may be detected in other parts of the body. In that case, and even when the cranium or the ossa innominata suffer, the disease is incurable, and we can only hope to prolong life by regimen, by narcotics, and other similar means.

DISEASES OF THE ARTICULATING SYSTEM.

The joints are subject to violence, which may produce a temporary or permanent change in their articular surfaces; the first are termed *sprains* or *strains*, the second *luxation* or *dislocation*.

The effect of violence, insufficient to produce luxation, may occasion distension or destruction of the ligamentary tissues, so as to constitute a sprain.

Those joints whose motion is very limited, and whose dislocation is unfrequent, are often the seat of distension or rupture of those tissues; but where the latitude of motion is considerable, we always find a certain number of muscles, capable of assisting the ligaments in resisting violence. Thus, the frequency of luxations bears a direct relation to the extent and variety of motion of a joint; the opposite state is the condition which favours sprains. It is absolutely true that the ginglymoidal articulations are more frequently affected by sprains than the orbicular. Some moderns go so far as to say that luxation at the wrist cannot happen, and that luxation of the foot cannot happen without fracture of the leg; but in both of these articulations sprains are frequent. Sprains differ much, according to the condition of the patient, the importance of the joint which has been injured, and the violence and the extent of the disorder which follows. If, in a person who has no scrofulous tendency, the ligaments be merely dragged, we may say the sprain is slight; it is more serious if the fibres have been ruptured; still more so when tendons, nerves, or important vessels, have suffered.

Symptoms.—The immediate consequences of a sprain are those which result from injury of the ligaments and the cellular tissue; they consist in an acute pain at the moment of the accident, which rapidly increases, and is soon followed by considerable tumefaction. The tumefied parts are at first elastic, and not very sensible to the touch, the skin is natural, and the pain is only increased by motion; but soon the swelling becomes renitent, and the pain more acute, so severe indeed that in many cases the slightest motion is insupportable, and certain changes in the dimensions of the limb are apparent, which seem to demonstrate that inflammatory action is excited, even in the joint itself; the thigh becomes

longer, the trochanter more prominent, in consequence of violence which has produced a sprain at the hip joint: this would indicate tumefaction of the head of the femur, the cotyloid cavity, or their cartilaginous surfaces. When things come to this point, it is rare that fever proportioned to the intensity of the irritation which has occasioned it does not supervene; this reaction is seldom violent, but it may be prolonged. In that case, and particularly if improper motion has been permitted, the tumefaction subsists, the skin reddens, and becomes hot, the pain is pulsative, rigors are experienced, and at one or many points around the joint fluctuation is manifested, and spontaneous openings may follow, through which pus, without or with synovia, may be discharged; colliquative symptoms may come on, and the patient may sink exhausted with pain and profuse suppuration: or the suppuration may lessen, the openings become fistulous, exfoliations may take place, the soft parts gradually lessen: the pain abates, ankylosis destroys motion, and terminates the disease. But a sprain is rarely attended by such serious consequences in ordinary cases: some days after the development of tumefaction the pain diminishes, the ecchymosis is dissipated, the swelling lessens, and motion is gradually restored. All these things render it impossible to deny that a more or less intense articular inflammation may and often does exist. With the exception of the synovial membrane, the articular apparatus is not very sensible to irritation determined by mechanical causes, and this is no doubt the reason why the consequences of sprain are usually not serious; why it so rarely happens that luxations are followed by dangerous inflammation, though the disturbance of parts may have been great. But the obscurity of the vital functions of those organs renders the work of resolution difficult: that is no doubt the reason why articular pain, once developed, is often long continued, and with great difficulty dissipated. It follows from what has been said, that we should anxiously endeavour to dissipate the ordinary effects of sprains, and this more particularly when, from the scrofulous diathesis or other circumstances, we have reason to apprehend a tendency to white swelling.

Treatment.—It must be evident to you that, in treating this accident, we must seek to prevent or to subdue inflammatory action at the injured joint. The ligaments are often destroyed; we must endeavour to bring about union, and we must seek to restore freedom of action at the joint. Cold water is much employed for the purpose of preventing the development of inflammatory action; it should be continued for many hours, otherwise, instead of

preventing the afflux of blood to the part, we favour it, by the reaction which follows. Some persons strongly recommend ice-water, but I have on a former occasion stated my objections to it; still I do not deny that it is one of the most powerful sedative agents we possess, and that I have seen almost miraculous effects to follow its judicious employment; but if the joint be deep-seated, or the injury very violent, it will be rather injurious than useful. My objection to it is, that it is rarely properly employed. It is applied at a very low temperature; it is renewed perhaps in an hour; by that time the temperature has been raised probably twenty degrees, and a corresponding reaction has come on; so from hour to hour there is alternate contraction and relaxation of the blood-vessels, and detrimental consequences follow; therefore it is that, if cold be used, I prefer it in the form of irrigation; but then it must be closely watched, or gangrene may follow. Local and general bleeding are commonly resorted to, and often with the best effects: if there be severe pain and sense of distension, we maintain perfect quiet, raise the limb so as to prevent stasis at the part. When by the use of these means, associated with emollients or narcotics, the irritation is calmed, pain and tumefaction diminished, we may proceed to use resolvent agents. During the treatment great care must be taken to avoid motion at the part, because it will prolong the irritation, and prevent union of soft parts. In the present day it is becoming the fashion, and a good plan it is, to preserve immobility by means of starch or white of egg bandage, or moulds of plaster; but these apparatus should not be applied until the immediate inflammatory action has subsided. Velpeau is an advocate for immediate compression in any case, to prevent the development of inflammatory action. I think more experience is necessary to fix the value of this agent. If the ankle be the joint affected, the patient should not attempt to walk until the pain and irritation are entirely dissipated, and then it is good to have the part well rolled, to assist the ligaments. Sometimes, after this kind of injury, the ligaments remain tense and rigid, so as to interfere with ordinary motion: in those cases douches and frictions are the best remedies. In all these cases the ability of the practitioner consists in distinguishing the moment when each remedy should be employed; when the inflammatory condition has sufficiently abated to allow of the beneficial employment of stimulants, which become necessary to remove that state of atony which almost always succeeds to this kind of injury.

PHYSIOLOGICAL OBSERVATIONS
ON
EYES OPERATED UPON FOR THE
CURE OF STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following physiological observations appear to you of sufficient interest for your readers, an early insertion in your valuable journal will greatly oblige, sir,

Your obedient servant,
AUG. FRANZ, M.D.

19, Golden Square, June 16th, 1840.

The following experiments and observations were made upon the seven cases of strabismus cured by the new operation, and reported in the *MEDICAL GAZETTE* of April 17th, May 23d, and June 12th, and embrace several interesting physiological inquiries relating to the functions of the retina.

In these experiments I assume the right eye to be operated upon for an inversion, and to be the subject of examination.

Experiment 1.—The person being placed with his back towards the light, closes his left eye, and looks with the right straight and horizontally before him, without swerving either to the right or left. If now a somewhat light object, *e. g.* an ivory paper-knife be held at some distance, exactly opposite the pupil of this eye, it will be more distinctly seen, when in this position, than when held somewhat to the left side, but it will be still more distinctly seen if placed somewhat to the right; there is moreover on this side a particular spot where the object is most distinctly seen, corresponding to that point of the retina on which the images of objects were formerly projected while the squinting yet existed. This point of the retina is of course the point of the most acute sensation, and all points situated around this diminish in sensibility in an exact ratio to their distance from it; and for this reason an object held exactly opposite or to the left side of the eye, and projecting its image on these less sensitive points of the retina, is less distinctly seen. Thence it follows that the point of most acute sensation in the retina of an eye, affected with inversion, is not situated in the centre of the posterior

hemisphere, as in a perfect eye, and that the axis of vision, which in a perfect eye corresponds with the axis of the eyeball, differs materially from it in a squinting eye, inasmuch as it has the direction of a line drawn from this abnormal point of most acute sensation through the centre of the pupil, and thus deviates from the axis of the ball; if the right eye be affected with inversion towards the right, if the left towards the left. The degree to which this irregularity may prevail in a squinting eye varies according to the extent of squinting; to ascertain which with precision, I have contrived an instrument by which I am enabled to determine both the degree of irregularity and the extent to which the squinting previously existed according to a mathematical scale, and which therefore may be termed *Strabismometer*.

This instrument is very simple both in its construction and in its application. It consists of a semidisk, 15 inches in diameter, equally divided by a mesial line, each half being again subdivided into 90°, as radii diverging from the centre of the semidisk to the periphery. A tube, 13 inches in length and half an inch in width, running from the periphery towards the centre, is fixed on the mesial line. The person who is the subject of experiment places his eyes on a level with the centre of the disk, so that in looking straight through this tube the centre of the pupil or the axis of the eyeball is directed parallel with the mesial line of the disk, whilst the experimenter can observe through the opposite extremity of the tube whether the eye is kept steadily in this position. A second portion of the apparatus consists of a short tube, 3 inches in length, the one extremity half an inch, and the other one inch in width, and moveable upon the semidisk, to concentrate towards the pupil the rays of light reflected from a light object, painted on a darkened screen. This screen, being situated behind the short tube, forms with the tube one piece, as it is made to slide in a groove, running towards the centre of it in order to approximate the object to be seen, or to remove it from the eye, according as this may be far or near-sighted. This second portion of the instrument is now to be moved upon the semidisk, according to the radii marked on it, until it arrives at that degree where the object painted on the screen is most distinctly

seen by the eye looking through the fixed tube. The number of degrees between the mesial line and that radius or degree where the object is most distinctly seen, determines the difference between the axis of vision and that of the eyeball, the distance of the abnormal point of the most acute sensation of the retina from the centre of the posterior hemisphere of the eye, and also the extent of the former inversion. In conducting this experiment the head of the person is enveloped in a dark curtain attached to the semidisk, to exclude those rays of light which might interfere with the progress of the experiment.

The above-mentioned seven cases were thus examined with the *Strabismometer* in the first week of the operation, when the functions of the retina are yet exactly the same as during the existence of squinting, for at a later period the retina accommodates itself in its functions to the new position in which the eye is placed by the operation. The number in each of these cases was found as follows:

1st Case,	36 degrees.
2d ...	28
3d ...	30
4th ...	25
5th ...	32
6th ...	26
7th ...	28

By the experiment just explained I have convinced myself that the abnormal point of most acute sensation in a squinting eye has nearly the same power of sensation as this point in its normal situation in the sound eye. The weakness of sight which is observed when, on closing the sound eye, the affected one is brought by an effort of will to bear upon an object, appears therefore to me to be dependent, in a great measure, on the circumstance only, that the image of the object which is seen, while the eye remains in this unusual position, is projected on a point of the retina situated at some distance from the abnormal point of most acute sensation, viz. on a point less sensitive. I moreover found that in the same ratio in which the point in the centre of the posterior hemisphere of the squinting eye acquires a greater sensibility, after having been placed by the operation in a position favourable for this development, the former, i.e., the abnormal point, decreases in acuteness of sensation.

When now the point of most acute sensation is by constant and free use of the eye in a condition favourable for which the operation has placed it, fully established it in its proper place, the sight is, in this eye, as perfect as in the other one; the axis of vision is one and the same with the axis of the eyeballs, and the visual functions are then in a perfect condition. But although the organ of vision is by the new operation at once placed in a proper position, the visual functions and the power of sight acquire but slowly perfection and acuteness. In my first two cases, which I operated upon on the 10th of April, the point in the centre of the posterior hemisphere has by this time gained in its sensibility a great ascendancy over the former abnormal point, which is, however, not yet entirely lost, as I have ascertained by the Strabismometer, an object being now seen by it with a greater distinctness, when placed in the proper, than in the former abnormal direction of vision. The one person who, on closing the sound eye, could, previous to the operation, distinguish large objects only, and was totally unable to read even the largest print, can now read a print of moderate size; and the other, who also could not read a very large print, now reads even that of a small size with facility.

Experiment 2.—For this experiment the eye must be examined a few days after the operation, and the person is directed to look with both eyes steadily at an object. If now the object is held to the right side of the eyes, it is seen single by all persons operated upon. If held exactly opposite to the eyes it is seen double by those only who have suffered an inveterate inversion to a great extent, but if the object is held to the left side it is seen double by all who have undergone the operation. The image, appearing at the right, is moreover the most distinct, the effigies at the left is less distinct; and if the left eye is closed, this latter is only seen by the right eye or the one operated upon. This double vision, and the difference in distinctness of the two images, may be explained in the following manner, as illustrated by the diagram subjoined. The image of an object (*d*) is depicted in the left eye (*L*), on the most acute sensation (*a*); the mind therefore perceives the impression, made by the object on the retina, in this eye distinctly; in the

right eye (*R*) the image of the object is projected on the point (*a'*), which is a less sensitive point of the retina, because situated at some distance from the abnormal point of most acute sensation (*b*), and therefore the mind perceives the impression of the object in this eye less distinctly. Farther, the image of the object (*d*) is projected on the centre of the posterior hemisphere of both eyes, in (*L*) on (*a*) and in (*R*) on (*a'*). In the left eye the point (*a*) is the point of most acute sensation, and also that point where the optic axis intersects the retina; the object is therefore seen in the direction of the optic axis, viz. in the proper place (*d*). In the right eye the point (*a'*), on which the image falls, is situated at some distance to the right of the abnormal point of most acute sensation (*b*). But as the mind is conscious that the point of most acute sensation in a perfect eye is always situated in the centre of the posterior hemisphere, the impression which is made by the object in (*a'*) suggests a sensation to the mind as if the image were at the same distance to the right of the centre (*a'*), as it is in reality situated to the right of the abnormal point of the most acute sensation (*b*); the mind therefore perceives the image in (*c*), and the object is consequently seen, not in the optic axis, but in a direct line drawn from the point (*c*), through the centre of the pupil, which places the effigies of the object in a different spot, that is, to the left of the real object, in (*e*). The distance at which the effigies is placed to the side of the real object is dependent on the distance at which the abnormal point of most acute sensation (*b*) is situated away from the centre of the posterior hemisphere (*a'*).

Hence it is evident that the effect of double vision, which is observed after the operation for the cure of stra-

bismus, is produced by the two images being differently situated with respect to the two points of most acute sensation of the retinae, although similarly situated with respect to the two centres of the posterior hemisphere of the eyes; that the difference in distinctness with which the two objects are seen by either eye is caused by those points of the retinae on which the images fall being different in their degree of sensibility: the impression made by the object seen produces consequently a sensation in the retina and a perception in the mind in the first case according to the situation of the image, and in the second according to the degree of sensibility; and lastly that, if the left or sound eye is closed, the distinct or real object must disappear, and *vice versa*.

[To be continued.]

OPERATION FOR CATARACT.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following case worthy a corner in the MEDICAL GAZETTE, I shall feel obliged by your inserting it.—I am, sir,

Your obedient servant,

G. HARVEY,
Surgeon.

Carth Hedingham, Essex,
June 7, 1840.

Daniel Maymond, aged 59, an agricultural labourer, of good health and very spare habit of body, has been affected with cataract of the right eye rather more than a year. The iris contracts and dilates freely and regularly; and although he cannot distinguish objects, is sensible to light. The sight of the left eye has lately become very dull and imperfect, so much so as to render him incapable of following his usual occupation; but no opacity is at present visible.

Under these circumstances I resolved to operate upon the right eye, after the manner proposed by Dr. King (vide MEDICAL GAZETTE, July 28, 1838, page 701; and Sept. 22, page 1009). Having previously given him a few doses of aperient medicine, and desired him to abstain from beer and other stimulants, I dilated the pupil by applying a little extract of belladonna between the eye-

lids by means of a camel's hair pencil; and this day, May 30, 1840, punctured the sclerotica with the curved needle of Scarpa, at rather more than the eighth of an inch from the cornea, near the inferior extremity of its vertical diameter. The needle passed in without the slightest difficulty; and when it appeared about the centre of the pupil, I gave it a rotatory motion, with the view of lacerating the capsule; but the cataract proving a firm one, the curved point of the instrument entered its substance, from which I was unable to extricate it. I found I could easily draw the lens down, or move it in any direction, so firmly was it fixed on the point of the needle. I therefore slowly drew it down to the bottom of the posterior chamber, and on withdrawing the needle the lens remained in its new situation, leaving the pupil perfectly clear and regular. The patient exclaimed that he could see the window, and that he had suffered little or no pain. The eye was instantly closed, and covered lightly with a thin handkerchief, the room darkened, the patient ordered to remain in bed, take nothing but gruel or tea, and on no account to admit any light to the eye.

After describing the manner of introducing the instrument and lacerating the anterior layer of the capsule, Dr. King proceeds to say, "In general the only remaining part of the operation may be said to be the withdrawal of the needle, which I effect by gently drawing it, with some slight rotations, back through the same path by which it was made to travel on to the pupil; for, almost always, the lens immediately follows its point, in a manner which I cannot but compare to that in which a piece of steel obeys the magnet, and lodges in the inferior external and anterior part of the vitreous humour, close to the little puncture made in the sclerotic, and just behind the posterior chamber of the eye."

I am inclined to believe that, in this mode of operating (which I greatly prefer to any other), the descension of the lens is always caused by the needle puncturing and drawing it down, and not by forming a passage through which, as the Doctor afterwards observes, "it falls almost by its own weight."

I hope Dr. King will excuse this remark, and if I am wrong in my conjec-

ture, be kind enough to set me right. I now proceed with my case*.

May 31st.—On lifting the shade for a moment the patient said he could distinguish my features. Pupil clear but contracted; scarcely any inflammation of the conjunctiva; has suffered no pain.

The handkerchief to be kept constantly wet with a cold lotion. Calomel, gr. iij. statim. Magnes. Sulph. ʒij. after two hours, in a cupful of gruel. The room to be kept darkened. Diet, tea and gruel.

June 1st.—No inflammation except two or three enlarged vessels near the puncture; suffered a little pain last night, which was relieved by a discharge of fluid from between the eyelids; pupil still contracted: bowels moved four or five times.

Applicetur Ext. Belladonnæ palpebris.

2d.—Eye looks very well; pupil dilated; says objects appear very white and brilliant.

On reflection I think the belladonna ought not to have been applied yesterday. The contraction of the pupil was nature's own curtain, partially closed for the express purpose of preventing too much light being admitted to the retina. It is very different in iritis, where belladonna is applied to enlarge the pupil, and prevent improper adhesions forming between the contracted iris and the capsule of the crystalline; but after the operation for cataract, the anterior portion of the capsule having been removed, there is nothing for the iris to adhere to; therefore the belladonna is not only useless, but likely to do mischief.

6th.—The eye is to all appearance perfectly well, but I have desired him to wear the shade sometime longer, to avoid stimulating drink or food, and to let me see him after a few days.

MALFORMATION OF ŒSOPHAGUS.

To the Editor of the Medical Gazette.

SIR,

I AM induced to transmit the accompanying case for insertion in your excellent journal, in consequence of its extreme rarity, and under the conviction

it may prove interesting to your numerous readers, should you deem it worthy of publication.

In the month of August 1839, Mrs. P. the mother of four healthy children, was delivered of her fifth, a fine, well formed infant, after a perfectly natural labour of a few hours' duration. When in due time the infant was put to the breast, it was observed that the nipple was scarcely retained in the mouth beyond a minute, when the little creature became apparently convulsive, and almost instantly rejected the nutriment which it had taken. On my subsequent visit I was made acquainted with the above particulars, when I felt disposed to assent to the opinion expressed by the mother, that flatulency might be the cause of the symptoms, and accordingly prescribed a simple carminative. This was almost immediately rejected, as the milk had been, the infant notwithstanding manifesting the greatest eagerness to supply its instinctive wants. Inferring the existence of some obstruction in, or malformation of the Œsophagus, I attempted to pass a common bougie, which however proceeded only for a very short distance, and then became curved upon itself, apparently not having arrived further than the commencement of the Œsophagus. Matters went on in this way for six days, no other evacuation having taken place from the bowels than the meconium, and the infant continuing to apply its mouth to the breast with no other result than that of a slight convulsive paroxysm so soon as the pharynx became filled, and the immediate repulsion of its contents. Early on the morning of the seventh day it died, when a post-mortem examination disclosed the existence of little more than the membranous pouch of the pharynx, which terminated in a cul-de-sac a little below the cricoid cartilage, no trace of the Œsophagus being visible beyond this part. The stomach presented no deviation from its ordinary form and dimensions, with the exception of its cardiac orifice, where there existed a slight bulging at the part corresponding with the termination of the gullet, and which was firmly united to the diaphragm. Further, a probe, introduced at this aperture, could not be made to pass into the stomach. Between this point and the sternum not the slightest trace of Œsophagus, or any bond of connexion whatever with the pharyngeal

* From this paragraph we perceive that our correspondent is not aware of Dr. King's disease.—ED. GAZ.

portion, existed. The stomach contained nothing but air and a little mucus; the other viscera appeared perfectly normal.

In juxtaposition with the foregoing case of defective conformation, I may mention an instance lately communicated to me by Mr. Heath, a highly respectable practitioner of this town. In this, the infant, which was of ordinary size, presented symptoms very analogous to those above described, and survived until the eighth day. On inspection after death, the duodenum was found obliterated to the extent of an inch or more, no further malformation having been observed.

I will close this communication with an extract from Meckel's Manual of General, Descriptive, and Pathological Anatomy, vol. iii. page 375, to which I was induced to refer, thinking it not improbable that I might therein meet with examples corresponding with that first described. In place of this, however, I find only the following remarks bearing upon the point in question:—"It sometimes, though rarely happens, that the pharynx and œsophagus terminate in a cul-de-sac, the one at its lower part, the other superiorly, in consequence of a primitive defect of conformation. In the first case the cavity of the mouth at least is almost always developed in an imperfect manner, and the lower jaw is either entirely, or in a great measure wanting. The same thing occurs when the pharynx opens into the neck by too narrow an orifice." Hoping that I shall not be considered as trespassing too far upon your columns, by requesting the insertion of the preceding,

I remain, sir,

Your very obedient servant,

THOMAS MELLOR.

Chorlton-upon-Medlock, near Manchester,
June 17th, 1840.

SINGULAR CASE OF IMPERFORATE VAGINA,

AND VICARIOUS MENSTRUATION FROM THE
BLADDER (?) WITH UNINTERRUPTED
REGULARITY FOR 27 YEARS.

To the Editor of the Medical Gazette.

SIR,

I BEG to send you the inclosed, if you think it will interest your numerous readers.—I have the honour to be, sir,

Your obedient servant,

RALPH MAPLETON.

St. Thomas's Hospital,
June 5, 1840.

Ellen S—n, æt. 40, and married ten years, presented herself as an out-patient at St. Thomas's Hospital, under the care of Dr. Cape, on Friday, April 24, 1840. She complained of a hard and painful tumor, about the size of a melon, situated in the uterine region, which could be felt above the pubis. She had no discharge, and her general health was not impaired. On examination per vaginam being attempted, no vagina could be found. She was then requested to retire to one of the female wards, where she submitted to an ocular examination; the labia, nymphæ, clitoris, and all the external organs of generation, were quite normal, with the exception of the vagina, which was totally imperforate, not amounting even to a cul-de-sac; being perfectly flat and unyielding, with a granulated red surface. On examining per anum, the tumor could be very distinctly felt, painful on pressure, and apparently of a subcartilaginous character. She has menstruated regularly ever since she was thirteen, the period lasting four days, and of the usual quantity. She was ordered

Potassi Iodidi, gr. v.; Tinct. Hyoscyami, ʒss.; Mist. Camphoræ, ʒiss. ter die.

She continued this medicine for a fortnight with considerable benefit; for though the tumor did not diminish in size it was much less painful; but as she complained of pain in the head, and giddiness, the hyoscyamus was omitted, and tinct. lavend. co. ʒss. substituted. This she continued for a week, when the headache and giddiness disappeared, but the tumor was more painful: she was therefore ordered the original medicine.

On Friday, the 15th May, the catamenia being present, it was thought a good opportunity for ascertaining whence the discharge flowed, as, on the previous examination, the only aperture visible was the orifice of the urethra; when it was seen distinctly exuding guttatim from the meatus urinarius.

Since then she has continued the medicine with much benefit; suffering much less from pain and pressure, and being able to take more active exercise.

STATISTICS OF SMALL-POX.

To the Editor of the Medical Gazette.

SIR,

A LETTER recently received from Dr. Heim, of Ludwigsburg, has enabled me to fill up some deficiencies in the very valuable table to be found at p. 406 of

his great work on Small-pox, and thus to draw a comparison between the results of his experience in the kingdom of Wirtemberg and that of the Small-pox Hospital of London. Some of your readers may, perhaps, take an interest in statistical notices of this kind, and with this view I have drawn up the following tables, to which I venture to append a few observations.

Statistical Notices of Small-Pox, as it appeared in the Kingdom of Wirtemberg, 1831 to 1836.

Period.	Total Cases of Small-Pox.			Normal Small-Pox.			Abnormal Small-Pox.		
	Numbers attacked.	Deaths.	Rate of Mortality.	Numbers attacked.	Deaths.	Rate of Mortality.	Numbers attacked.	Deaths.	Rate of Mortality.
Five Years. <i>July 1831 to June 1836.</i>									
Unvaccinated, but with preceding small-pox ..	57	16	28	39	14	36	18	2	11
Vaccinated	565	107	19	528	92	18	37	15	40
Total unvaccinated	622	123	20	567	106	19	55	17	31
Vaccinated	1055	75	7	186	64	34	869	11	1
Total.....	1677	208	16	753	170	22	924	38	4

Statistical Notices of Small-Pox, as it appeared in the Small-Pox Hospital, London, 1835 to 1839.

Period.	Total Cases of Small-Pox.			Normal Small-Pox.			Abnormal Small-Pox.		
	Numbers admitted.	Deaths.	Rate of Mortality.	Numbers admitted.	Deaths.	Rate of Mortality.	Numbers admitted.	Deaths.	Rate of Mortality.
Five Years. <i>January 1, 1835, to December 31, 1839.</i>									
Unvaccinated, but with preceding small pox ..	5	2	0	4	2	0	1	0	0
Unvaccinated.....	1041	377	36	971	375	39	70	2	3
Total unvaccinated	1046	379	36	975	377	39	71	2	3
Vaccinated	748	53	7	270	46	17	478	7	1½
Total.....	1794	432	24	1245	423	34	549	9	2

1. The first reflection which will naturally occur to any one on perusing the foregoing tables is, that, in Germany,

second attacks of small-pox are ten times more frequent than in London. I am wholly unable to account for this

discrepancy. The extreme severity of these cases in Germany (which proved fatal at the rate of 28 per cent.) induces me to suspect that the fact of prior small-pox was there assumed on very imperfect evidence.

2. The second circumstance which will attract attention is the marked disproportion between the numbers of the vaccinated and unvaccinated (having small-pox) in the two countries. Out of 1600 cases in Germany, 1000 were vaccinated, and 600 unvaccinated. Again, in London, out of 1700 attacked with small-pox, 1000 were *unvaccinated*, and only 700 vaccinated. This shews how much more extensively vaccination is practised in Germany than in England.

3. It will be observed, thirdly, that the rate of mortality among the unprotected was much higher in London than in Wirtemberg. The rate of mortality is seen to have been 36 per cent. in London, and only 20 per cent. in Germany. This discrepancy may fairly be attributed to the different circumstances under which the cases occurred. The German cases happened over a vast extent of country, and were for the most part treated in private houses. The London cases were engendered in a comparatively confined locality, and treated within the walls of an hospital.

4. The fourth circumstance which will probably excite attention, will be the singular *uniformity* in the mortality of small-pox, as it occurs in both countries, after vaccination. It will be seen, that in Wirtemberg, between 1831 and 1836, out of 1055 cases, 75 proved fatal; being at the rate of 7 per cent. Again, in the Small-pox Hospital of London, between 1835 and 1839, out of 748 cases, 53 proved fatal; being also at the exact same rate of 7 per cent. This can hardly be an accidental occurrence: the numbers are too large to admit of such a supposition. There must, I apprehend, be some law of the animal economy influencing this very curious but most interesting result.

I have the honour to be, sir,

Your obedient servant,

GEO. GREGORY, M.D.

31, Weymouth Street,
June 16, 1840.

MR. NASMYTH AND MR. OWEN ON THE TEETH.

[In consequence of having received the subjoined communication from Mr. Nasmyth, we have thought it better to postpone the reply of our reviewer till next week.—ED. GAZ.]

To the Editor of the Medical Gazette.

SIR,

I HAD determined to continue to practise forbearance, and to take no part whatever in the discussion respecting Mr. Owen's plagiarisms from my writings on the teeth, which was commenced by your reviewer, in the number of the MEDICAL GAZETTE for June 5th last; but as Mr. Owen's letter, in reply, contains personal accusations against me, which I alone am able to meet, I can, of course, no longer remain silent, more especially as they can only be regarded as a continuation of the peculiar line of conduct he has thought proper to adopt with regard to me. I shall proceed at once to collect these personal charges against me, contained in Mr. Owen's lengthy and, as it seems to me, confused epistle; I shall attempt to lay them clearly before your readers.

It is stated by Mr. Owen that I furnished reports of my papers, read at the last meeting of the British Association, to the Athenæum and Literary Gazette of September last, and that the abstract just printed in the Transactions of the Association has been altered from the original papers, so as to take in Mr. Owen's more recently published views. My answer to this is, that I did *not* furnish the report to the Literary Gazette, from which Mr. Owen draws much of his pretended evidence, and that the notice of my papers, which I sent to the Athenæum, was so abbreviated and cut to pieces that I cannot be responsible for it. But, notwithstanding certain errors contained in the reports of the Literary Gazette and Athenæum (which, however, are very trifling, considering the difficulty of the subject,) and the disadvantages under which my views are there necessarily represented, I am still quite content that these views should be gathered from these journals, without any reference whatever to reports subsequently published, provided allowance is made for what are obviously inaccuracies.

racies, and an impartial judgment exercised. *The abstract of my papers given in the Transactions of the Association contains no interpolations whatever — no matter which was not contained in the papers themselves*: I wish the same could be said of all Mr. Owen's reports published in the same work. The promptness with which that gentleman at once accuses others of the practice of interpolation, appears to have its origin in the circumstance that he is far from being unfamiliar with that practice himself. I should advise him, before he again "prays" Prof. Phillips to compare my abstract for the Transactions with the reports in the Literary Gazette and Athenæum, to request the secretary to institute a similar comparison between his own abstract, in the Transactions published in 1839, and the reports given in the weekly journals, shortly after the meeting of the Association in 1838. Prof. Phillips would, by so doing, be able to make out a case of interpolation so flagrant, that all Mr. Owen's disinterested indignation against such proceedings would be perfectly explained. In the eighth vol. of the Reports of the British Association for the year 1838, p. 136, the following passage occurs in the abstract of Mr. Owen's paper.

"Purkinje and Fränkel also added to dental anatomy several new and interesting facts relating to the structure of the enamel, pointing out more especially the form and characteristic transverse striæ of the component crystals: and lastly, they determined the true osseous nature of that distinct layer of substance which had been previously known to surround the fang in the teeth of man, and which they once observed to be continued on the enamel of a human incisor. *This observation Mr. Owen proceeded to state he had confirmed, and he exhibited several sections of the simple teeth of the mammalia, in which both the ivory and enamel were invested by a layer of osseous substance, identical in its structure with the cement which enters more abundantly into the composition of the compound teeth of the herbivora.*

Not a word, however, of all this is contained in the lengthy report of Mr. Owen's paper printed in the Athenæum, which he acknowledged to me was furnished by *himself*, nor the Literary Gazette; and for the best of

all reasons, viz. that at the time when his paper was read, and the Athenæum report of it published, Mr. Owen had *never seen* the work of Purkinje and Fränkel; though in his report he would fain lead the reader to believe that he had been well acquainted with these writers in the autumn of 1838. The following letter to me shews that he did not even receive a copy of their work till the spring of 1839:—

April 1, 1839.

My dear Nasmyth,—I received from Baillière, on Saturday last, the enclosed copy of Fränkel*, and as I shall not have time to look into it till the end of the Lectures, I send it to you, knowing your anxiety to see it. I may ask for it again towards the end of June. * *

Believe me, dear Nasmyth,

Yours very truly,

R. OWEN.

After perusing this, I think you will agree that Mr. Owen is not exactly the person in whom it is safe policy to write a letter to Mr. Phillips, containing unjust accusations of interpolation against another party. Mere interpolation, however, although not to be commended, is a matter of no great consequence, unless it be adopted from some reprehensible motive. Let me state what was the motive of Mr. Owen in this particular instance. It can have been no other than that of appropriating to himself a discovery to which he had not the slightest claim, as I shall prove even by his own written admission. By his own report of his paper, read at the British Association in August, 1838, we learn that he then made no mention of the enamel-capsule, nor did he of the researches of Purkinje and Fränkel, for the very valid reason communicated above. Shortly after his return from Newcastle and the continent, however, I sent him a paper containing an account of my discovery of the enamel-capsule, which was afterwards published in the 22d vol. of the Med.-Chirurgical Transactions. This paper he returned to me with the following note, dated

December 11, 1838.

Dear Nasmyth,—Hearing that you had made inquiries about the MSS., I return them without delay. I have marked in pencil all that occurred to me in the way of amendment, and I think it will

* In which Purkinje's researches are published.

be an acceptable paper for the Medico-Chirurgical Society.—I am, in haste,

Faithfully yours,

R. OWEN.

In April, 1839, he obtains the work of Purkinje and Fränkel, and then, on preparing the abstract of his papers read at the Association in the month of August previous, he inserts a passage, in which he represents himself as having there stated that he had confirmed and followed out their researches, and anticipated my discovery of the existence of a capsular covering external to the enamel.

It is a great pity, as I have before hinted, that Mr. Owen, who, in the year 1840, displays such virtuous zeal, in writing to Mr. Phillips to prevent the reports of papers for the Transactions from being modified, so as to comprise an account of discoveries made since those papers were read, did not manifest the same laudable anxiety in the year 1839, since, at present, his ingenuous cries for justice are quite uncalled for; whereas, last year, had he prayed Professor Phillips to compare the proofs of abstracts for the Transactions with the reports published at the time in the hebdomadal journals, I might have been spared the pain of exposing what, I think, must appear to all impartial eyes, a very equivocal transaction, more especially as it was perpetrated under the guise of friendship.

Mr. Owen appears to possess certain qualities to such a remarkable extent, that he cannot imagine them absent in others: for instance, he accuses me, throughout his letter, of versatility—a quality with which I have never, to my knowledge, been before reproached, but which I am quite sure, and shall immediately proceed to render evident, he possesses in no trifling degree. In the summer of 1838, I prepared for the press a translation of the work of Professor Retzius, of Stockholm, entitled *Researches on the Microscopic Structure of the Teeth*, and advertised it for publication: this translation Mr. Owen borrowed of me in the course of the same summer. Before advertising its publication, I had inquired of Mr. Owen whether he intended to publish anything on the subject. He replied in the negative. However, as he continued to retain my manuscript of the translation of Retzius in his possession, and as other circumstances had led me to believe that he might, nevertheless, entertain the idea

of writing on the structure of the teeth, in which case I should with pleasure, as I told him, have abandoned my intention in his favour, I repeated the question in a letter, to which I received the following reply:—

July 25th, 1838.

Dear Nasmyth,—Many things have interfered to prevent my returning you the translation of Retzius earlier, but as you have not sent for it, I hope without inconvenience to you. *As I have before said, I have neither desire nor object in bringing before the public any of the general observations on the structure of the teeth, which I once hoped were new; but now perceive to be mainly anticipated by the industrious and sharp-sighted Swede.* It will obviously, however, be a source of great credit, and a matter of importance, to whoever practising in the line of dental surgery should combine these discoveries with the *practical or remedial* part of the science†. * * * * *

Believe me, dear Nasmyth,

Ever yours,

R. OWEN.

It will scarcely be believed, but it is no less a fact, that, in spite of this letter, and of my having in consequence of Mr. Owen's repeated assurances advertised a work on the subject of which the translation above alluded to was to form a prominent part, that gentleman, within about one calendar month after the date of the above epistle, not only published all the new "general observations on the structure of the teeth," but also all the "practical" deductions from them which he was capable of drawing; that is to say, besides the anatomical details, he laid before the Geological Section the deductions from them bearing on natural history generally, which I had already alluded to in my advertisement; and before the Medical Section he treated the subject "combining these discoveries with the practical or remedial part of the science." For proof of this, the reader has only to refer to the *Athenæum* of September 1st, 1838, and to the *Literary Gazette* of September 15th, 1838, where the "elaborate and voluminous" reports of his papers, read at the British Association, on the *Structure of the Teeth*, are published. What renders

† The remainder of this letter I omit, as it contains matter which Mr. Owen wished to be considered confidential.

this proceeding still more remarkable is, that he gave his "analysis of the laborious and accurate microscopical observations of Professor Retzius, as related in the original Swedish Memoir of that author," (vide *Athenæum*,) a memoir with which he was only acquainted through the translation he had borrowed of me, which he had never asked permission, and had, therefore, no right to make use of, and which he had returned to me, as the reader has seen from the above note, with an assurance "that he had neither desire nor object in bringing before the public any of the general observations on the structure of the teeth." I think your readers must allow that I have now established my point, and that Mr. Owen is, indeed, versatile with a vengeance.

The appearance of his "voluminous" reports naturally vexed me not a little. I was indignant, that a person, calling himself my friend, should publicly make use, for his own advantage, and without my leave, of a manuscript which I had prepared and advertised for publication; but, nevertheless, I remained silent on the subject, because I hoped that his interference was now, at any rate, at an end, and that from him I had no further competition to expect, as he, indeed, gave me to understand was the case. However, I was disappointed. Having once broken his promise, he was not to be deterred from aggravating the offence. It would be wearying your readers were I to follow him through all the evasive windings of his course—from the time when he had "neither desire nor object to publish," to the day when the advertisement of the first part of a bulky work on the subject issued from M. Baillière's shop. Suffice it to say that, at first, he was "persuaded" to publish; then he was "determined to publish," but only on a limited scale; until, finally, he resolved not only to give to the world the whole subject, and nothing but the whole, but also to render his work "as generally useful as possible." Throughout his whole correspondence with me, he has shewn himself to be nothing if not versatile—to use no harsher term.

The merits of the question respecting his recent plagiarisms I leave for your reviewer to decide on. All that I can here say, with respect to it, is to repeat that I am content that the reviewer should rest his case on no other documents than

the reports in the *Athenæum* and *Literary Gazette*, incomplete as such reports must necessarily be, however carefully made. Thus Mr. Owen's charges of interpolation and versatility fall to the ground, were they not otherwise absurd: as it is, they are doubly futile. I am sorry that he has made them, because, by so doing, he has forced me to show that the facility with which he has recourse to them seems to originate in his having practised both to perfection himself.

Your obedient servant,

ALEX. NASMYTH.

IODINE IN HYDROPHOBIA.

NOTE FROM DR. RANKIN.

LOOKING over some old numbers of the *LONDON MEDICAL GAZETTE*, I observe two cases of rabies, reported by Dr. Hawkins and Mr. Curling, which strongly resemble a case of supposed incipient hydrophobia which came under my care in 1836, and which was cured by iodine. The patient was a sepoy of 51st N. I., who had been bitten about a month before. The wound (in the leg) had a dark and indolent appearance, with rough and elevated edges. The pain, extending up the limb, was so intense as to prevent all rest, even with the aid of opiates, and, a day or two after admission, large buboes appeared in the groin of the affected leg. This visible cause of absorption suggested to me the use of iodine, which was immediately given, in doses of ten drops, four times a day, with marked benefit almost from the commencement, the buboes and pain gradually subsiding. The patient came into hospital on February 5th, 1836, and was discharged on the 12th March; the bite having healed very reluctantly, and only by the continued internal administration of the iodine; nitrate of silver, and other external applications, producing no effect. I have not since had an opportunity of testing the remedy further: the superintending surgeon, on seeing the case, declared his conviction that it was hopeless. The sepoy, Rugheen Ling, is still doing his duty in the regiment, at Barruckpore.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégier."—D'ALEMEERT.

The Principles and Practice of Obstetric Medicine: comprising the Structure of the Female Generative System, the Process of Parturition in all its Details, the Management of the Puerperal State, the Physiology and Diseases of the unimpregnated Generative System, the Physiology of Conception, and the Diseases of Utero-Gestation. By JAMES BLUNDELL, M.D., late Professor of Obstetric Medicine at Guy's Hospital. Carefully revised and corrected, with numerous Additions and Notes, by ALEXANDER COOPER LEE, and NATHANIEL ROGERS, M.D., Member and late President of the Hunterian Society of Edinburgh, and Corresponding Member of the Medico-Chirurgical Society of Dublin. 8vo. pp. 1155. London, 1840.

It has rarely fallen to our lot, as medical reviewers, to meet with a work so full of sound practical instruction, and, at the same time, so guiltless of unnecessary amplifications, as the one now before us. Indeed, it should rather be called "a Cyclopædia of Practical Midwifery;" for every author of eminence, who has contributed any thing worth knowing on the subject, has been heavily taxed in the preparation of this volume; and yet, in justice to the editors, we must acknowledge, that while no superfluous matter has been introduced, the materials—varied as they are in their nature and sources—have nevertheless been arranged and combined in so skilful a manner as to impress us with a strong sense of their clearness, conciseness, and intelligibility.

Were we merely to regard this volume as a new edition of Dr. Blundell's excellent obstetric work, it would be entitled to our warmest recommendation, as the contribution of one of our best teachers on that subject—a teacher who, to an extended practical knowledge that few can equal, added a classic elegance of style, which rendered his lectures valuable for the sterling value of their materials, and pleasing for the almost poetic fervour which pervaded

their diction. But the present work, although it bears his name, and consequently contains all his valuable instructions, is entitled to our consideration on other grounds; we therefore propose briefly to examine the materials of which it is constituted, and the manner in which the editors have performed their delicate and important task.

On the subject of classification, we cannot do better than let the editors speak for themselves. They tell us, in the Preface, that they "have arranged the work in two principal divisions. The first, consisting of three parts, is purely *obstetric* in its character, and is consequently the most important; while the second, including the last two parts of the work, embraces the physiology and diseases (functional and organic) of the female generative system, during the successive periods of female existence, and in all circumstances." In this arrangement we fully concur, as it appears to possess advantages which do not belong to any other; for the subjects of parturition and female generative physiology and pathology are so essentially distinct, that no advantage can possibly arise from the manner in which they are jumbled together, in most works on the subject.

The first part, consisting of 84 pages, contains a description of the bones, ligaments, and articulations of the pelvis; the obstetric properties of the pelvis; the structure of the pelvic viscera; the obstetric characters of the fœtus, and the manner in which it is transmitted through the pelvis: giving a comprehensive view of the mechanism of all the parts concerned in parturition, and therefore forming the most appropriate prelude to the second part, which is devoted exclusively to the description of the process of parturition and all the circumstances attendant on it. This part is by far the most bulky, extending to upwards of four hundred pages, and contains the most important part of Dr. Blundell's lectures. It embraces, besides, a full and minute description of natural parturition, and of all the complications and difficulties which may arise during its progress. We would more particularly direct attention to the chapters on flooding, transfusion, and the employment of instruments, as containing much valuable information and useful cautions (that cannot be too often repeated) against the rash and

dangerous employment of artificial aids to a process, which, in the vast majority of instances, is purely natural, and requires no assistance. We cannot refrain from giving the following quotation, as eminently characteristic of Dr. Blundell's style of instruction:—

"When, from large experience and much reflection, you have formed for yourselves better rules of guidance, then, by all means, and not till then, let these now given be laid aside as superannuated and defective. Nothing can be more abhorrent from my wishes than to exercise over the mind any influence which does not emanate from truth and reason. Be that far from both you and me! There is not, perhaps, any intellectual habitude more certainly preventive of our progress in solid knowledge, than that which leads a man indolently to neglect the exercise of his own observation and reason, and to adopt servilely the opinions of those who have gone before him. Observe for yourselves; think for yourselves. He is surely less than the least of all philosophers, one who is not worthy to be called a philosopher, who does not inculcate these maxims. Think for yourselves, then;—not arrogantly; not inconsiderately; not invading those regions of thought which lie beyond the sphere of human understanding; but on topics within your reach, with observation and reflection deep and broad, think for yourselves. Never bury in indolence that inestimable gift of nature, so much insulted and disparaged, reason; *lux, lumenque vitæ; divinæ particula auræ*;—the fair mother of philosophy—the brightest and noblest inheritance of the human species."—P. 125.

The third part, on puerperal diseases, extends to 120 pages, and bears evidence of extraordinary diligence and research having been bestowed on its preparation. It commences with an introduction on "Puerperal Diseases in general," from the pen of Dr. M. Hall; which is one of the clearest and most comprehensive sketches we have ever read. The article on "Puerperal Fever" has been completely remodelled; and, from the extensive additions which have been made from the most valuable sources, is well deserving of an attentive perusal. It contains also important articles on "Intestinal Irritation;" "Effects of the loss of blood on the Puerperal State;" "Puer-

peral Mania and Phrenitis;" "Slight Febrile Affections from mixed causes;" "Structure and Diseases of the Mamma;" and "The Effect of previous Disorder of the general Health on the Puerperal State;" every one of which, strange to say, had been passed by in silence by Dr. Blundell, when treating of puerperal diseases. We consider, therefore, that the editors have done good service by the important and judicious additions which they have made to this part. The following quotation is selected from a number which present themselves, as eminently characteristic of the valuable practical hints with which it is interspersed:—

"Our systems of nosology have, I am persuaded, greatly erred, in attempting to separate diseases from each other, and describe them as distinct, when they far more frequently occur in conjunction; so that the mind of the medical student is not at all prepared for the cases which most frequently occur to him, when he first enters upon practice. A little experience teaches him the difficulty, nay, the absurdity, of attempting to give each individual case a name, or to put it down in a list of diseases. Each patient, on the contrary, presents to him a new congeries of symptoms—a new complication of diseases or disorders."—Page 557.

The fourth and fifth parts, which extend to 500 pages, contain a full description of the physiology of menstruation, generation, conception, and all those affections which are peculiar to the female organization; indeed, they might with great propriety form a separate volume. To attempt an analysis of them would extend our notice to an undue length; we shall, therefore, content ourselves by stating, that Dr. Blundell's lectures on these subjects form, in many instances, a mere skeleton, or outline, to be filled up with materials derived from Sir C. M. Clarke's work on the "Diseases of Females," Montgomery's "Signs and Symptoms of Pregnancy," Goode on the "Diseases of Women," Naegle on "Obstetric Auscultation," and many others. Of the manner in which it is executed, we cannot but speak in terms of high commendation, in which we think that all who read the book will join.

One other feature remains to be noticed, and that is, the introduction of several new chapters on "The Signs of

Delivery," "Impotence and Sterility," "Rape," and "The Signs and Duration of Pregnancy;" subjects which frequently form the subject of legal inquiry, and on which the accoucheur is not unfrequently called to give his opinion. These we consider a highly judicious addition, because they serve as points, or foci, to which much useful matter, scattered through the work, may be directed.

Thus far we have gone in the analysis of this work; and it must be evident, from the survey we have taken, that, although it was put forward as a new and improved edition of Dr. Blundell's lectures, it really has been enlarged to such an extent, and so thoroughly revised, as to entitle it to the rank of a new work. It might, indeed, be questioned how far these additions were advisable, and whether it would not have been better to give Dr. Blundell's own matter, unalloyed by any such additions. For our own part, we think not; because Dr. Blundell's matter is of too partial a character to admit, with propriety, of its publication under so general a title as that which is prefixed to the present volume; since, without intending to detract from the Doctor's acknowledged reputation, it cannot be denied that, while he has treated some subjects in the most admirable manner, he has merely glanced at others, perhaps, of equal importance. This is not peculiar to Dr. Blundell, who, in this respect, only partakes of the common failing which causes men to become proficient in one subject, while they neglect others. But, at the same time, it serves to point out the importance of the present and all similar works, where it is sought rather to give the collected opinions of the best authorities on that particular subject, than the special opinions of one particular individual. By such a course, the inequalities which some valuable works present are avoided, and a greater uniformity is preserved between the different portions of the same work.

Of the "getting up" of the book, we can only express our entire approval. Every possible care seems to have been taken in its preparation; a copious table of contents and index has been prepared, and the whole has been carefully elucidated by numerous explanatory notes.

Anleitung zur Uebung angehender Aerzte in Krankheits Beobachtung und Beurtheilung. Von FRIEDRICH NASSE, Director der medicinischen Klinik zu Bonn. Bonn, 1834.

Elementary Exercises for the Use of Young Physicians in Observing and Judging of Disease. By FREDERIC NASSE, Director of the Medical Clinic at Bonn. 8vo pp. 142.

AFTER some preliminary observations on the progressive steps by which the beginner should be led forward in the study of diagnosis, Dr. Nasse enters at great length into the details of those inquiries by which the physician judges of the state of his patient. The student is to investigate the normal state of structures and functions in himself and other healthy persons; besides which, the teacher is to demonstrate what is normal in the clinical patients, as well as what is abnormal. Thus, to take an example of our author's minute investigations, we are to consider *in the head*, "its general form, laterally and vertically; the superficies of the skull, with its smaller and larger elevations and depression, which differ, indeed, in different persons, without going beyond the limits of the normal; the facial angle of Camper; and the regions above the eyebrows, and at the root of the nose, with regard to the sound which may be remarked in them during respiration, by means of the stethoscope." For examining these and other small spots in the head, says Dr. Nasse, the instrument should be provided, at its removeable extremity, with a projecting cylinder only half an inch in diameter.

We are then to ascertain the effect produced upon the retina, by little or much light, by straining the sight, and by quick movements; to observe the features when the mind is tranquil, and when it is disquieted; to examine the sides of the face, with regard to the sound which is perceptible by means of the stethoscope, when placed upon the alveolar process of the upper jaw, or on the malar bone; the state of the teeth at different periods of life, particularly during childhood; as well as the appearance of the uvula, the velum pendulum palati, and the tonsils; the region of the mastoid process, with regard to the motion [sound?] which is perceptible in it by means of the stethoscope, during inspiration and loud speaking; the appearance of the membrana tympani

in the light; and lastly the quality of the saliva, of the mucus of the nose, and of the cerumen of the ear.

We are then taught to observe all that concerns the patient in his apartment and accommodations; and the remainder of the chapter is occupied by questions relating to the state of organs or excretions diseased, or supposed to be so.

The following passage is but a very small part of the inquiries which Dr. Nasse directs us to make concerning the abdomen:—

We are to observe, he says, whether the cavity of the abdomen, as viewed by the eye, or more accurately measured with a string above, in the middle, and below, is not abnormal in its whole circumference; whether it is unusually broad or narrow; whether it is not deficient in depth from before backwards, (in settling which points the eye must be assisted by laying both hands upon the hips, as well as upon the lower part of the anterior side of the abdomen, and upon the sacrum); whether the abdomen is irregularly prominent or flat, hard or soft, elastic or yielding, full or fallen in; whether it is not abnormally broad when the patient lies in a horizontal position; whether there are no single prominent or sunken spots in it; what is the form and extent of these projections and depressions; whether they disappear, increase, or change their situation during inspiration or expiration, coughing, or a change in the position of the abdomen; whether a finger can be pressed in upon the prominence; whether a margin can be felt surrounding it, and what is the hardness and tension of this margin; whether the prominence can be pushed away by the hand either laterally or inwardly; and if the latter, whether it cannot be made to disappear entirely; whether a depression is not to be felt in the place of the prominence which has disappeared; whether the prominence does not return; whether the integuments of the abdomen do not any where present those abnormal appearances, which have been mentioned in § 6, as occurring upon the skin; whether, when drawn up in folds, it is not too thin or too thick; whether inequalities are not to be felt under it; whether the movements of the abdomen in inspiration are not too strong or too weak, and unequal in rhythm, &c.—
Pp. 64, 65.

The second chapter instructs us as to

the inquiries to be made concerning the present and previous state of the patient, and the mode of combining the results of this inquiry with those previously obtained by observation alone. It is divided into six sections. The first contains general directions; the second, the method of inquiring into the present state of the patient; the third, the method of obtaining the history of the case; the fourth is an inquiry through intermediate persons; the fifth, on uniting the inquiry by observation with questions concerning the present state of the patient, and the history of his case; and the sixth suggests questions on the alterations that may have taken place in the state of the disease.

The third chapter treats of the method of enlarging or limiting our examination as circumstances may require. If we wish to take down a case for future reference, or to describe it completely for another person, the examination must comprehend all the details previously given. But it may be limited if we have only some special object in view, such as ascertaining if the person examined possesses some particular capability; or making out the diagnosis of a case which is to be medically treated, &c. On the other hand, there are cases where additional points must be inquired into; such are the cases of infants, pregnant or suckling women, the deranged, and those who are suspected of wishing to deceive the observer.

The fourth chapter treats of semeiotic exercises, and is divided into two sections; the first giving the requisites necessary for these exercises, and the second, the problems in the order in which they are to be proposed.

The fifth chapter treats of exercises in diagnosis; the sixth, of exercises in prognosis; the seventh and last chapter consists of precepts for drawing up the history of a case.

This work is extremely creditable to Dr. Nasse, both as a physician and a teacher; and it evidently shows that, not content with allowing his pupils to learn, he actively and zealously teaches them the most difficult of all arts. Our limits, as well as the nature of the book, have compelled us to indicate, rather than analyse, its contents; but we strongly recommend its perusal to those skilled in German, and think that a translation would be very useful to the medical community.

The Medical Jurisprudence of Insanity.

By J. M. PAGAN, M.D., Lecturer on Medical Jurisprudence, Member of the Faculty of Physicians and Surgeons of Glasgow, &c. &c. London and Glasgow, 1840. 12mo. pp. 327.

THIS work is divided into eight chapters; the subjects being unsoundness of mind, insanity, the causes of insanity, mania, monomania, dementia, idiocy, and the deaf and dumb.

Dr. Pagan has given a fair compendium of what is known on the subject of madness, at least of what is known to physicians, for he "has sought for his authorities and illustrations almost exclusively in the records of medicine, and has availed himself but little of those of the law." This is a fault, undoubtedly, in a book on medical jurisprudence; but it is one which the author will easily correct in a second edition. As it is, his book affords much useful information.

MEDICAL GAZETTE.

Friday, June 26, 1840.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in l'pauicum sit, dicendi periculum non recuso." CICERO.

THE VACCINATION BILL.

THERE are few things that testify less creditably of the majority of our legislators, than their comparative carelessness for the result of any question, however important to the public, which does not nearly interest their own political power. Let a measure be brought forward which will have a remote tendency to disfranchise a few hundreds of voters on either side, and every energy will be exerted that not a member may be absent from his seat, and all talent and industry will be employed, in public and in private, to carry or to reject the bill. But let another measure be introduced, in the result of which the lives and health of thousands are intimately concerned—on which may depend the propagation or the suppression of the direst scourge of the land—only let it be probable that the mortality will fall with an

equal weight upon the supporters of both political parties, and some sixty members will come lazily together, of whom fifty, at least, will take no part or interest in the discussion, but will calmly vote in whichever way they are requested by the one or two of each party who have made the bill their especial business.

Such has been the case with the bill for the extension of Vaccination, which has lately been virtually passed. The questions involved in it were, in fact, nothing less than whether the most important and beneficial discovery ever made in medical science should be permitted to have its full application; and whether the greatest pest that is indigenous in our land should be encouraged or nearly exterminated. Immediately before these questions came on, there were assembled ninety-five members, which number soon diminishing, presently began to oscillate between fifty and sixty, and of whom not more than six appear to have had any personal feeling upon the subject. What wonder, if that which even we must regard as of very minor importance, the interests of the medical profession, were totally overlooked, and if the only protest made against the infraction of a severe and evident injury upon its members, were disregarded!

It is but little credit to the legislature, as a body, that a measure which may be regarded as one of the greatest boons that has been for many years granted to the public, has been passed into a law. The great majority of those by whose votes it has been effected were altogether indifferent to, and probably unconscious of, the probable results to which it will lead—results so important to the credit and science of medicine, that, though by the same act he has been visited with no small amount of insult and injustice, there can scarcely be a member of our profession who will not,

in the prospect of them, easily forget for the time his own injury.

The bill plainly divides itself into two parts; one conferring benefit on the public; the other throwing a fresh insult upon the profession through the medium of their old enemies—the Poor Law Commissioners. The benefit to the public is, that every child may now, without cost, and almost without trouble, be subjected to the protective influence of vaccination, for the practice of which every facility and encouragement is afforded to parents; and that by the total suppression of inoculation, the artificial introduction of small-pox into a previously healthy neighbourhood, and its needless propagation in one already infected, are effectually prevented. We have heard and read a good deal of vapouring upon the subject from many of the non-professional correspondents of the daily newspapers, who seem to have entirely misunderstood the nature and probable effects of the measure about which they offer their opinions. Their notions would scarcely deserve refutation, if it were not that the attainment of the full benefit of the bill will depend, in a great degree, upon the manner in which it is received by the public; of whom “constant readers,” when they become occasional writers, constitute a very active and somewhat influential part. For this reason only we will briefly direct the attention of our professional brethren to some of the prejudices which they will have to subdue.

The heavy penalties levied upon the practitioners of inoculation are declaimed against as inroads upon the liberty of the subject. For the same reason they might cry out against the prohibition from selling poison to those who cannot render a good account of what it is their intention to do with it, or who cannot bring with them a witness to its purchase; a prohibition which it would be well to enforce, by punishing the incau-

tious vendor of poison as severely as the inoculator. But if these objectors admit with the rest of the world, that the sale of poison, if not punished with “present death,” should, at least, be placed under close restrictions, how much more strongly would they hold this right, if each dose of poison were a source not of individual injury only, but of a spreading pest! Yet such is the poison of inoculation. The matter of contagion conveyed by it into a healthy district is capable of infinite multiplication, and is not one whit less mischievous in all the neighbourhood than the severest epidemic originally generated there, or accidentally introduced. It is undoubted, that a single germ (shall we, in compliance with the theory of animate contagion, which every day’s researches render more probable, call it ovum or animalcule?) of small pox, is capable of multiplication to numbers which we may call infinite, whether itself were generated after accidental contact, or after inoculation. The drop of variolous poison inserted in the arm of one child, may, and often does, within a month, increase to a sufficient quantity of matter of contagion to produce small-pox in every individual of the population who is not protected by a previous attack, or by vaccination. Surely a conviction of the truth of this may be enough to authorize a little curtailment of the “liberty of the subject”; and to justify the threat of a month’s imprisonment being inflicted upon any one, high or low, unauthorized or diplomatized, who hereafter runs the risk of propagating small-pox by inoculation.

The inclusion of the authorized practitioner who would inoculate from any other motive than ignorance, with those who might be supposed to do so without any clear idea of the mischief they inflict, we regard as the most salutary of the amendments upon Sir Jas. Graham’s bill. There are few, we are sure, in our

profession, who would be induced by any motive or persuasion to adopt a practice so contrary to that which they know to be right, and these few may justly be treated as if they were not members of it; nay, considering the great evil which would result from an example in error being set by one whose station and pretensions might render him an object for imitation, we question whether the punishment upon a professional inoculator should not have been made to fall more heavily than upon one whose ignorance can more easily give way to his cupidity.

Another class of objectors argue for the danger of multiplied and indiscriminate vaccination among the poor, that no child can ever be deemed secure from having some fearful disorder ingrafted upon him with the cow-pox. Such need to be told that the children of the poor are not more liable—perhaps, indeed, not so liable—to scrofula and syphilis, and all the other constitutional diseases that they hold in such fear, than the rich are; and that nine-tenths of the material by which the children of the rich have been protected from small-pox, since the discovery of Jenner, have been supplied from the arms of those of the poor. It may be very consolatory to parents to be able to believe that a taint of scrofula has been implanted in their offspring from any other source than themselves; and especially it must be pleasing to a father to have even a distant notion that the indiscretions of some other man's celibacy than his own, have made his child so puny, and so liable to ill-looking disorders; but the plain truth is, that there is no proof whatever that with cow-pox any other disease can be communicated, while all facts and probabilities militate *in toto* against such an opinion.

If hearty efforts be now commenced and steadily continued, there is good reason to hope that in another century small-pox in this country

will be known only by the same historical notoriety as the plague and the sweating sickness; if its propagation by inoculation be rigidly prevented, we much doubt whether any self-originating epidemic (if it can occur in that form), or any accidentally introduced contagion, will ever be able to make head in a vaccinated population.

Such a glorious triumph has never yet been gained by medicine as we may fairly hope for, if vaccination can now be spread with all the energy and ardour that inspired the philanthropic mind of Jenner. But he was scarcely more obstructed and insulted in the early dawn of his discovery, by the ignorance and prejudice of the multitude, than his successors now are by the overweening desire for a monopoly of government, that is permitted, without restraint, to guide the triumvirate, to whom all that in the most distant manner concerns the welfare of the poor is entrusted. These gentlemen have again contrived to have the measures upon which they are to act so framed, that they may at least secure a reputation for that which, at any expense of good, is their main object—economy. They have made even the dispensation of the benefits of vaccination a matter of contract, and they seem to think that they have conferred a great privilege on the profession by permitting the competition to be open to all practitioners, as well as to the union surgeons. They have, unfortunately, been able to discover too plainly, that a medical practitioner thinks it better to work for nothing, or at a loss, than to let his opponent hold the whole practice among the poor of a district at even the smallest profit; that, in truth, practice among the poor is one, and to some the only apparent, way to practise among the rich; and that thus there is scarcely a union in England but some authorized practitioner may be found who

will take charge of all diseases in it, though he can look for no other recompense than the exclusion of his opponent from the small advantages that a higher contract could yield.

And just so will it be with vaccination: The Poor-Law Commissioners knew well enough that no medical man would willingly allow the whole of its practice to be monopolized by one, who would thus soon gain the reputation of being the only one competent to perform the operation, or on whom dependence could be placed for a ready supply of pure ichor;—they knew that no one would willingly run the risk of another being introduced, even in this unimportant capacity, among his patients, and they gladly seized this opportunity for another application of the *tender* system.

Still we hope even this will not prevent the full public benefit being obtained by this shamefully alloyed bill: the flagrant evils of the Poor-Law cannot much longer be allowed to insult and injure our profession, and we look anxiously, but with no despair, for the day when the whole burden of it will be thrown from our shoulders.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

PATHOLOGICAL DEPARTMENT.

June 16, 1840.

DR. CLENDINNING IN THE CHAIR.

[Continued from page 523.]

Disease of the Kidney.

MR. PHILLIPS exhibited a preparation of a kidney containing calculi within it, and related the particulars of the patient's symptoms during life. The man from whom the specimen was taken was thirty-four years of age. He had suffered for a considerable period from occasional pains in the region of the loins; but stated that the pain had latterly become more constant to one point, at the side of the lumbar vertebrae. It being thought that he suffered from disease of the kidney, the condition of the urine was frequently exa-

mined; but at no time was there any thing unhealthy or unusual observed in the urine. After the lapse of some time, a swelling arose in the back, where the pain was situated, and fluctuation was presently felt. From having found the urine, in all the examinations that were made of it, so healthy in its appearance, it was considered that this abscess was connected with a diseased condition of the bodies of the vertebrae. It was opened, and a small quantity of pus, which was thin and extremely fetid, was evacuated. No constitutional disturbance followed the opening of the abscess. The swelling, however, gradually increased, and extended eventually to such a degree, that the matter reached from the sacrum to the upper part of the scapula. The abscess was again opened, and a large quantity of offensively smelling pus was evacuated. During all this time the appearance of the urine was attentively noticed; but nothing was observed to indicate any disease in that organ; and the impression was retained that the patient had disease of the lumbar vertebrae.

Upon dissection, it was found, by laying open the abscess, and introducing a long probe into its deepest part, that the abscess communicated directly with the substance of the left kidney. The probe struck upon a calculus, which was lodged external to the kidney. Three other calculi were found impacted in the infundibula.

Mr. Phillips drew the attention of the society to the difficulty presented in this case of distinguishing between renal disease and lumbar abscess consequent upon caries of the bones of the spine; and was anxious to profit from the experience of any of the members, who might be able to point out by what means the difference could be ascertained, in cases of a similar nature to that which he had described.

Dr. Clendinning, and Mr. Gregory Smith, related, at some length, interesting cases in which abscesses had formed in the lumbar region, presenting many of the characters of lumbar abscess, but which were found to be connected with the presence of calculi in the kidney.

Mr. Arnott remarked that the connection of abscess in the loins with disease of the kidney, was not always easily or satisfactorily made out during life; and that when such connection did exist it was not always owing to the presence of calculus in the latter organ. He had been requested by Dr. Watson to see a patient of his, a female, in the Middlesex Hospital, who had had pain in the loins, and some indistinct symptoms of affection of the kidney, but nothing positive, and in whom a swelling had formed in the right loin.

There was tenderness, redness of integument, and deep-seated fluctuation here, with much constitutional disturbance. Mr. A. judged from its acuter symptoms, and more rapid progress, that the swelling was not connected with disease of the vertebræ, and opened it, giving issue to a quantity of pus. The aperture discharged for some time, and then healed. Swelling again took place, and this was opened, the pus being thinner and more offensive than before. But neither now nor afterwards, more than at first, could any trace of urine be discovered in the matter discharged from the loins, and no pus could be observed in the urine passed from the bladder. The patient dying worn out, a communication was found to exist between the abscess in the loin and kidney, on the outer surface of which last was an opening the size of a crow-quill leading into its interior. There was no calculus in the organ, but the ureter was contracted and obstructed.

Malignant tumors connected with bone.

Mr. Mayo proposed to shew to the meeting three preparations of malignant disease connected with bone, and to describe the symptoms which had accompanied the progress of each case.

CASE I.—The summer before last, Mr. Mayo proceeded—"I saw in consultation a gentleman about 40 years of age, pale and emaciated, looking like one in an advanced stage of consumption; bed-ridden from disease about his right hip. He stated that several months before, when getting into an omnibus, he felt something snap near his right hip, which caused him extreme pain. The pain continued, and for several weeks was very severe; then it gradually lessened, but he was left lame of that hip, any motion of which brought back pain. On examining the hip from the nates, it appeared broad and flattened, as in hip-joint disease, but with an undefined enlargement involving the joint and the trochanter; the leg was not shortened. On examining the hip in front, a considerable soft swelling could be felt that extended from Poupart's ligament four or five inches down the thigh. By pressure, which gave no pain, this could be repelled; but the moment the hand was taken away, the swelling reappeared. The surgeon, who was in regular attendance upon the patient, considered the swelling to be a rupture; to myself it appeared likely to be a chronic abscess, perhaps extending into the pelvis and connected with disease of the hip-joint. What gave this conjecture plausibility, was the simultaneous existence of a serous abscess on the right shoulder. The patient, notwithstanding every means were used to recruit his strength, grew daily weaker, and died in a

little more than a month. I examined the body, and found the tumor in the groin to be fungus hæmatodes of the neck of the femur. The head of the bone was excavated, the neck nearly wholly absorbed, a shell of the outer and back part alone being left, and that being disjoined from the head; the inner aspect likewise of the upper four inches of the shaft having disappeared: the space was occupied by medullary sarcoma, originating in the bone. The same had formed the tumor which had been felt in the groin.

CASE II.—George Barnes, aged 19, a farmer's labourer, was admitted three weeks ago into the Middlesex Hospital, with enlargement of the head of the right tibia. He stated that nine weeks before he had struck the inside of the knee against a ladder smartly, but not so severely as to make him lame the next day. In two or three weeks, however, the knee began to swell, and was a little stiff. In a fortnight more, it had further increased in size, and become painful; then he lay up, and the pain went away. On his admission, the head of the tibia, enlarged to twice its natural size, presented on the fore and inner part, two round swellings, which were soft and elastic: one was punctured with a grooved needle, when blood alone flowed. After remaining in the hospital eighteen days, the patient consented to amputation of the limb. During this period the swelling had increased considerably; there was a blush of inflammation on the skin at the front of the knee, and the veins of the leg were large and tumid. Pain, like that which he had experienced before he lay up, now returned; he described it as violent shooting pain, not continuous aching. It was relieved by leeches and fomenting.

The limb was examined shortly after the amputation on Friday last. Beneath the skin and fascia of the inner and upper part of the leg some effusion was found, partly serous, partly gelatinous and greenish. The swelling was found to be confined within a strong white fibrous capsule, which was continuous with the periosteum of the sound bone below.

On cutting this through with a scalpel, and making a section of the bone, the following appearances presented themselves:—The disease involved nearly the whole circumference of the head of the tibia; the interior of which was soft, and was sawn through easily, in consequence of the absorption of much of the proper osseous tissue, and the substitution of vascular texture, which was evidently of the same nature with the external tumors; the head of the bone was not enlarged; the mass of the tumor was external to the bone, being contained between it and the thick-

ened and expanded periosteum. The tumor, which projected in several rounded elevations, displayed in different parts different characters; at the lower part were two rounded portions of the size of walnuts that were filled with what resembled clotted blood, forming fungus hæmatodes; the mass of the tumor on the inside presented the familiar appearance of medullary sarcoma, or encephaloid tumor, looking like vascular cerebral matter; here and there of a darker colour, and lobulated. Round the upper part of the head of the tibia the tumor was firmer and whiter, here and there almost fibrous, but having generally the texture which Mr. Abernethy described under the name of mammary sarcoma. The disease appeared to have commenced between the periosteum and the bone, and to be progressing inwards, as well as developing itself outwards. At the back of either condyloid fossa, the last described growth pierced through the cartilage of the tibia; and one of the semilunar cartilages was at one part intensely vascular, and seemingly going into malignant disease.

CASE III.—A gentleman, about thirty years of age, fourteen months ago, had a tumor form upon the gum at the root of the left bicuspides of the lower jaw: a surgeon in the country cut it away, and applied caustic; the part healed, and continued well for some months. Early in the spring of this year the patient observed that the swelling had returned; it grew rapidly; and he came to London, and placed himself under my care. There was a firm vascular swelling on the alveolar part of the lower jaw, extending from the symphysis to the first molar tooth of the left side, and occupying both surfaces of the bone. I recommended him to submit to the removal of this portion of the jaw; Sir Benjamin Brodie gave him the same advice: the tumor was enlarging daily. I removed the portion of bone from which it grew, after taking out the right middle incisor and the left first molar tooth, by dividing the skin parallel to the base of the jaw, separating the integuments and flesh from the bone, and sawing the latter with a narrow saw introduced beneath the integuments, just clear of the tumor. The outer wound healed by adhesion, the mucous membrane within and subjacent tissue swelling, folded over the sawn surfaces of the bone; and on the eighth day from the operation the patient left town well. I saw him lately: there is little disfigurement; he articulates very perfectly, and masticates his food nearly as well as before.

The tumor is firm and white, and appears to be connected with the bone superficially only; growing from its surface, not out of its interior texture.

Congenital Malformation of the Bladder.

Dr. Boyd presented to the meeting a model in wax of a malformation of the urinary organs, in a boy 13 years of age, who has been an inmate of the Marylebone Infirmary for several years. The appearances were the same that have been described in many recorded cases. There was absence of a portion of the abdominal parietes, above the pubes; and the anterior wall of the urinary bladder was also deficient; so that the mucous lining of the posterior part of the bladder was exposed to view, exhibiting the orifices of both the ureters. At the lower part of this red vascular surface was a part corresponding with the penis, which appeared to consist merely of a tubercle formed by the corpora cavernosa, there being no structure resembling the spongy body, or any thing like the urethra, to be recognised in connexion with it. The scrotum was not developed; both the testes were found lodged in the inguinal canal, in the sacs of congenital herniæ. The urine could be seen constantly dribbling from the orifices of the ureters. The boy has always enjoyed good health.

Fatty Tumor lodged under the tongue, at the side of the frænum.

Mr. Arnott exhibited a tumor, composed of fatty substance, which he had recently removed from a part where it is not usual to find tumors of that description, namely, the root of the tongue, close to the frænum. Besides the specimen, he showed two drawings of the tumor, made by Mr. Lonsdale, before the operation. The tumor was of the size and shape of a walnut, only it was pointed at its most prominent part, not unlike the tip of the tongue. It was of a pale red colour, with smooth glistening surface, lodging under the tongue, between it and the gums. Being attached to the tongue it could be protruded between the teeth, or withdrawn into the mouth, at the will of the patient. It was soft and compressible, and communicated to the touch the feeling of its being a sac, with thick coats, partially filled with fluid. The patient, a farmer's labourer, 38 years of age, first observed it eight years ago, when it was about the size of a pea; and it had the same colour at that time which it now presents; that is, it was not blue, but of a light red colour. It was occasionally much larger at one time than at another; he frequently injured it by accidentally biting it when eating; it also made his speech indistinct, and he was desirous of having it removed.

Mr. Arnott acknowledged that when he proceeded to the operation, he was under the impression, judging from the situation of the tumor, that it was a ranula; the parietes of which had acquired greater

thickness than usual, from its long standing, and the repeated injuries, as well as the friction, to which it was subject. It was his intention to have removed it by the curved scissors, at its root, and then to have destroyed the remaining part of the sac by caustic. In commencing the operation, however, it soon became manifest what was the true nature of its structure, and he excised it with the knife. The patient recovered in a few days, and left the hospital.

The tumor, when cut into, consisted obviously of adipose tissue, like that in the common fatty tumor found in other parts of the body. It was observed, however, to be paler, or of a less pronounced yellow colour than belongs to the common fat. This difference in its appearance seemed to depend on a greater proportion of cellular membrane entering into its composition than what is generally observed. Mr. Arnott added, that the situation of the tumor was not one where such growths are usually met with by the surgeon; but he was aware that M. Dupuytren, in his *Leçons Orales*, and Mr. Liston, in his *Principles of Surgery*, had described and given representations of tumors consisting of fat in the same part.

Dr. Clendinning announced, before leaving the chair, that this was the last meeting for the present season of the Pathological department of the Society.

EMPHYSEMA OF THE SUBMUCOUS TISSUE OF THE STOMACH.

DR. HUTTON laid before the meeting a stomach, in the submucous tissue of which air had been secreted in large quantity, elevating the mucous membrane, and forming a congeries of transparent vesicles, situated towards the greater extremities of the stomach; the lining membrane of the organ was slightly inflamed, but nowhere softened; the œsophagus superficially ulcerated, and the duodenum preternaturally vascular; the liver was hypertrophied and the kidneys in a state of congestion. The cavities of the heart were empty, and the lining membranes of the great arterial trunks were tinged of a deep scarlet colour; the left cavity of the pleura and the lungs contained dark coloured fluid blood; the brain presented nothing abnormal, with the exception of slight effusion into the ventricles. The specimen was taken from the body of a man, æt. 36, who was admitted into the Richmond Hospital, labouring under the usual symptoms of delirium tremens, but not to an alarming amount. On the evening, however, of the day after his admission, he was attacked with violent delirium, followed by rigors, cold perspi-

rations, and convulsions, and died at twelve o'clock at night. Dr. Hutton alluded to the cases of pneumatosis of the intestinal mucous membrane, recorded by various authors and concluded, by drawing the attention of the Society to the connection that appeared to exist in such cases between the fluid state of the blood and the occurrence of emphysema in various tissues of the body. (Museum, Richmond Hospital.)—*Dublin Journal of Medical Science.*

RUPTURE OF THE RIGHT VENTRICLE OF THE HEART.

MR. SMITH exhibited the heart of a man, who for two years previous to his death had suffered from repeated attacks of rheumatism. He never complained of any affection of the heart until the night of the 11th November, when he was suddenly seized with symptoms of collapse, and anxiety about the præcordia; his pulse fell to forty in the minute, his extremities became cold, his countenance pale, and his whole body was bedewed with cold perspiration. He remained in this state for eighteen or nineteen hours, and died upon the 12th. Upon examination after death, the pericardium was found distended with blood, and a small lacerated opening was seen in the apex of the right ventricle, near the septum: the parietes of the ventricle became gradually thinner towards the seat of rupture; in other respects the heart was healthy. From a table drawn up by Dr. Townsend, it appeared that of twenty-five cases of rupture of the heart, in only three was the right ventricle the seat of the rupture; and of nineteen cases collected by Bayle, but three occupied the right ventricle. Mr. Smith remarked that the case he brought forward he considered interesting from its rarity, but it derived an additional interest from the circumstance that the symptoms would lead to the supposition that the rupture had taken place eighteen hours before death: life being prolonged under such circumstances could only, he conceived, be explained upon the supposition, that a coagulum had blocked up the opening in the right ventricle: he supposed that death at length took place when the coagulum was expelled, and concluded by alluding to the cases recorded by Cruveilhier and others, where a firm fibrinous concretion plugged up the fissure. (Museum, Richmond Hospital.)—*Ibid.*

DR. JOHN BADHAM.

(From a Correspondent.)

DIED at Nice, on the 11th May, aged 33, Dr. John Badham. With a mind full of activity, he had chiefly given himself up to

that profession which through a short but useful life he conscientiously and honourably exercised. Endowed with that real talent for observation which education cannot impart, he was prompt and courageous in emergencies, fertile in expedients to meet them, and regardless of personal ease in their application; to all of which, if there be added the advantages of a person that immediately pleased, and manners that immediately conciliated, it should seem difficult to combine qualities more fitted to conduct their possessor to early eminence and success. Yet was his career one of almost unmingled pain and trial: from 19 years of age he could not be said to have enjoyed a single week's exemption from sickness, or to have ever released his friends from an abiding sense of insecurity of a life which after a thousand reprieves, and after most severe and unusual suffering, was destined to terminate in his 33d year. The fatal disease (phthisis) to which at length he fell a victim, began to develop itself in its least equivocal signs fourteen years ago, at which period it consigned him, as apparently his only chance, to the solitude of a small West India Island, from which, after a few years' residence, and a fallacious truce, he, perhaps unfortunately, returned to settle in England. Soon after his arrival he was induced, through the recommendation of the late excellent Dr. Maton, to undertake the medical charge of the Duke of Newcastle's family and dependents at Clumber, and settled at the neighbouring town of Worksop; but, in the course of two or three winters, finding his complaints aggravated, and his intervals of comparative ease abridged, it became necessary to give up his post, and to place himself in a less inclement climate, and amidst duties at once more grateful and more easily performed. He was recommended to fix at Tours, where he again for a season became better; relapses, however, without number occurring, even in the mild climate of Touraine, and his sensations leading him constantly to desire more warmth, he went in 1838 to Rome, with a lady, since deceased. During last winter he again repaired to that city, in attendance on Lady Clare; but the present year had made but little progress when he found himself compelled, by increasing illness, to throw up all the engagements which were pressing fast upon him, from rapidly extending confidence in his abilities, and fall back upon Nice, where three final months of very aggravated distress, but amidst whatever alleviations the presence of his family could afford, conducted him to the grave, esteemed by all who had known him in his social, or consulted him in his professional capacity.

Several pages of useful and clear descriptive writing from his pen, on the diseases of the West Indies, have scarcely been overlooked by the readers of the *MEDICAL GAZETTE*; his extensive knowledge of the moral and social condition of the negro was exhibited in a series of Letters, without signature, published in the papers at a time when that subject was much agitated, with a view to legislative enactments. Such subjects as these were the relaxation of his leisure hours; and the whole turn of his habitual conversation was sufficient to show the lively interest he took in public affairs, and the possession of much more than ordinary insight into what was going on in the world in questions which affect the improvement and the happiness of mankind.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

—
DISEASES OF THE ARTICULATING SYSTEM, *continued.* DISLOCATIONS *considered generally*—Particular Dislocations. — The LOWER JAW—the OS HYOIDES—the PELVIS—the CLAVICLE—the HUMERUS. — *Their Nature and Treatment.*

DISLOCATION.

IN surgical language, the term dislocation is usually applied to that condition of a joint, in which, whether from accident or disease, a change of relation has occurred between the bones entering into its composition.

At present, we shall, however, restrict the term to those cases produced by external violence. Hereafter we shall consider those cases in which the displacement has been a consequence of disease, and also those which are termed congenital.

All moveable joints are subject to dislocation, but those are more especially exposed to it whose extent of motion is considerable, those placed at the extremity of a long lever, those whose surface of contact are least extended and whose form is most simple; those in which the concavity or cup is shallow, and whose ligaments are least numerous and least strong.

Dislocations are described as complete or incomplete; in the first, the articular surfaces have entirely ceased to correspond; in the second, there is still some contact between them, but they have acquired new relations.

For a long time it was thought that complete dislocation could only happen at orbicular joints, but that this is not strictly correct will be shown hereafter. In the ginglymoid articulations, on the contrary, incomplete dislocations are not frequent; and complete luxation of these joints cannot occur without destruction of the ligaments and some of the muscles which surround them.

Anatomists have been disposed to deny the possibility of certain luxations, which positive experience has yet shown to happen: thus Boyer denied the possibility of carpal dislocation, still it has been seen; others have denied the possibility of the luxation forwards of the forearm upon the arm, without fracture of the olecranon, yet this has happened; others, again, have maintained that the scapular extremity of the clavicle could not be displaced downwards under the acromion; this also has been witnessed. Indeed it is almost impossible to set limits to the consequence of external violence: I myself have known a complete dislocation backwards of the astragalus, so as to let the tibia and fibula rest on the calcis. I have known the atlas completely dislocated, without injury to the spinal cord.

Dislocations are commonly named according to the direction which is taken by the bone furthest removed from the trunk; thus five dislocations are described at the hip, according to the position of the head of the femur: upwards and outwards, in the iliac fossa; downwards and inwards, upon the foramen ovale; backwards, into the sciatic notch; forwards, upon the pelvis; downwards, upon the ischium. In the ginglymoid articulation we count four, which are described as anterior, posterior, internal, and external, according as the inferior bone is in either situation.

A luxated bone may, after its primitive displacement, change its position; this new displacement is termed consecutive:

thus when the humerus is luxated into the axilla, and afterwards is drawn between the scapula and subscapularis muscle, it undergoes a consecutive luxation.

No luxation from external causes can occur (unless there be some vice of conformation, or an accidental or congenital relaxation of the ligaments,) without more or less of distension, rupture, or injury to the ligaments, muscles, nerves, and vessels connected with the joint.

In all luxations of orbicular joints, the synovial and fibrous capsules are necessarily destroyed to admit of the escape of the head of the bone.

If no attempt at reduction be made, or if the attempt be unsuccessful, the cavity is gradually effaced, and a new cavity is by degrees hollowed out, upon, or within which, the head of the bone rests; around the luxated bone and the new cavity which receives it, the compressed cellular tissue takes a membranous form, and ends by constituting an articular capsule; internally, smooth like a synovial membrane; externally, cellulo-fibrous: the thickness and consistency of this capsule increases with age. Among these abnormal articulations, some allow of extensive motion: such are those where the humerus or femur is unreduced; others possess a very obscure movement: such are those observed in ginglymoid joints.

Dislocations are held to be simple when they are susceptible of immediate reduction, and the reduction is followed by prompt return to the natural condition of the part; complicated, when other particular lesions accompany the displacement: such are violent contusion, penetrating wounds, rupture of vessels, with external communication, the contusion or destruction of a nervous trunk, fracture of the luxated bone, or of that with which it articulates.

The greater number of luxations are seen in adults; in aged persons the bone itself commonly yields sooner than the ligaments: in children the epiphyses are separated, under the same causes which in a later period of life produce luxation.

Causes.—The causes of luxations are either predisposing or efficient. Among those which predispose to this accident, are laxity of ligaments, either congenital or acquired; as a consequence, for instance, of articular dropsy, feebleness of surrounding muscles, shallowness of the articular cavity, and the extent of motion at the part. The efficient causes are two-fold, external violence and muscular contraction.

The luxation of ginglymoid articulations is instantly produced by external violence, unless there be some malformation; that of orbicular articulations is almost always a consequence of the combined action of external violence and muscular

action. A single example will make this evident. The greater number of luxations at the shoulder occur as a consequence of falling forward. In this case there is an instinctive movement to protect the head and face; the arm is raised and carried forwards, so that the hand or the elbow shall come in contact with the ground. If at this moment the latissimus dorsi, the teres major and the pectoralis major, contract violently to sustain the trunk, they cannot displace the inferior extremity of the humerus, which rests on the ground fixed and immovable; the superior extremity will then yield, which it cannot do without destroying the capsule, and becoming luxated.

Symptoms.—The signs of luxation are either rational or sensible: the former are derived from the knowledge we may acquire of the situation of the body at the time of the injury, and the position of the limb; and the mode in which the injury has been applied, as well as the sensations experienced by the patient at the moment of the accident: e.g., we may presume that a person has suffered a luxation of the humerus into the axilla, when we find that he has fallen violently forward with the arms extended, and at the moment experiences a sensation of tearing or giving way in the axilla. The impossibility of executing certain movements which naturally are easy, the difficulty of moving the limb at all, are more certain signs; but these signs may be a consequence of severe contusion. In other cases, in ginglymoid joints, on the contrary, excessive mobility may be good evidence of luxation.

The sensible signs of luxation are derived from particular deformity at the part, from a change in the relation of apophyses, the lengthening or shortening of the limb.

It might be supposed that few diseases could be more easily detected than luxation; but it is not so. The local signs may be masked by tumefaction following the injury, and a dislocation may be taken for a contusion or a fracture.

As to a prognosis in cases of luxation when accidents occur, they are more frequently a consequence of concomitant lesions, than of the displacement of the bone and the rupture or the ligaments: luxations of orbicular have usually less formidable consequences than those of ginglymoid joints.

Whatever be the seat, a luxation is as much more easily reduced as it has been more recently occasioned; certain luxations, those of the thumb for instance, become irreducible in a few days. The ginglymoid become much sooner irreducible than the orbicular joints. In the shoulder, three months, in the hip, two, are periods beyond which we shall rarely succeed in

reducing a dislocation, except in a very feeble subject. Still no precise limits can be laid down: Cooper, Boyer, and others, have seen cases reduced at the end of three, four, and six months. Authentic cases are stated, where a much longer time had elapsed: ten, twelve, seventeen, and even twenty-four months, have elapsed without rendering reduction impracticable.

The *treatment* consists in replacing the dislocated bone, maintaining it there, and treating properly any complications. The reduction of a luxated bone should be proceeded in without delay, whenever there is no complication which would render delay prudent. The means employed in the business of reduction, are extension, counter-extension, and coaptation. The first is the effort exerted upon the inferior part of the luxated limb to disengage it from its new position: this power should be applied on a large surface, so as not to damage the integument; and it should be applied far enough from the joint to avoid irritating the muscles around it. Boyer believed it better to apply the power to a bone beyond that which is luxated. Sir A. Cooper and the ancients prefer applying extension to the bone itself. The degree of force to be employed should be proportioned to the resistance of the muscles. Thus, a luxation of the thigh would require more force for its reduction than a similar injury to the arm. Extension should be made, in the first place, in the direction which the bone has taken; but as the muscles yield, the person to whom the limb is confided should bring it towards its natural direction. *Counter-extension* is the resistance offered to extension, and, of course, it should be equal with it; it should be applied a little above the luxated joint, so as to maintain it fixed: it may be confided to an assistant, or it may be executed by fixing the bandage to a ring in the wall. Sir Astley Cooper believes that a great cause of failure in reduction depends upon the carelessness with which this is done. *Coaptation* results from the movements which the surgeon impresses upon the luxated bone for the purpose of replacing it, when extension has brought it to the level of its natural cavity. It is often useless in orbicular joints, because the muscles tend to replace the bone when it is brought to a proper level; but in ginglymoid joints it is always necessary.

The resistance of the muscles is the principal obstacle to surmount in the reduction of luxations, and extension is intended to vanquish it; but it may be eluded or lessened by other means. Petit advised that the limb should be placed in a state of semi-flexion, for the purpose of avoiding the powerful, elongated, and tense muscles. He insisted too strongly on the necessity for

this. My own opinion is, that, according to the case, complete flexion or extension is the best position. We easily reduce the dislocated patella during complete extension, by which we relax the rectus: luxations of the thigh yield often when we strongly flex the thigh upon the pelvis, and rotate the limb at the same time. A more important principle, much insisted on by Cooper and Dupuytren, is to divert the patient's attention from his situation, and thus for the moment interrupt muscular contraction. In a vigorous person, it is not prudent to insist upon violent attempts at reduction; they should be suspended, and other means employed to diminish muscular contractility. One thing, however, should not be lost sight of; a single person making the attempt directly after the accident, when the patient is alarmed, faint, or drunk, and muscular contractility is very inconsiderable, will often succeed in effecting reduction.

The means we usually employ to lessen muscular contractility are bleeding, warm-baths, tartar emetic, given at short intervals, and opium. Sir Astley Cooper strongly commends tartar emetic to lessen the power of robust individuals: he advises the exhibition of a grain every ten minutes. He states that, in this dose, it produces only nausea and prostration, without vomiting. My own experience certainly has shewn that vomiting usually supervenes. During the prostration so produced, the efforts at reduction are to be made. Boyer prefers opium for the purpose; but unless the contractions are a consequence of pain, this is not usually effective. Some persons have recommended spirituous liquors in quantity enough to produce intoxication, as a means of lessening muscular action. Abundant bleeding, from a large opening in a large vein, so as to produce speedy syncope, the warm-bath, and tartar emetic, are the means upon which reliance should be placed. Still, whatever means we employ to relax the muscular system, it will often be found that powerful and sustained efforts are necessary to effect reduction.

Many persons are opposed to the use of pullies, and, indeed, every species of machine: on the one hand, they urge the impossibility of estimating the power employed, and, consequently, the danger of rupture and inflammation; on the other, the impossibility of changing the direction without suspending the extension. Sir A. Cooper strongly recommends them in luxations of the thigh, and in old cases of those of the humerus. In France, their employment is, to a certain extent, resuscitated, since M. Sedillot has invented a "dynamometer" by which the force employed can be ascertained. When it is necessary to use

much and sustained force in reducing a dislocation, none of the reproaches to which I have alluded can fairly attach to the prudent use of pullies; by them, extension can be made under the most favourable circumstances; it may be made permanent and equable; it may be increased or lessened with great facility; there are no shocks, no oscillations, which must always happen when extension is confided to assistants. When extension is employed, it should be continued without interruption until the muscles yield. When pullies are employed, the bone returns into the cavity without noise or shock, because the muscles are so completely relaxed that they retain no more tenacity, and the surgeon is often not aware that the reduction is accomplished until the apparatus is relaxed.

When the luxation is reduced, the limb should be kept perfectly quiet, and placed in such a position that the muscles around the joint shall have no tendency to produce a new displacement. The time during which it is necessary to maintain absolute quiet at the part varies with the bone luxated, and the extent of injury. I believe the common practice of allowing the patient to use the limb at the end of a fortnight, or even three weeks, is unwise. When we consider, in fact, that no luxation can happen without destruction of the capsule, of muscles, of ligaments, and so on, it is evident that these injuries should be repaired before the limb is used. M. Malgaigne shews that forty days are necessary for the complete reparation of the injury done in luxation at the shoulder; sixty days for the hip; and this interval should be even longer in old dislocations. It is probable that the frequent recurrence of dislocation of the inferior maxilla and the patella is a consequence of the neglect of these precautions; the ligaments remain relaxed, and the displacement is reproduced with great facility.

In some cases, a luxated limb remains totally or partially paralyzed. This is gradually dissipated when it is a consequence of slight contusion of nerves; but it may be incurable when the nervous trunks have been greatly distended or contused.

Luxation of ginglymoid joints occasions now and then a good deal of tumefaction around the joint, and much embarrassment in motion. This is usually relieved by moderate movements carefully made; by embrocations, douches, or counter-irritation.

There are some complications, such as violent contusion of the soft parts around the joint, which make it prudent to defer all attempts at reduction. In many cases of penetrating wounds, however, it will be

proper at once to endeavour to reduce the displacement, if we hope to save the limb; but the edges of the wound should be brought together, cold should be applied, with bleeding and rigid diet: if, however, the joint be largely opened, and the articulating surfaces injured, amputation will most probably be necessary. The wound of an artery is a reason for postponement, unless the reduction can be very easily made. A fracture is usually a reason for a similar course. If, however, the luxation be very recent, and affect a hinge joint, it is generally easily reducible, and it should not be deferred. If, instead of that, the luxation should affect the shoulder or hip, the humerus or femur being fractured, we cannot usually reduce the dislocation; we must first attend to the fracture, and, when that is consolidated, we may sometimes succeed in reducing the dislocation.

LOWER JAW.

Luxation of the lower jaw is an accident which not unfrequently comes under our notice. For its occurrence, it is necessary that the branch of the inferior maxilla, by which the condyle is supported, should describe, with the base of the cranium, an angle, acute backwards and obtuse forwards. In the ordinary condition, it meets the base of the cranium at an opposite angle: the sinus of this angle varies with the different periods of life. In the child the obliquity is so great, that in the greatest removal of the jaw the angle never becomes right; and therefore the luxation in young children is held to be impossible. This condition is, to a certain extent, reproduced in persons of advanced age who have lost their teeth.

This bone can be luxated only in one direction; in any other it is anatomically impossible. This direction is forward, below, and in front, of the transverse root of the zygomatic arch. Most frequently, both condyles are luxated at the same time; in a few cases, one alone abandons the cavity, the other retains its proper place. Sir A. Cooper gives to the first the term complete, and to the second incomplete. Boyer attached to the first the term luxation of the lower jaw, and to the second luxation of the condyle — right or left, as the case might be. When we consider the circumstances as applicable to other joints, Boyer's designation seems best. Indeed the terms complete and incomplete, as applied to other joints, cannot, I think, be applied to the maxilla. It is hardly possible that the condyle should rest first upon the border of the glenoid cavity; it must either fall back into the cavity or be projected forward in front of it. It is, however, true that Sir A. Cooper admits an incomplete luxation,

characterized by the condyle passing under the transverse root of the zygoma. This kind of luxation is owing to the relaxation of the ligaments; the jaws are slightly separated, there is inability to shut the mouth, and slight pain at the luxated region. Usually, muscular efforts are enough for its reduction; yet Cooper has seen it persist for some time. As there was no dissection given, I confess my doubts of the nature of the case.

I know of no dissection of a recent luxation: if we produce the condition in a dead body, we find that the condyle passes below the transverse root of the zygoma, and rests immediately in front of it; the inter-articular cartilage remains applied upon the condyle; the portion of the capsule is partially destroyed; the external lateral ligament changes its direction.

Causes—It is desirable to study carefully the causes by which this accident is produced: the most frequent, unquestionably, is yawning. The ascending branch, in this act, is brought to form with the base of the cranium an acute angle, whose sinus is presented backwards; the condyle glides forward, carrying with it the cartilage, and resting on the transverse root of the zygoma. The external pterygoid muscle then becomes convulsively contracted, and the condyle is pushed forward. It is by a perfectly similar mechanism that dislocation takes place in the act of vomiting; it is probably still the same in some other sudden spasmodic contractions of the muscles, when the mouth is open. The accident occurred to a lady in the hands of Mr. Fox, while extracting a tooth. It has been observed also in a maniac, during the efforts necessary to get food into his mouth. It may result from direct violence—a blow with the fist upon the chin, the mouth being open, or by a fall upon the same part. Luxation of one side is produced by the same mechanism as when the accident occurs on both.

Symptoms.—In this dislocation the mouth is more or less open, the chin depressed, the cheeks flattened, by the elongation of the masseter temporal and buccinator muscles. Below the malar projection, or within the mouth, is a projection formed by the coronoid apophysis; the inferior dental arch projects beyond the superior; the open mouth allows of the flow of saliva involuntarily, and articulation is difficult. In front of the meatus auditorius a depression is found, corresponding to the place occupied by the condyle. To these signs, common to the displacement of one or both condyles, may be added certain symptoms which are peculiar to the first: thus, when one side is luxated, the chin and the inferior dental arch

are sensibly directed to the opposite side; the finger placed in front of the meatus auditorius, only distinguishes a void on one side, and the muscular tension is not marked except on that side. After a short time, in cases of luxation of the inferior jaw, the condyles find their way into the zygomatic fossa: the jaw is a little raised; the lips are so far approximated as to prevent the escape of saliva; deglutition, at first impossible, may be accomplished; the patient is able to speak, but with difficulty; and, after some time, mastication can be performed.

Treatment.—The treatment is evident—to reduce the luxation and to prevent a new displacement, which is always to be apprehended. The reduction may be effected by placing the patient sitting before you, his head resting upon the breast of an assistant. The thumbs of the operator are then to be padded, and introduced into the patient's mouth, so as to rest on the last molar teeth in the luxated jaw; with the other fingers he grasps the body of the maxilla. Pressure is now made downwards by means of the thumbs, until the condyles are carried downwards and backwards, the chin being at the same time directed upwards and forwards. At this time the condyles being disengaged, the muscles acting upon the jaw being spasmodically contracted, the reduction is suddenly accomplished, and with a loud snap; and at that moment, if the thumbs were not well protected, the operator would be severely bitten: at all events, it is wise, even then, to slip the thumbs between the cheeks and the teeth. Sir A. Cooper describes another method. The handle of a common fork is introduced behind the last molar teeth on each side. While an assistant maintains them there, the operator places himself behind the patient, and forcibly drags the inferior towards the superior maxilla, until reduction is accomplished. This method presents, at all events, one recommendation—the operator's thumbs run no risk. Beyond a month to six weeks, it is commonly apprehended that this luxation is irreducible; and even before that, it may be necessary to employ other means than those we have described. Stromeyer invented a rather complex instrument, of considerable power, for this purpose; it is described in Rust's Magazine, vol. 39, part 2, page 219. He employed it in the case of a young woman, aged 23, whose jaw had been luxated thirty-five days, by yawning. The reduction was accomplished in half an hour, and, in consequence of the relaxation of the muscles, there was no noise. Junk invented another instrument (see Rust, vol. 39, part 2, page 222), but his instrument is certainly inferior to that of

Stromeyer: but as accidents may find us without such instruments, we may recur to a method recommended by Professor Asti (*Archiv. Gen. de Med.* t. v. p. 144). He treated a woman in whom it supervened during convulsions occurring in labour, a month after the accident happened. With the hands alone, reduction was found to be impossible. He used two pincers, the blades of which were padded, and the handles long; the blades, closed, were introduced on each side between the last molar teeth; the blades were forcibly separated, the chin maintained, and reduction effected. To maintain reduction, the chin should be supported by a bandage, and the patient fed upon liquids, as it is always probable that a slight movement may cause a new displacement. As a consequence of this accident, the masseter muscles remain sometimes painful or paralysed; this is owing to the distension or other injury of the masseteric nerves which pass in front of the neck of the condyles.

OS HYOIDES.

Luxation of this bone is, in many works on surgery, an undescribed disease. Valsalva (*De Aure Humana*, c. 2, Number 20,) has first observed and described this condition, but the few particulars of the case which he has given would warrant us in doubting whether it were really luxation of the hyoides. This displacement is more probable in two cases described by Molinelli; in one a young student was seized by the throat by a man much stronger than himself; at the moment he disengaged himself from the grasp he tried to swallow, but neither fluids nor solids would pass. Molinelli saw him in an hour—his anxiety was extreme, a cold sweat covered his body, the pulse was small, and his death seemed near; still the voice, speech, and respiration, were unchanged, neither was any deformity apparent in the region of the larynx, but between this organ and the mastoid muscle a tumor existed, the slightest pressure upon which caused very acute pain. He passed his finger down, between the right tonsil and the base of the tongue; at the same time he applied two fingers on the right side of the neck, in the situation of the horn of the hyoides: pressure was made from within outwards: the patient was much relieved, and could swallow a little water: this manœuvre was repeated a second and a third time, when the relief was complete: the second case was a consequence of a blow. Mugna (*Annali universali di Medicina*, Nov. and Dec. 1828.) described a case in which it seemed to be produced by an effort made to swallow a piece of cartilage; the symptoms were similar, so was the mode of relief, to Molinelli's case. It is difficult to admit that it could succeed to

the act of deglutition, still it is maintained by Valsalva, and his opinion is adopted by Morgagni (*de Sed. Ep.* 28. Sect 14,) and by many other succeeding authors. Certainly in Mugna's case there does not seem to have been a projection such as existed in Molinelli's. The subject, however, requires new opportunities for careful investigation.

LUXATIONS OF THE BONES OF THE PELVIS.

The mode and the extent of the articulations of these bones, the number and power of their ligaments, ought to render these displacements rare and incomplete. Very rarely indeed is a case presented in such a state of simplicity as would justify us in considering the luxation as the principal injury; in fact, to produce it, a prodigious force is necessary, a fall from a great height upon the legs, or a heavy weight falling upon the shoulders or upon the pelvis: in these cases, not only one, but many surfaces suffer; there is great contusion of the soft parts, and probably fatal injury of some organ contained within the pelvis.

Whether the sacrum be driven in, or one or both of the iliac bones be jammed in, the sacrum retaining its proper place, the ligaments of the sacro-iliac symphysis, or those of the pelvis, must be ruptured; from whence it happens, that there is much in common in the symptoms. There is severe pain over the articulation, whose ligaments are ruptured; this pain, upon the slightest movement, becomes intolerable. In all cases the luxated bone is so moveable that it is alternately raised and depressed, as the thigh of the corresponding side is flexed or extended. The injury to the soft parts having been great, there is much subsequent external and internal mischief; the legs, the rectum, and the bladder, are either very painful, or insensible, or paralysed: whether the case be one of displacement of the sacrum, or that of the iliac bones, the symptoms are very similar, and the tumefaction of the soft parts is usually so great as to mask displacement; and as the symphysis pubis usually continues intact, the mobility of the ossa innominata causes us to suspect luxation. When only one iliac bone is luxated, the injury is very easily detected; in that case, if the bone be forced upwards, there is rupture of the sacro-iliac and pubic symphyses. The iliac spine of the injured side no longer corresponds to the other, but is raised, and with it the limb of the affected side.

All these injuries are most serious, from the great injuries to the soft parts; the consequences are almost always a long exhausting suppuration, and often paralysis also, as a consequence of the profound injuries which the sacral plexus usually

sustains: still some cases of cure are on record, but they are few. In the memoirs of the Dijon Academy is a case of such a luxation, unattended by very serious symptoms: it was seen by Eneau, Hoin, and Chausssier; the patient fell from a great height; the attempts at reduction which were made, were accompanied by great pain, and were therefore suspended. When he moved about on crutches, the weight of the limb ultimately reduced it, and he resumed his ordinary occupations. If the sacrum be depressed, reduction is impossible, but the iliac bones may be acted upon without much difficulty, by fixing the pelvis, and making extension with the thigh; but there is much difference of opinion, whether it can be prudently attempted, and the Dijon case favours the opinion that it cannot. Some persons maintain that reduction should always be attempted, and accomplished if it be easy, and that it should not be persisted in if found difficult. This is all very well, but where does the difficulty begin? There is always pain upon the slightest motion at the part; how shall we set bounds to it? Certainly the results of the Dijon case shew the happy results which followed the use of crutches: the reproduction of pain when reduction was attempted, seems to indicate that we should abstain from violence, and limit ourselves to the energetic employment of antiphlogistics when necessary.

RELAXATION OF THE PELVIC SYMPHYSES.

A species of luxation may occur at these symphyses during parturition; the relaxation is usually not great, but cases are recorded by Bianchi, Morgagni, Hunter, and others, where the bones moved on each other to the extent of an inch. It may occur at an earlier period of pregnancy: Bertin has seen it in the fourth month, Desormeaux in the fifth. Bassius speaks of a student of law, who, in fencing, produced this condition. In the Philosophical Transactions is a case in which the pubal bones at the symphysis were removed to the extent of four inches; it had succeeded to a leap on horseback. In the memoir of Louis is a case communicated to him by Philippe, where a man, while resting his arm on the back of a chair and leaning forward, received on the small of the back a sack of wheat weighing more than 300 pounds, which slipped from the grasp of another man: at first there was numbness, then pain, succeeded by accidents which destroyed his life in three weeks: in this case the pubal symphysis was disjoined.

When the bones are disjoined or the symphyses relaxed at the period of parturition, the woman experiences pain in these various regions; this pain is scarcely per-

ceived when she rests quietly in the horizontal position, but motion produces it; if she attempts to walk she is sensible that the sacrum moves between the iliac bones; progression becomes more difficult and painful, and at last impossible without support; at this time, if the hand be placed over a symphysis, while the patient is attempting to walk, the mobility is readily discovered.

In women consolidation of the symphyses may occur; Smellie has seen it after six months, Baudelocque after nine months. Denman attended a patient who for eight years was unable to walk without crutches; but the symphysis may continue disunited through life. Mr. Cline shewed Denman a case where false joints were formed at the symphyses. Suppuration may follow, and destruction of the part or even of life may be the consequence. In whatever mode it may have been produced, complete rest of the pelvis is the first point to be attended to: good has been derived from salt water douches directed upon the parts: when we have no further reason to apprehend inflammatory complications, a kind of girdle or truss is employed by some persons to surround the pelvis, for the purpose of guarding against the motion of one bone on another. If any symptoms of inflammation are developed, active antiphlogistic treatment must be at once employed.

LUXATION OF THE RIBS AND THEIR CARTILAGES.

Buttet advanced the opinion that a shock directed against the posterior extremity of a rib, or a corresponding transverse process, may cause a direct luxation of that extremity; he also supposed that it may be detected by an acute pain at the articulation, increased at each inspiration, by the mobility of the rib in its whole length, and by a crepitation sensible to the touch; but in the present day we think that luxation of the posterior extremity of a rib is impossible, and that if it could exist, the signs furnished by Buttet would be insufficient to recognise it. The case brought forward by him was no doubt a fracture.

The structure of the ribs, the flexibility of their cartilages, the solidity of their sternal and vertebral articulations, the number and thickness of the muscles which cover the latter articulation, as well as the facility with which they are fractured, fully explain the absence of facts of costal luxation; it is, therefore, astonishing that Juncker and Heister should have described different species of a luxation which seems almost impossible, and taught several modes of reduction.

Luxation of the costal cartilages has really occurred, but it is very rare; it has only been observed to affect those of the sixth, seventh, eighth, and ninth ribs. For

it to happen it is necessary that the trunk be strongly extended backwards: at this time one of the cartilages we have mentioned may glide below and behind the cartilage immediately above it, and push it forward so as to cause it to project. In this displacement the contraction of the abdominal muscles necessarily plays a part, and there is rupture of the ligamentary fibres of the two corresponding cartilages.

At the moment of the accident an acute pain is felt at the point where the projection exists; there is difficulty of respiration, and sometimes a spasm of the thoracic muscles. It is believed that if left to itself the displacement would be gradually reduced, during some excited acts of respiration; at all events, that the pain and spasmodic action would cease; but it is a wiser course to seek to reduce it at once. To reduce it, pressure from below, upwards, is made on the projecting cartilage: by this means the cartilage which is behind may, by its own elasticity, disengage itself and resume its proper place. A roller and quiet complete the cure.

CLAVICLE.

From its situation the clavicle is particularly exposed to fracture and luxation. A case is described by Portal, and I know of two others, where there was a double luxation, that is, both extremities were displaced; the external upwards, the internal forwards. In Portal's case the patient was a carpenter, who fell from a third story upon the pavement.

Luxation of the *sternal* extremity of the clavicle is a very unfrequent accident. To admit a luxation *upwards*, we must admit that the shoulder may be depressed so far as to allow the middle of the clavicle to rest on the first rib, as a point of support, this bone thus becoming a lever of the first kind, the sternal being raised while the external extremity is depressed: now such a movement is in my opinion impossible. The *downward* luxation is prevented by the cartilage of the first rib; therefore the luxations we admit are the *anterior* and *posterior*, and by many persons the latter is denied, because the resistance of the costo-clavicular ligaments, that of the trapezius and rhomboid muscles, whose contraction would be opposed to a movement of the shoulder forward, sufficiently extensive to admit of it, would constitute an almost insurmountable obstacle. Boyer doubted whether it could occur without violence directly applied to the internal extremity of the bone. Sir A. Cooper, although he never saw a luxation backwards, from concussion, thinks it possible; but the only luxation backwards which he has seen was the consequence of a particular deformity of the spine. Pellieux's case is conclusive

as to the possibility of the accident; a horse fell upon his rider, and it was suddenly produced.

The luxation forwards, then, is almost the only one which has been observed; and when we regard the organization of that articulation we cannot be surprised that the accident does not oftener occur. It happens from falls upon the shoulder, which carry it inwards and backwards. It has been produced by putting the knee between the shoulders, and forcibly dragging them backwards. Desault describes a case where a porter was carrying on his back a heavy burthen, which was supported there by slings passed around the axillæ: wishing to rest his burden on a stone, he missed it, and the arms were dragged backwards.

Symptoms.—There is usually no difficulty in detecting the injury, the kind of accident, the pain instantly supervening at the sterno-clavicular articulation, the shoulder easily depressed, and placed nearer to the thoracic parietes, a tumor in front of the sternum, moving with the clavicle, but disappearing if the shoulder be carried outwards, are signs sufficiently conclusive of the accident. In spare persons these signs are very evident, but in fat persons there is occasionally some obscurity, especially if luxation be incomplete. Now such a tumor as we have described has been mistaken for exostosis: but there must have been gross inattention. An aneurismal tumor of the innominata has been known to luxate the clavicle forwards (Laugier).

The luxation backwards by violence inflicted at the point, destroys the capsular and costo-clavicular ligaments, and the bone would glide behind the sternum; there would be depression of the shoulder, obliquity of the clavicle, and a depression corresponding to the sterno-clavicular articulation; but then there would be pressure upon the jugular and subclavian veins, and, as in the case of Sir A. Cooper, pressure and pushing aside of the trachea, and pressure upon the œsophagus. A distortion of the spine, by which the shoulder was brought forward, made such progress that the clavicle was gradually luxated backwards, the œsophagus was so compressed, deglutition so interfered with, that the patient was marasmic. Mr. Davie, of Bungay, saved the patient by excising the internal extremity of the clavicle.

Treatment.—Compared to the luxation backwards, the luxation forwards is an unimportant disease. To reduce the forward luxation, the corresponding shoulder must first be borne outwards, then backwards, so as to disengage the extremity of the clavicle; then forwards, to replace it in its proper position. The mode of accomplishing this object is as follows:—the

patient sits on a chair or bed; the surgeon places himself on the injured side, places one hand on the upper and inner part of the arm, with the other he grasps the elbow, makes of the humerus a lever of the first kind, of which the point of support is the hand in the axilla. If the luxation be backwards, the shoulder should be borne outwards and forwards, then outwards and backwards. In these luxations the difficulty is not to reduce the bone, but to maintain it when reduced. A cushion should be placed in the axilla; the arm should be fixed to the side of the chest, and sustained there. When the luxation is forwards, pressure must be made at the point, by means of starch or other bandages, by which a sort of papier maché is formed, which is better calculated to maintain reduction than any other agent I know.

The scapular extremity of the clavicle may be luxated, but it is an accident of rare occurrence, because the scapula and clavicle move together; the accident, therefore, can only happen when the scapula is fixed, and the clavicle moved by muscular action. From its anatomical disposition, from its strong ligamentary attachments with the acromion and coracoid apophyses, from the support it obtains from the latter process, displacement might be expected to be unfrequent. Those arrangements would indispose me to admit, with Petit, that the downward should be more frequent than the upward luxation—indeed, I agree with Boyer, that the downward luxation is almost impossible: certainly there is no undoubted instance, that I know, of its occurrence, except that referred to by Malgaigne, where he says the possibility was proved by dissection, sixty years ago, and that of Tournel, in the military hospital at Cambrai. The upward luxation was occasionally observed, even in the time of Hippocrates; and Galen himself seems to have been the subject of it during some gymnastic efforts. It usually happens from a fall upon the shoulder, the scapula being fixed to the ground by the weight of the body, while the clavicle is dragged upwards by the violent contraction of the clavicular portion of the trapezius. The luxation may be complete or incomplete. J. L. Petit has seen the clavicle scarcely losing its connexion with the acromion. In the case of Galen there was a separation to the extent of three fingers' breadth; but no similar displacement seems to have occurred in the cases which have been since observed.

Symptoms.—We detect this accident by the circumstances of the fall, the pain felt and increased by moving the arm, especially raising; the manifest projection

apparent to the eye; the obstacle met by the finger in passing along the spine of the scapula towards the acromion; and the depressed shoulder, evidently brought nearer to the sternum.

Diagnosis.—No doubt, however, can be entertained that this accident has been confounded with fracture of the acromial end of the bone; but the seat of pain, the absence of crepitation, should prevent this. It has been mistaken for luxation of the humerus; the projecting clavicle has then been confounded with the acromion; but then the absence of the head of the humerus in the axilla should prevent this. Galen was the victim of this mistake. Again, it may be confounded with fracture of the acromion; but then we shall find it moveable, and separated by the contraction of the deltoid, while the clavicle will be found in its proper place if we pass the finger from the spine of the scapula over it.

Treatment.—If left to itself the pain soon ceases, and the ligaments keep it from moving far. It is easily reduced; we use the humerus as a lever of the first kind, by means of which we carry the shoulder outwards, then we carry it upwards, while we make pressure upon the humeral extremity of the clavicle; but the difficulty of maintaining reduction is as great as that which attends the sternal luxation. A pillow should be placed in the axilla, and the elbow should be fixed to the side, and strongly pressed upwards, so as to bring the acromion as near as may be to the displaced clavicle. Starch bandage should be moulded on the part, so as to maintain the two bones in their proper connection. Whatever means be employed, it is rarely that we obtain a consolidation without deformity; but no great inconvenience is ordinarily experienced by the patient.

HUMERUS.

Probably luxations of the head of the humerus are more numerous than all others put together: this is explained by the mechanism of the joint, and the extent of motion. Much as has been done on the subject of luxation of the humerus, there is still left very much to be accomplished. Hippocrates admitted four species of luxation of the shoulder, which were distinguished as inferior, superior, anterior, and external; but, strange to say, he only observed one, the luxation downwards: this classification was adopted by Galen and Paré; the latter modified it by maintaining the luxation inwards to be the most frequent, the luxation downwards the rarest. Duverney believed the downward luxation to be the only primitive

one. Desault returned somewhat to the ideas of the ancients, and described, as the only primitive luxations, the downwards, the inwards, and the outwards, holding the upward one to be consecutive. Boyer held the directly upward luxation to be impossible, in consequence of the obstacle presented by the acromion and coracoid process, and their connecting ligaments.

Petit, Boyer, and Sir A. Cooper, have described an incomplete luxation, in which the head of the humerus has not totally abandoned the glenoid cavity; indeed Cooper does not regard it as a rare accident, neither does Brodie, and a certain number of cases seem to warrant this opinion.

Before proceeding farther, we must say a few words upon the anatomical arrangements of this joint. The head of the humerus is hemispherical; its extent, perpendicularly, is double: transversely it is treble, that of the glenoid cavity; therefore it cannot be received into it as the head of the femur is into the acetabulum. From this disproportion, and the laxity of the capsular ligament, it results that the arm enjoys great extent of motion; but rolling as the head does, on an almost plane surface, it is displaced with comparative facility. If we judged of the relative facility of displacements by the form of the glenoid cavity, we might think, that as it is narrower in its superior third, in this direction the head of the bone would most easily pass; but the acromion and coracoid processes and their ligaments, the resistance offered by the subscapularis, forwards and inwards; the supra-spinatus, upwards; the infra-spinatus and teres minor, outwards or backwards; and the deltoid, above, are so many obstacles to the upward movement. The mobility of the scapula, which accompanies the humerus in most of its movements, is another obstacle to displacement; but as soon as the scapula is fixed, and the arm moves alone, this difficulty is lessened; and, as in all extended movements of the arm the scapula is fixed, we cannot be surprised that luxation is frequent. It is towards the inferior part of the joint, in the inferior half of the glenoid cavity, that displacements oftenest occur. In this direction the capsule is thinner and larger than at other points; no muscle is opposed to the motion of the head of the humerus, except the triceps, whose long head renders very rare what was called luxation downwards.

There are two directions in which the head of the humerus ordinarily escapes, forwards, towards the axilla, backwards, towards the infra spinatus fossa. The

first is incomparably the most frequent; it is what is termed downwards and inwards. A long hospital practice may never give you an opportunity to see a dislocation backwards into the infra-spinatus fossa. It has been said that directly upward and directly downward luxation is impossible; it should, however, be added, that the acromio-coracoid roof may give way, and the head of the humerus may then pass upwards; that the tendon of the triceps may be destroyed, and the head of the bone may pass directly downwards. These things are not absolutely impossible, for nothing is impossible in the way of displacement, but these are very rare exceptions, which cannot serve as the bases of a division. I think it unwise to multiply distinctions dependent upon the accidental position of the head of the bone. Larrey mentioned having seen, in Prochaska's museum, at Vienna, a specimen, where the head of the humerus rested between two ribs, having destroyed the intercostal muscles; forthwith an intercostal variety was instituted. In a case mentioned by Percy, the humerus passed through the chest: this would be a thoracic variety. I mention these things to show how ridiculous these distinctions appear.

Of the forward luxations it is well to make three divisions:—*sub-pectoral*, when the head of the humerus is in the axilla, between the subscapular and pectoral muscles; *sub-scapular*, when the head is lodged in the axillary fossa of the scapula, and separated from the axilla by the sub-scapular muscle; and *sub clavicular*, when the head of the bone is found near the root of the coracoid process. Of the backward luxations there are two varieties: the head may be removed more or less from the acromion process towards the infra-spinatus fossa, so that we may get *sub-acromial* or *sub spinatal*.

It rarely happens that there is dislocation on both sides of the body at the same time. Sanson mentions a case of a porter who rested both hands on the hinder part of a cart while he inclined his back to receive a sack of corn; the sack suddenly fell upon the upper part of his back, which gave way with the load, the arms being fixed: there was forward dislocation of both humeri.

Sir A. Cooper thinks the most frequent cause of *forward* luxation to be direct—that is to say, a fall in which the shoulder comes against an unequal surface, the head of the humerus being pushed when the muscles are unprepared to resist. Other authors maintain that the most frequent cause is an indirect one—a fall on

the hand or the elbow. It is brought about as follows:—The arm is removed from the trunk; the elbow or the hand comes in contact with the soil, and is the fixed point; the head of the humerus becomes the moveable point, and the power which accomplishes the luxation is represented by the *latissimus dorsi* and *pectoralis major*. In many cases the following is the correct explanation:—The arm strongly raised, represents a lever of the first kind; the surgical neck of the humerus takes as a support, the acromion; the power is towards the hand or the elbow, and the resistance on the inner side of the joint, between the coracoid process and the tendon of the triceps; the capsule gives way, and the bone escapes. It is not always a fall which produces this luxation—it is not always a violent convulsion: there are cases where the cause is slight; then the recurrence may be frequent. In most hospitals there are well-known faces of persons who apply to have dislocations reduced. Sir A. Cooper describes the case of a man who luxated his arm in bed; and this had occurred several times, even from rubbing his eyes or scratching himself. I should think that, in such cases, the displacement must be favoured by some change in the constituents of the joint. The general characters of a luxation forward are as follow:—The shoulder has lost its roundness, because the head of the humerus no longer supports the deltoid, and, if the hand be placed upon it, it distinguishes a hollow. There is a projection of the acromion; the head of the humerus forms a round tumor in the axilla; the elbow is removed from the side; the forearm is flexed; the arm is longer—that is to say, the space which exists between the external angle of the acromion and the external condyle of the luxated humerus is greater than in the natural state of the arm. The head of the patient inclines towards the injured side, and the luxated arm is supported by the other: this lessens the pain, which is transferred into numbness, extending to the fingers. Voluntary movement of the arm is impossible; if it be moved it is painful, difficult, and very limited, especially when an attempt is made to bring it to the side: to remove it from the side, or to carry it backwards or forwards, is less painful.

ON THE
TREATMENT OF FISTULA IN ANO,
WITH SOME REMARKS ON THE OPERATION
OF M. ROUX, IN THE HÔTEL-DIEU, PARIS.

By JOHN CHARLES HALL, M.D. F.L.S.
Fellow of the Royal Medico-Botanical Society;
and Member of the Royal College of Surgeons,
London, &c. &c.

[For the London Medical Gazette.]

THE present paper claims not to offer any thing that is new, in the treatment of this very frequent disease. After the number of works that have appeared from the earliest times to the present day; after the talents of so many surgeons have been devoted to the task; and after the able remarks of Sir B. C. Brodie, in the *MEDICAL GAZETTE* (vol. for 1835-36) much additional information could scarcely be expected; and yet, some epitomized account of the treatment advocated, with some remarks on the plan, found to be most successful by the author, in numerous cases, may not, perhaps, be useless to the student, or uninteresting to his professional brethren. My attention was more particularly directed to this disease when in Paris, both from the great number of cases that came under my notice, and the difference in the mode of performing the operation; for no English surgeon, entering the Hôtel-Dieu for the first time, can fail to draw a comparison between the operation there performed, and that he has constantly been in the habit of seeing in his own country. I have just remarked, that the number of cases admitted for operation, into the wards under the care of M. Roux, appeared to be very great; but I could not learn whether this arose from the complaint being more frequent in Paris than in London, or from the celebrity this splendid operator has obtained, inducing all who possibly could to place themselves under his care; for during my sojourn there he certainly had more cases of fistula than any other of the surgeons. I know of nothing in the diet, or mode of life, of our continental neighbours, more likely to produce this malady than in England. This, however, leads us to consider,

I. *The causes of Fistula in Ano.*

We have long been too apt to call every formation of pus, situate near this

part, a fistula, and this wrong appellation has, not very unfrequently, given rise to a plan of treatment certainly not calculated to produce the desired effect. Our ancestors supposed any small opening, leading from a large and deep cavity, containing matter, to be a fistulous opening; and with this term they also couple an idea of induration, and supposing this hardness to be a cause, and not an effect of the disease, and having no idea that it could be removed, not supposing that when the cause was removed, this hardness, as a matter of course, would disappear also; and supposing the proper treatment to consist in the removal of such callosity, they vigorously attacked it, with the view of either at once removing it with a cutting instrument, or destroying it by the application of some powerful escharotic. In speaking of the causes of fistula, we shall do well, perhaps, as we go on, to describe the symptoms attendant upon each form of the disease.

Mr. Cooper remarks that collections of matter, from inflammation, wherever formed, if they be not opened in time, and in a proper manner, do often burst. The hole through which the matter finds vent is generally small, and not often situated in the most convenient, or most dependent part of the tumor; it, therefore, is unfit for the discharge of all the contents of the tumor, and instead of closing, contracts itself to a smaller size, and becoming hard at its edges, continues to drain off what is furnished by the sides of the cavity.

All abscesses near the rectum may, without some little care and attention in their examination, be mistaken for fistula when suffered to burst; the little opening, with its indurated edges, leading to a large hollow cavity; the daily discolouration of the linen, by a slight discharge from its sides of matter, and the general hardness of the surrounding parts, all tend to confirm the supposition that there is a fistula; nor is the difficulty lessened by the variety of forms such abscesses assume. Sometimes the patient is attacked with rigors, followed by pain in the part, and hardness of the buttock, which assumes a bright red tinge; in a few days, a portion of the swelling becomes of a deeper red, the integument covering it grows gradually thinner, and a sense of fluctuation is communicated to the finger. However

great may have been the pain—however tender the part—much as the general system may have sympathised—may have suffered—all the unfavourable symptoms subside with the evacuation of the matter. The redness, sometimes, is more diffused, the hardness being less circumscribed; the skin assuming an erysipelatous appearance. The inflammation here is evidently more superficial, and the disease subsides without the formation of any considerable quantity of matter.

Again, neither of the above states may be the condition of our patient; instead of the bright red on the surface of the skin, with considerable pain, and a large, hard, and circumscribed tumor, or an erysipelatous blush over the surface of the skin, we may have a destruction of the cellular membrane, and a carbuncular kind of inflammation. The skin is of a dirty red colour, something like the broken surfaces of an old brick, or even may assume a purple tinge; the surrounding parts, it is true, are something harder than usual, but they communicate not the peculiar feel which we have either in phlegmon or erysipelas. The sufferer has, at first, a full, hard, whipcord-like pulse, and great thirst; complains of head-ache, and is very restless. The tongue is dry and coated, and the motions unhealthy; there is some feeling of tenderness over the region of the liver, with a peculiar sallow countenance. If the disease be not checked by proper treatment the pulse becomes faint, fluttering, and unequal; the strength gradually decreases. The matter is small in quantity, and of a peculiar unhealthy character, and the adipose membrane is sloughy throughout the whole extent of this discoloured surface.

It has been remarked by Mr. Pott that the disease now and then commences in the induration of the skin, near to the verge of the anus, but without any pain; the hardened surface gradually softening, at length breaks, and the matter is discharged. For the most part it is healthy and small in quantity, and the wound, being superficial, soon heals; it now and then, however, happens that the cavity is of very considerable size, and the matter discharged, large in quantity and particularly offensive. I remember the case of a poor woman suffering from softened

tubercles of the lungs, who was not aware of the existence of a fistula before the abscess broke one night, when in bed, and discharged a considerable quantity of matter. Sir B. C. Brodie has related the case of a gentleman who was not aware of the existence of any local disease. He had for some time past been subject to head-ache, was languid, and obliged to go home and lie down for a few hours in the middle of the day. One morning, as he was walking in the street, the abscess burst, and discharged its contents, which was the first intimation he had of its existence.

In cases like this, it is quite evident that to prevent suppuration is out of the question; the sooner matter forms the better; nature may, therefore, be assisted by fomentations of warm water and linseed-meal poultices. Mr. Pott used to allow the skin to become very thin before he made an opening, but in the present day it is thought (and doubtless is) better to freely evacuate the contents of the abscess as soon as matter is formed; leeches and cold lotions are worse than useless, and in some cases I have even seen them continued long after the matter had formed. This kind of tumor is generally found in persons of very full habit, as butchers and farmers; in men who consider it necessary to partake of animal food three or four times in twenty-four hours, and therefore, in some cases it may be necessary, if the pain be great, and the constitutional symptoms run high, to bleed, and to moderate the inflammation by gentle cathartics; or one or two small doses of calomel, followed by saline aperients, and very small doses of emetic tartar. If the inflammation be of the erysipelatous character, it is of no use to remain until matter forms; the quantity is very small in comparison with the size of the swelling, which is, in truth, not a separate cavity containing pus, but a dead, sloughy, fœtid condition of the cellular membrane; it is, therefore, evident that the sooner we lay this open with the knife the better: if we remain till the matter comes to a point, we may remain long enough; we are waiting for that which will never take place, and all the time that we are looking on with our hands in our pockets, doing nothing, the disease is extending itself into the surrounding parts.

But we have mentioned a third form in

which the skin puts on a dirty brick-dust or purple colour, and has a doughy feel, and is possessed of little sensibility; when conjoined to such appearances we have a weak, small pulse, a declining appetite, a continual drowsiness, a failure of strength, and a lowness of spirits, the case becomes truly fearful; for experience teaches us that death will sooner or later terminate the case. It is needless to point out the subjects of such attacks; there is evidently some want of tone in the system—some want of nervous energy; this may be constitutional, but more frequently we find it produced by intemperance and dissipation. Strangury, dysury, and sometimes complete retention of urine, may be produced by abscesses near the rectum and neck of the bladder, of course more frequently when the abscess has formed; in the latter situation the retention may continue until the evacuation of the pent up matter; or commencing with the first blush of inflammation, subside in ten or twelve hours, long before suppuration takes place.

It has often been attempted by designing quacks to throw a cloud of mystery over diseases of the rectum, endeavouring to separate them from the principles of general surgery; and it would be well if the public mind were disabused from this foolish notion: it would be well for them to know that the human frame can only be regarded as one; to be aware that the stomach, brain, lungs, heart, and intestines, are not to be acted upon as mere mechanical contrivances for the transmission of certain extraneous substances; on the contrary, they are highly organized, highly sensific parts, giving and receiving acute sympathies to and from the other portions of the economy; and this knowledge alone will enable them to avoid the non-cutting operations of designing charlatans, the following, whose creed is either the besetting fashion or besetting ignorance of the present day. It is upon the public at large that the knaves fatten, while their terrified and poisoned victims quail under their grimaces, and totter to an untimely grave under their ligatures and drugs. But says Mr Liston, "there is no such difficulty as has been supposed in understanding the nature of diseases of the rectum: the principles which should guide their management are simple and the means operative, and otherwise easily enough applied."

The cause being removed, the local treatment is simple enough, and remedies may be applied to the part with every prospect of success, and the hope of speedy relief, with every certainty of that hope being realized, honestly held out to the patient. But to what are we to trace congestion of the lower bowel, hæmorrhoids, protrusion of the lining membrane, every kind of inflammatory swelling, acute and chronic abscess, and almost their invariable result—*Fistula in Ano*? In my opinion, to a disordered condition of chylopoietic viscera, and to some irritation or enlargement of the genito-urinary organs. The evacuation of the contents of the alimentary canal, and a prevention of their accumulation for the future, an improvement of the condition of its lining membrane, and the secretion from it by injections and a well-regulated diet, must therefore be enjoined; nor must it be forgotten that such a state of things is frequently produced by a derangement of the liver; hepatic diseases must not therefore be overlooked. The best medicine to effect this will be small doses of blue and compound rhubarb pills at bed time, with a warm aperient draught morning and midday.

Again, some cases will require attention to be paid to the viscera of the pelvis; in fact, any thing which tends to produce or keep up irritation must as soon as possible be removed.

Some persons are habitually costive, which is almost always accompanied with a painful distension and enlargement of the hæmorrhoidal vessels, both internal and external; if a considerable load of hardened feces be detained in the large intestines, the system generally becomes disordered; and the symptomatic fever, accompanying the formation of matter, is considerably increased by this state of things; if, then, the vessels surrounding the rectum are distended, as they are both large and very numerous, it necessarily follows that all the evils of inflammation and irritation are augmented. Hence, we must employ a mild, laxative, and cooling diet; clysters of warm water should be frequently thrown up the rectum; this will not only soften the swollen and indurated piles, but also tend to prevent the formation of matter. I have spoken of habitual costiveness as a frequent attendant upon this kind of inflammatory swelling. Persons so afflicted will do well to study the rules laid

down by Dr. Burne, in his late valuable work. This condition of the body may, I am certain, be removed by making it a rule to endeavour always to evacuate the contents of the bowels at one stated period,—say after breakfast; by never resisting the calls of nature, and by the frequent use of lavements: no patient can object to so simple a remedy; and if relief can be obtained in a few minutes by the injection of a few ounces of warm water, surely so simple a plan must be far preferable to the daily exhibition of drastic pills and violent purges. The evil ends not here; by the constant use of purgative medicines, it is difficult to obtain any evacuation of the contents of the bowel without their use; and I have been consulted in numerous cases where this costive state of the body was induced by the folly just alluded to, and in which I have succeeded at once in effecting a cure by the simple plan above mentioned.

We find that in many patients who consult us for diseases of the rectum, this is not the only complaint under which they are suffering; and before we decide upon an operation it will be necessary to discover whether any symptoms are present denoting the impossibility of effecting a cure by the usual means; for it would be unpardonable only to discover this when we find that the divided sinus will not heal. Abscesses near the rectum are frequently present in patients labouring under diseases of the lung: it will, therefore, says Sir B. C. Brodie, be very prudent to ascertain if they exist. "Persons," he continues, "with diseased livers and other visceral diseases, are liable to the formation of such abscesses." Two reasons, therefore, will prevent our operating in such cases: first, because we should not get the parts to heal; and, secondly, because if we did so, in all probability the disease of the internal organ would then proceed with increased speed: and for the reason first stated no surgeon would be justified in performing any operation if stricture or carcinoma be present; it is useless to do so—the parts will never heal, however frequently we may lay them open. All we can do in such cases is but little; we may endeavour by air and proper exercise to render a miserable life as tolerable as possible, under existing circumstances; by opiates or injections of starch and opium, to relieve the poor creatures' most

acute sufferings; and by frequently changing the linen, and washing the parts with warm water, and a solution of chloride of lime and water, to render them as comfortable as we can.

II. *The treatment of Fistula in Ano.*

From what has already been said in speaking of the causes of this disease, it will at once appear evident that before any operation be attempted for the relief of the local affection, the general state of the patients health must be attended to. If the fistula has been the result of constipated bowels, that must be obviated, and, in fact, whatever may have been the predisposing cause, it must be removed. The great fault of the hospital practice in Paris is non-attendance to the state of the system. French surgery consists in the dexterous performance of difficult operations; they combine not the office of the physician with that of the surgeon; and no man can be a good surgeon who is not at the same time fully competent to attend to the medical as well as surgical treatment of his patient; in truth, all the best surgeons of the past and present day have been and are good physicians also. To quote the words of a very high living authority, "surgery in France is nothing but operations, and the after treatment in cases of operation is little attended to." The treatment of these cases as far as the knife is concerned, consists in laying open and dividing the sinus or sinuses in such a way that matter cannot by any possibility be retained; such cavities should be opened into the rectum. The dressing should consist of a bit of thin lint, covered with some simple ointment, as dry lint is very apt to produce irritation and uneasiness.

When the intestine is found to be separated from the surrounding parts by the matter, the operation of dividing it should be performed at the time the abscess is first opened, and not deferred. If it be done properly, little additional pain will be experienced, so little in fact that the patient will be unable to distinguish the opening of the abscess from the cutting of the rectum; but if left for a time another operation has to be performed, and the patient is kept in a feverish state of anxiety by the continued dread of a second cutting. Mr. Liston, however, is of opinion that this ought not to be done; he observes, that "it has been recommended that in abscesses extending

along the gut, the cavities of the bowel and abscess should at once be laid open, and into each other, by the same incision; I have done so, but always found the cure to be tedious. It is better that the matter should first be evacuated through an external opening, that the painful symptoms and constitutional disturbance should be allowed to subside; and after the cavity has contracted, and the extent of the sinus been ascertained, the operation should be performed."

It must ever be remembered that after an abscess near the rectum has been opened by a simple incision, and its contents evacuated, a cavity is left, which cavity has to be filled up; this will be best effected by the dressing being as simple as possible, and small in quantity: nature must be in a great measure allowed, unassisted, to do her own work. By such treatment a large abscess will sometimes be cured without any necessity of meddling with the bowel; but in the majority of cases, although there may be no communication between the abscess and the intestine, still its coats are so injured that the abscess will never heal until both are laid into one. The aim of this operation is to divide the gut from the anus as high up as the top of the cavity in which the pus has been formed; for, by thus laying the cavity of the intestine and the cavity of the abscess into each other, we produce an open wound in the place of a fistulous sinus; we prevent the lodgment of matter, which is enabled to escape as soon as formed, and by frequent ablutions with tepid water and proper dressings the patient soon recovers.

But the operation is performed on another principle, well described by Sir B. C. Brodie, whose words I shall take the liberty of quoting. "When the abscess is laid open, the fibres between it and the bowel must be divided, and the sphincter muscle being thus set at liberty, not only is there a free and ready escape for the matter, but the action of the muscle which prevents the healing of the abscess is put an end to. This then is the mode of curing the abscess: lay it open into the bowel, dividing at the same time the fibres of the sphincter muscle which lie over it."

For this operation the probe-pointed knife, with a long and strong narrow blade, will be the instrument selected. The finger must be introduced in the bowel till the point of the knife is felt,

which, being taken hold of by the finger, is prevented from deviating, and the parts are thus freely laid open. If there be no opening between the abscess and the rectum, very little force will be required to make one; the knife is in either case received by the finger, and the operation very easily performed.

The operation over, the wound must not be crammed full of all kinds of dressings; nothing should be applied that is at all irritating. One very troublesome symptom following the operation for fistula is a diarrhœa, attended with tenesmus. I do not contend that such symptoms may not be produced by the mere division of the sinuses, but in the cases I have seen it could be traced to improper dressing; for every application not of the simplest nature, particularly if forced to the very bottom of the wound, is certain to produce a painful irritation in the extremity of the gut; and as this irritation is almost always attended with frequent discharge of fœces, it proves not only debilitating to the system, but also tends very considerably to interrupt the completion of the cure.

The night before the operation is performed it will be advisable to give a dose of blue pill and colocynth, followed early in the morning by a senna draught, so that the bowels may be freely opened and the large intestines emptied of their contents; for this purpose clysters are particularly useful. As soon as the operation is performed the wound should be lightly dressed with lint covered with the ungt. cetaceum, or an ointment composed of olive oil and wax; the sores first being well cleansed with water: this completed, and a compress, secured by a T bandage, applied over the whole, the patient should be carried to bed, and a dose of liquor opii given, not so much for the purpose of allaying pain as to produce costiveness. Nor must we allow our patient much food; a little toasted bread, and a small quantity of rice pudding will be all he will require: you wish to keep the parts in a state of rest, the giving a large quantity of food therefore is worse than useless. The dressings must be removed after every stool, if these are frequent; the parts being each time well cleansed with warm water: thus treated, the sore will heal exactly as if in any other part of the body, for in spite of every effort made to induce us to suppose something peculiar or mysterious to exist in sores about the

anus, the fact is undoubted that they are of the same nature, and heal in exactly the same manner as any other sore in any other part of the body. They must therefore be treated in exactly the same manner—be lightly dressed, and kept perfectly clean; care being taken to remove any fœces that may lodge in the lips of the wound, as gently and with as little force as possible. We have already remarked that by steadily persevering in this simple plan of treatment, the end in view will generally be obtained. This is not however always the case; instead of laudable pus, with fresh, red granulations, with which the wound when healthy will always be covered, it may acquire an unhealthy, soft, flabby appearance, the matter discharged from it being then fetid, and in some cases highly offensive, and mixed with blood: this may arise from two causes.

First, from some morbid condition of the system; from some derangement of the chylopoietic functions, which must at once be attended to; their healthy condition restored, the wound changes its aspect, and heals kindly.

But we may not always have it in our power to remove this condition of the system which may be produced by organic disease, by some affection of the lungs or liver, and therefore we must (as before remarked) be ever careful to discover that no such disease exists before the operation is commenced; for even if we could remove the fistula, and dry up the discharge, it would not be prudent to do so, as in all probability the internal disease would advance more rapidly.

Secondly; this unhealthy condition of the parts may be induced by a sinus, perhaps situated at some distance from the verge of the anus. Upon examination, the matter is found to lodge in it; it must therefore be at once freely laid open, and instantaneous relief will in all probability be experienced.

"Sometimes," says Sir Benjamin Brodie, "in attempting to cure what seems to be a common fistula, we find that it does not get well, and in the end a copious abscess is discovered high up, which prevents the smaller ones from healing." He relates the case of a lady on whom he operated for several sinuses near the rectum, but she continued uncured for a considerable time, during all which she complained of uneasy sensations, which could not be accounted for.

After repeated examinations, a sinus was detected high up; not more than an inch in length, and seemingly involving the levator ani. This having been laid open, a cure soon followed. Now and then we may meet with a case where an abscess near the rectum having discharged its contents heals up; but for the most part it continues discharging more or less. The surgeon just quoted, who, perhaps, has had more experience than any other man, remembers the case of a gentleman who had suffered from an abscess near the rectum for twenty years, sometimes discharging a little, then stopping, then discharging again. Three or four months before he was consulted, the orifice closed, and did not open again as usual; after this, the patient began to suffer much pain, and became exceedingly ill. The rectum was examined, and a large abscess discovered; a lancet was introduced by the side of the rectum, and it passed quite up to the handle before the matter was reached. When a little matter had escaped, a director was introduced, and about a pint of highly offensive matter escaped. The wound required to be again dilated, and the patient recovered.

"In all cases in which there is a communication between the cavity of the abscess and the bowel, the discharge is doubtless kept up by the escape into it of flatus and fluid fæces; its fistula may consist of one sinus, more or less, narrower, and extensive, running from an opening between the verge of the anus and the point of the hip towards and along the coats of the bowel—the blind external form; or there may be a communication established with the rectum some where above the sphincter—the complete form: more openings than one may exist in the integument, and there may be a good deal of hardness around. Several tracks may communicate with the principal one from the buttock, perineum, &c. the result either of the large original abscess, or of consecutive ones."—(Vide Liston's *Operative Surgery*, page 387.)

With the view, then, of favouring the contraction of the suppurating tracks, and of causing sores about the anus to become healthy, an operation is to be undertaken; and in order to remove the irritability and painful contraction of the orifice of the bowel, the surgeon

must widen the outlet, and destroy for a time the action of the sphincter.

The more steps of the operation I shall not dwell upon; they are described in every work on surgery, particularly in the valuable work of Mr. Liston, "*on Operative Surgery*." After the operation has been performed, it is highly advantageous to keep the parts in as quiescent a state as possible for two or three days, particular attention being paid to the simple plan of dressing already pointed out: be it also remembered, that the division of the sphincter is of the utmost importance, inasmuch as it affords that quiet to the parts which alone enables them to heal. I never, except in one case, saw any hæmorrhage arise that could not be stopped by a little bit of lint, and the continued pressure of the finger; and this arose in operating on an abscess, high up, without regarding the highly prudent advice of Sir Benjamin Brodie: "when the abscess is high up by the side of the rectum, and above the sphincter, the lancet is to be carried through the skin by the side of the anus until the matter flows. Then a probe-pointed bistoury must be introduced, and the rectum divided at the lower part of the abscess, and the incision carried through the sphincter."

Like all other operations, that for fistula in ano may be followed by erysipelas; and some instances are recorded in which it has been followed by traumatic tetanus. Sir B. C. Brodie mentions a form of erysipelas not described, that I remember, by any other surgeon, in which it extends along the mucous membrane of the rectum into other parts of the intestinal canal. The pulse becomes rapid, weak, irregular, and intermitting. The abdomen tympanitic; there is great prostration of strength; and the patient expires in three or four days, sometimes sooner. In the case of a lady, the attack began when the incisions had nearly healed up, and died in forty-eight hours. I have, however, not as yet met with such a case, which doubtless is uncommon.

M. Roux, of the Hôtel-Dieu, Paris, performs this operation in a different manner to that performed by Pott, and followed by English surgeons. He introduces a long piece of boxwood into the rectum, having its concavity towards the fistula. A silver director is then

introduced along the fistulous track, and its end made to come in contact with the wooden gorget in the bowel. A long, strong, narrow sharp-pointed knife is then introduced along it, till it comes in contact with the piece of boxwood. The director is then withdrawn, and by keeping the point of the knife fixed upon the gorget, and withdrawing both together, all the parts between the fistula and the rectum are divided. This part of the operation completed, the bistoury is exchanged for a scalpel, and all the hardened base is carefully dissected out. A thick long probe is then procured, having a button at one end; this is covered with charpie, smeared over with some yellow-looking ointment, and the wound crammed full of it to the bottom.

This operation I ever have regarded as open to three objections. 1st. The boxwood gorget can only be of use in saving the finger of the surgeon, which is not very likely to be injured; and if the finger be not employed, the sense of touch cannot be available, and we are operating in the dark with nothing to guide us. Nor is it a very easy matter to introduce the point of a director at once through the opening into the rectum; this is admitted by M. Richerand, who adds, "that in this circumstance, the point of the director may be introduced into the rectum without lessening the chance of the success of the operation."

2nd. I object to the dissecting out of the hardened integument at the edges of the fistula, which is done by two incisions crossing each other at right angles, the flaps being each lifted up with a pair of forceps, and cut out with the knife. What end is sought by this part of the operation? what object is there in view? what good can possibly result from it? what advantage attends this increase of suffering to the patient? The old surgeons supposed that there was something malignant in the hardness and callosity attending this disease, and were not content with opening the cavities, but endeavoured to dissect out the whole of the parts, and if unable to do this, they finished the work with the red-hot iron. Such practice may be worthy of a day gone by, but certainly not of the nineteenth century.

3rd. I must beg leave to enter my most earnest protest against filling the wound daily with large quantities of

charpie. This plan is attended with great pain, produces considerable uneasiness, and most certainly impedes the cure. The wound cannot be dressed too lightly, and the less it is disturbed the better. But if the surgeon crams it every day with lint or charpie, the sides of the cavity cannot contract; they become hard and callous, nor is there any thing in my opinion so likely to reproduce the disease as this system of filling it with dressings. Mr. Cooper, of University College, well remarks, "a sore so cramped will not permit the matter to escape. A patient, who has been so treated, has generally some degree of fever; has a pulse which is too hard and too quick; is thirsty; and does not get his due quantity of natural rest."

When a sore has been so treated, there always is a very considerable degree of inflammation about the verge of the anus, the lips of the wound are tumid and everted, red, and painful in a high degree, and all the lower portion of the bowel partakes of this state of things, producing frequent desire to go to stool, and considerable irritation; nor is any thing more calculated to produce that fatal erysipelas before described than this mismanagement of the wound. If we were called upon to treat such a case, the first thing would be to remove the dressings to foment the wound with warm water. At the same time attention must be paid to the state of the system, and treatment directed to calm the general disturbance that may have arisen made use of.

M. Roux, whose talents and great experience entitle any opinions he may express to the greatest possible attention and respect, in a critique published some years ago, upon the manner of performing this operation in England, censures our plan of not filling the wound with charpie; but, says Sir B. C. Brodie, "it is chiefly in consequence of the use of too much lint in dressing that further operations are so frequently required before the cure is completed;" this opinion also coincides with the experience of Mr. Liston, who strongly reprobates the plan of filling the wound with lint or charpie.

I have thus endeavoured to group together the most important and interesting facts connected with the causes and treatment of fistula in ano; the study of this disease is of considerable

interest, and highly important, from the frequency with which it occurs. The subject is, however, far from exhausted, and before long I trust to be able to resume its examination. In conclusion, however, may I be permitted to advise such of the readers of "The London Medical Gazette" as are students, carefully to examine every case of fistula they may meet with in the wards of the hospital, and to attend the *post-mortem* examination of such cases as may die from other disease, but who may have fistula also. We are all of us too apt to neglect, when students, "those simple cases," as we term them, forgetting that, in the majority of patients, such "simple cases" will be what we shall be called upon to treat. On the successful treatment of such "simple cases," the foundation for future fame is laid; and wise is that man who not only attends to cases of hernia and stone, and the operations for them, but also devotes some portion of his time to the study of the treatment of simple wounds and ulcerated legs. Nor will any class of cases that he can select be more worthy of his most careful attention than diseases of the lower bowel; for when in practice for himself, no disease will more frequently require the exercise of his professional skill than fistula in ano.

Bath Place, June 1840.

REPORTS OF CASES, &c.

By H. M. HUGHES, M.D.,

Physician to the Surrey Dispensary.

RUBEOLA.

THERE are perhaps few diseases which, regard being paid to all its relations, present more anomalies than measles. Whether the medical history, the severity, the plans of treatment that have been adopted, or the progress and termination of the complaint, are considered, it may be said to abound in varieties. In the main, regular, as to the duration of the preliminary fever, it sometimes comes on without any premonitory symptoms whatever, and constitutes the *rubeola sine catarrho* of Willan. Frequently, perhaps generally, of so mild a character as to require little or no medical superintendence, and often treated by the never-failing *saffron tea* alone; it appears according to the statement of Sydenham,

to have been the cause in his time of more deaths than even the small-pox, unmitigated as it then was by either inoculation or vaccination; and if the pneumonia, acute bronchitis, cancrum oris, and sloughing, which occasionally succeed to it, are taken into the account, it may perhaps be with truth asserted, that it is even, at the present day, the most fatal scourge of the infant population of this country.

The most opposite plans of treatment have been at various times, and by different authors, practised and advocated. Sydenham's treatment during the existence of the rash was very simple, and he recommended venesection only when the "eruptions turned livid or black," and when "after the departure of the disease, symptoms of peripneumony supervened." Mead advised blood to be taken away before the rash appeared, or if that could not be effected, after it had come out, with the view of preventing, as speedily as possible, the inflammation of the lungs—the source of the greatest danger. Heberden says, in like manner, "bleeding may be used at any time of the measles, and is always beneficial where the symptoms are very distressing, particularly if there is an oppression of the breath." Mr. Magrath, of Plymouth, has used and recommended cold affusion, from which he never witnessed any untoward circumstances, and which, he was persuaded, prevented the inflammatory affections of the chest, which often appear on the decline of the rash, by the suppression of the early excitement; to the violence of which they are, he supposes, chiefly attributable. Other, and by no means the least successful, practitioners administer ammonia and stimulating diaphoretics, with the view of increasing the cutaneous efflorescence, and producing an abundant and vivid rash, with the same ulterior object as those who adopt an antiphlogistic plan. I have heard it asserted that a gentleman who employed ammonia, and other stimulants, had, after an active practice of forty years, never lost a single case of measles. Whatever may be thought of the practice adopted, I fear that an equal amount of success has fallen to the lot of very few. In the treatment of measles, as in most other cases, the proverb "in medio tutissimus" will, I believe, be found the safest guide to practice, under circumstances in which opposite extremes have

been advocated. From personal observation, I am inclined to think that any very active treatment, whether of the antiphlogistic or stimulating kind, in the ordinary forms of the complaint, is likely to be prejudicial, and that the disease would generally terminate more successfully if the operations of nature were less interfered with. Many children do perfectly well without any medicine, or at most with a little saffron tea—the constant remedy of nurses and grand-mammas; and I feel assured that here, as well as in the scarlatina simplex, the disease may become dangerous, “*a minia diligentia medici.*” Dr. Willan has, with his ordinary good judgment, stated that the mere oppression of the respiration and the labouring pulse, on the first or second day of the eruption, are common to other eruptive fevers, and usually disappear in the course of a few hours; but that when the rash has disappeared, and symptoms of thoracic inflammation become severe, venesection, cupping, and other similar remedies, may be repeatedly necessary. Every practical observer will, I think, acknowledge the general accuracy of these remarks; my own experience certainly accords with them, and by no means supports the notion that the subsequent affection of the chest bears a direct proportion to the amount of cutaneous excitement. I have, on the contrary, often seen the most vivid rash, with turgid face and swollen eyelids, disappear without being followed by any serious obstruction to the breathing, and sometimes with scarcely any pulmonary complaint whatever. On the other hand, I have seen the most dangerous disease of the lungs, or bronchia, supervene upon the sudden retrocession of the rash, and on this account have been particularly careful, during the progress of measles, to prevent the exposure of the surface to cold. Gentle laxatives, salines, and light bed-clothing, have been ordered, when the rash has been general and vivid; but diaphoretics, with ammonia, and the warm bath, have been prescribed when the surface has been cool, and the eruption slight and pale. I have, I believe, never thought it necessary to abstract blood generally, and but very rarely locally, during the existence of the disease itself. When, however, the rash has disappeared, and the measles, properly so called, have ceased, the secondary affections I have

often found not only to bear, but to demand very active treatment. The use of mercury, however, if possible, and of blisters, I have endeavoured to avoid, as sloughing blisters, and gangrene of the mouth, always indicative of danger, and usually followed by fatal consequences, particularly in young children, are, I believe, in no disease so common as after measles. Without intending to assert, or even to imply, that *cancerum oris*, as it is improperly termed, never occurs where mercury has not been administered, it is, I believe, generally admitted that the disease usually follows the use of that medicine, and appears to depend upon its peculiar action on the gums, cheeks, or lips; although sometimes exhibited only in such small, occasional, and alterative doses, as, in the ordinary state of the body, would have produced no effect upon the mouth. Though, therefore, the essential cause of this horrible disease, without doubt, exists in the state of the constitution at the time, its immediately exciting cause appears in many cases to be the local irritation produced by the action of mercury: on that account I refrain, as much as possible, from its employment. In consequence of the great tendency in measles of blistered surfaces to slough, which cannot always be prevented by the interposition of lawn paper, or gauze between the blister and the skin, or by the removal of the vesicatory after a certain number of hours, I rarely, if ever, make use of them as counter-irritants in the inflammatory affections of the chest, which so frequently succeed to that complaint.

But though the gangrene of the mouth, and the sloughing of blisters, are almost always followed by death, neither they nor pneumonia have, in my experience, proved so fatal after measles as acute bronchitis, with want of power. Perhaps those only who are in the habit of seeing disease among the poor are fully aware of the severity and unmanageable character of this affection, as those only have an opportunity of witnessing the complaint fully established, and far advanced before any medical treatment has been adopted for its removal. I know not any disease in which I have been more foiled in affording even temporary relief to distressing symptoms, in which contra-indications have been so numerous, or so perplexing, and in which all the remedies employed

have so completely failed in producing any beneficial effect, as in the affection under consideration. Called to young children, who have just passed through measles, who have already been suffering from their complicated disease for two or three days, without any regular medical advice, and who have been given up to other hands by the quacks, nurses, or druggists, who had previously prescribed for them just at the time when almost all hope of any efficient treatment had passed, I have not unfrequently found them with a pallid skin, cool or cold extremities; purple cheeks and lips; a tongue coated and moist, but of a deep blue colour; dilated and inactive pupils; lethargic drowsiness, heaviness, and tendency to coma; profuse diarrhœa; hurried respiration, with a loud mucous and soft crepitating rattle in every part of the chest; and a weak, frequent, and fluttering pulse. When some of these symptoms appear at the onset of measles, the late Dr. Armstrong recommended "the prompt administration of a warm bath, a moderate bleeding, an antimonial emetic, and a purgative;" and says that, "unless they are quickly employed, the little patient sinks rapidly under an apparent load of phlegm in the bronchia," and when the physician is called, early in the progress of this complaint, though succeeding to measles, these remedies may be generally useful in relieving or even efficient to cure; but when they have already existed several days without treatment, and have arrived at the stage which I have briefly sketched above, the employment of the active means advocated by him will, I think, be found not only inapplicable and unefficacious, but dangerous and even fatal. The warm bath, leeches, and mustard poultices to the chest, mineral emetics, antimonials, aperients, stimulants, and calomel, in various combinations and at different times, I have tried without any good effect, and I must confess myself still undecided as to the most desirable mode of treatment, as all hitherto tried have signally failed.

The cases of measles which I have seen during the past year, however, with the exception of the following, which for many days I expected to terminate fatally, have all been of a character so mild and regular, that it would be useless farther to refer to them.

M. A. Nash, aged 9, a small delicate

child, of light complexion, who from infancy had been far from robust, came under my care Oct. 17, 1839. She resided in a confined alley, and had two days before been rather suddenly attacked with vomiting, epistaxis, and purging; the matters passed by the bowels being semifluid and sanguinolent, and the dejections occurring from eight to ten times in the twelve hours. She complained of considerable pain and griping of the abdomen, but had no coryza, sneezing, or cough. The skin was not hot, but there was a slightly elevated rash on the trunk and extremities, composed of spots rather larger than millet seed, of a dark crimson colour, and not arranged crescentically. The tongue was rather dry, the tip and edges red, and the dorsum coated with yellowish fur. The face was not swollen, nor the conjunctiva injected; but considerable languor, and some anxiety, were depicted in the countenance, and some tenderness existed on pressure at the *scrobiculus cordis*: the pulse was small, frequent, and sharp. As neither the premonitory symptoms nor the rash were characteristic of measles, I was at first disposed to doubt the existence of that complaint, and to consider the affection as *purpura urticans*; but from the fact of rubeola being prevalent in the immediate vicinity, and a child having died of it in the next house two or three days before, I concluded that my patient was suffering from an irregular form of the disease. This opinion was afterwards verified by three children in the same family being attacked with measles in its ordinary and milder form. Some practitioners would probably have ordered venesection in this case, with a view of relieving the internal congestion, and though I think it would have been a hazardous expedient, it might possibly have been more quickly effectual than the temporising plan of treatment which I adopted in consequence of the natural debility of the child, and the additional weakness already induced by the epistaxis and the diarrhœa. She was ordered simply—

Pulv. Ipecac. gr. x. ft. pulv. emetic. st. sumend.—Ol. Ricini, ʒij. hor. ij. post pulv. sumend.; et Mist. Cretæ, ʒiv. cujus capt. ʒss. hor. iv. post ol. et singulis 4tis horis.—To be kept warm.

18th.—The emetic acted well; the

bowels still were much relaxed; the motions reported to be very fœtid, and to resemble soot and water. The rash was more distinct on the hands, arms, and lower extremities, but of the same dull colour and irregular form as the day before. She had no swelling of the face or hands, but complained much of headache and pain of the abdomen; the face was rather flushed, and the conjunctiva slightly injected; pulse feeble.

Hirudines iij. temporal. Applicand.
Fotus Papav. abdomin.

R Mist. Cretæ, ʒj.; Conf. Aromat. gr. x.; Tr. Opii, ʒij.; Tr. Cinnam. C. ʒxv. 4tis horis.

19th.—Pain of head relieved by the leeches, but the diarrhœa continued, though the evacuations were of more natural colour. She had some hacking cough, with much bronchial rattle, but no heat of skin, dulness on percussion, or crepitation, in any part of the chest, and the rash was fading.

Lin. Ammon. thoraci infricand.

R Syr. Papav. ʒj.; Mist. Amyli, ʒj. st. injiciend., et rep. vespere si opus fuerit.
Cont. mist.

She continued without much alteration till the 22d, when symptoms of laryngitis appeared, viz. loss of voice, pain, and tenderness of the larynx; a frequent, shrill, and crowing cough; a rather hot and dry skin; and a more jerking pulse; in consequence of which I thought it necessary, notwithstanding my fear of its injurious operation in and after measles, and the still remaining diarrhœa, to administer calomel. I therefore ordered, together with the mixture formerly prescribed—

Pulv. Cretæ C. gr. v.; Hydrarg. Chlorid. gr. j.; Antim. Tart. gr. ʒ; Pulv. Ipecac. C. gr. j. M. ft. pulv. 4tis horis sumend.

The next day the pain of the larynx, and the other symptoms of inflammation of that part, had increased; but as the diarrhœa and pain of the abdomen had not been aggravated, I ordered her to continue her medicines.

25th.—The laryngeal symptoms were less urgent, and the powders, therefore, ordered to be given only every six hours, and the next day every eight hours.

29th.—Laryngeal symptoms almost gone; appeared exceedingly feeble; bowels still relaxed, but complained of no pain, and had little or no cough.

R Inf. Gentian. C. ʒss.; Tr. Catechu, ʒss.; Syr. Papaver. ʒxx.; Conf. Aromat. gr. x. 6tis horis sumend.

The bowels from this time became gradually more regular; and after a course of astringent tonics of nearly three months' duration, she slowly regained her strength, and was at length discharged perfectly well.

June 18, 1840.

SWALLOWING PINS.

To the Editor of the Medical Gazette.

SIR,

I AM induced to forward the following curious case for insertion in your journal, should you think it sufficiently interesting. Although I am aware it is not the first or second of the kind on record, yet, I believe, more pins and needles have been extracted than from any other.

Your obedient servant,

H. BIRT, M.R.C.S.L.

Ashington Storrington, Sussex,
June 13th, 1840.

Fanny Jeal, æt. 23, of West Chillington, became an inmate of the Thakeham Union House, in July, 1839. Previously to this she had been under the care of R. H. Hurst, Esq., of District 1, in the same Union, who had extracted 27 pins from the left mamma. On examining the cuticular surface, I could discover several others on the left side of the neck, face, forehead, about the orbit, on the breast, left knee, ankle, and foot. She had been accustomed to paupers' diet, which being on the Malthusian principle had no tendency in assisting the vis medicatrix naturæ in bringing them sufficiently near the surface for extraction. However, this was ultimately effected, by allowing three half pints of porter daily, with animal food ad libitum. In the course of four months from the time of her admission, I find on referring to my notes I had extracted 254 pins and needles; all, with the exception of one pin, had lost their heads, and this head was so small as to be scarcely perceptible.

She is now gone to her parents, restored to her pristine health and bodily feeling. From what few facts I can gain of her history, these pins (that is, the greater portion) have been lying dormant in the

system for the astounding period of thirteen years. About that period she was accustomed to swallow them, for no other motive than puerile aggrandisement, or a spirit of daring, or for the palatable delights of barley-sugar or gingerbread. She has frequently had pulmonic attacks similar to pneumonia, affecting only the lobes of the left lung, which mostly have been difficult to combat with, since the period of pin-swallowing. Her mother states positively she has not swallowed any since leaving school, or she must have discovered it. The girl also declares she has no recollection of having ever done so; yet I place but little regard on her statement, she being of weak intellect, almost amounting to idiotism. Several of her school-mates can distinctly recollect her having done so, from the motives I have previously mentioned. The two remarkable features of this case are, the pins exuding from the left side of the body only. Can any of your readers favour me hypothetically why?—also the manner in which the heads have become lost? Were they pulled off by the peculiar action (muscular) of the stomach or bowels, after the aperture had been made by the apex for passing through its coats?

TREATMENT OF CROUP.

To the Editor of the Medical Gazette.

SIR,

WILL you allow me to offer a few practical remarks on the treatment of croup, which appear to me of some value, and to lay before the profession my experience of a remedy which has been strongly recommended in the disease just named. I begin with the latter—the remedy. Since I first noticed in the *British and Foreign Review*, April, 1836, the high commendation of the sulphate of copper as a remedy in croup, I have made a fair and careful trial of it in six cases; in all the issue was death. My disappointment has been great; for relying on the authority, the respectable authority, for the success of the sulphate, I hoped that some of that success might fall to my share, and began my trials with considerable hope and confidence. Hoffman gave a quarter to half a grain every two hours, and were we to believe him, with

complete success: during a period of sixteen years he never lost a patient. The success of Serlo and Zimmerman, recorded in Hufeland's *Journal*, would persuade us that no one need now perish of this hitherto very intractable disease; in short, that the age of miracles had returned. In proportion to my expectations was my zeal, and ultimately my disappointment. After experiencing six defeats in succession, is it any wonder that I have now determined to abandon the remedy in despair, and to publish (if you will allow me) the result, to prevent others from being deceived, and having strong hopes grievously blighted, as has been my misfortune.

I may mention the form and doses in which I gave the medicine in question.

CASE.—A fine healthy boy, two and a half years old, was on the 27th of May, during convalescence from measles, seized with croupy cough and hoarseness; he had an emetic of considerable power, and a stimulant embrocation to his throat: four leeches were applied to each foot, an unsuccessful attempt having been made to open a vein, and he had a warm bath. At this stage I first saw him: the remedies employed did no good; his cough and difficulty of breathing were on the 28th decidedly more croupy, and febrile symptoms ran high. I directed twelve leeches to his throat, a blister to the top of sternum and lower part of throat, rubbing in very assiduously of mercurial ointment on several parts of the surface; inhalation of vapour of water, and four grains of the sulphate of copper in an ounce of water, to be followed with a quarter of a grain of the sulphate rubbed up with ten grains of sugar every two hours.

30th.—The four-grain doses of sulph. copper caused severe vomiting, followed by some slight relief, but no very decided improvement: it was carefully administered every two hours. Cont.

June 1st.—The sulphate has been continued for two days; dose occasionally increased to one grain every two hours; sometimes it seemed to cause vomiting. No improvement, cough more frequent, sound of it like barking of a dog, and his breathing is quicker and more difficult; a whitish coating over all inside of throat and fauces; tongue covered with white spots of aphthous character; resonance of chest natural; vesicular respiratory sound gone on right side,

bronchial breathing still heard. Early on 31st. observing but little improvement from *S. cupri*, I thought it prudent not to rely on it alone, and proceeded to the administration of calomel and opium; the sulph. of copper was also continued most regularly: gums are this morning obviously affected by the calomel and inunction.

Cont. *S. Cup. et. Cal. et Op.*

5th.—Aggravation of every symptom: thirst, heat, and dryness of surface: crepitant rattle on right side; percussion natural, or nearly so; tongue covered with innumerable white spots. Is obviously sinking; pulse at wrist gone; eye often fixed; cough gone; voice hoarse or whispering; breathings thirty-six in minute; frequent vomiting; fluid vomited sometimes like prune-juice, but devoid of all smell: restlessness and jactitation.

6th.—Mustard poultices were applied to feet; attempts to give stimulants caused great distress, nearly suffocating him: an attack of convulsions at one A. M., on the cessation of which he seemed much exhausted. Died in twenty minutes thereafter. I need not detail the interesting morbid appearances presented at the post-mortem inspection, though I purpose doing that at another time, as my present object is to speak of the inefficacy of the much lauded *S. cupri*; in another case, I gave it without any other internal medicine.

The case came under my care pretty early in its progress, but the croup was unequivocally formed before I was called; after copious bleeding, general and local, I gave the sulphate, as directed by authority, continued it steadily, and gradually increased the dose. Blisters were applied to the throat, after leeches to the nucha and superior part of chest. I could not perceive the least benefit from the remedy: it caused vomiting at first, the dose being four grains. From a failure of this remedy in a previous case or two, I would not have felt myself warranted in trusting to it, or prosecuting my trial any further; but I justify myself on the grounds that the sulph. cupri may be administered along with the measures in which I have most reason to repose confidence, viz., bleeding, local and general: even these, I acknowledge, have too often failed: but I contend that my experience does not shew that they will derive any increase of power from the remedy proposed—the sulph. cupri; a drug which has failed most egregiously

in my hands. It might be said that I should have had recourse to mercury, a remedy, we are told, enjoying high consideration and repute. On this last point I find practitioners entertaining most opposite opinions, which, from their very contradictory character, neutralize each other, and leave the inquirer to the results of his own proper experience as his guide. I am sorry that I cannot offer my testimony to its efficacy. At the close of a very interesting and fatal case, in which every effort was made that united diligence and skill could accomplish, I find amongst my remarks the following:—"It has been supposed that in those cases in which mercury has failed to cure the disease, that it either had not time, or that it could not affect the system: I have seen it fail in more cases than this, in which it had decidedly produced its peculiar action, and my faith declines daily in its efficacy." 12th of Feb. 1836. In another case, "The gums were rapidly and decidedly affected by assiduous inunction of ungt. hyd. fort., and by calomel with opium, yet the result was fatal, and adding another to my former list of cases, shewing the want of efficacy in the mercurial treatment." I have of late years given an opiate along with the emetic, at the beginning of the disease, and have reason to think highly of the practice. To an infant ill of the disease in question, I give a solution of tart. antimon.; say four grains of the tartrate dissolved in three ounces or three ounces and a half of water, with an ounce or half an ounce of the syrup of poppy, to make up a four ounce mixture: of this I give from half an ounce to an ounce, every fifteen minutes, till free vomiting be induced. I have lately used the solution of one grain to the ounce, and added to the first dose of it as large a dose as caution would permit me to give of the solution of muriate of morphia: the opiate thus given allays the irritation in the air tubes, is immediately followed by rest and sleep, during which the patient may be kept in bed, the best place for him; besides, sleep overpowers him, and the crying and fretfulness so common, and so injuriously irritating to the throat, is completely and happily prevented. I am quite confident that the constant crying of a child after an emetic, given without the anodyne, has frequently aggravated the irritation of the throat, and done much mischief, whereas the deep sleep into

which the opiate, administered at this time, throws the patient, insures exemption from this source of aggravation of the symptoms, and procures a truce with the disease. Nor do I think that the free perspiration which follows an opiate, particularly if bleeding be premised, and a warm bath employed, should pass unnoticed as one of the good effects of this piece of practice. I have also a strong impression that a large opiate in such cases, and in many cases of mucous inflammation, is an auxiliary antiphlogistic of great power. In a case now under treatment I have derived much benefit from opiates: a very stout boy, of three years of age, who was seized, along with a brother, with deep lividity, swelling and pain of fauces: no febrile symptoms; soon the inflamed fauces became covered with a whitish layer, and the larynx became affected in both; one sunk, and died in a most unexpected manner, unexpected by either practitioner or parents, who did not observe the danger, as the constitutional affection was not severe or urgent. The younger boy came under my care, and to him I steadily administered the sol. of muriate of morph. with a most soothing effect; good nights, and days free from the jactitation and distress before experienced. An emetic* with an anodyne admixed in this case brought away the layer of lymph from the fauces with great relief to the breathing and general distress. The parts from which the layer came away presented a very fiery red ulcerated or abraded appearance, and new but very thin patches of lymph formed on them. He has been benefited by touching these parts with equal parts of syrup and mucilage, sharply acidulated with muriatic acid: he has had wine, beef tea, and ale, as he prefers it; and the manifest improvement, together with his having weathered nearly three weeks, encourages us to hope the parents will be spared a double bereavement. With your permission I shall transmit you my notes of a few causes of croup, which I trust may be practically useful, though devoid of any great novelty.—I am, sir,

Your most obedient servant,

ALEX. J. HANNAY, M.D.

Prof. of Physic, Andersonian University, Glasgow.
June 17, 1840.

* I am bound, in candour, to say, that the emetic employed in this case was the sulphate of copper.

A CASE OF CRANIOTOMY.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case of difficult labour, which occurred in my practice lately, arising from a hydrocephalic head, worthy of a corner of your valuable journal, you will oblige me by inserting it.—I am, sir,

Yours respectfully,

R. ROBERTSON,
Lecturer on Midwifery, University
and King's College.

Aberdeen, June 14, 1840.

On Sunday, the 3d of May, 1840, about ten p. m. I was sent for to see Mrs. McDonald, a poor woman, a patient of my Lying-in-Dispensary. About half-past ten p. m. I visited her, in company with Mr. Shearer, one of my senior pupils, and found her lying in bed; she stated that it was her eighth pregnancy, that she had always previously had natural and easy labours, and had been attended in all her deliveries by a midwife; that she had sent for me on account of her having a presentiment that all was not right with her; and that she felt not as she used to be in any of her former pregnancies; and she told me likewise that she believed she would die before she was delivered. She had been in rather bad health during her present pregnancy; and before my arrival, according to her account, the membranes had ruptured. On making examination, per vaginam, I found the os uteri open to admit two fingers, and the head presenting; the parts of generation moist, from the oozing away of liquor amnii. The pains which she experienced in the abdomen and back did not seem to affect the os uteri in the least, so that after waiting two or three hours in attendance upon her we left her, as she was inclined to sleep, and gave instructions to be sent for when she grew ill again. Accordingly I was sent for on Monday (next day) about five o'clock p. m. Being then in the country, my brother saw her along with the pupil who had visited her with myself the night before; they were informed that she had no pains till afternoon, when they came on very violently; and on making an examination, per vaginam, the os uteri was found dilated to the size of half-a-crown, soft and easily dilatable. The bowels had been open during the day.

She now became so unmanageable that she was continually getting out of bed, and at one time standing on the floor, and at the next tumbling into the bed, and tossing about in all manner of ways, so that they deemed it proper that I should be sent for. Having just arrived from visiting a patient in the country about seven P. M. I went along with the messenger to see her, and found her rolling about in bed, and it was with the greatest difficulty and persuasion that I could get her to lie still for a few minutes till I made an examination: on doing so I found the os uteri dilated to the size of a crown, soft and lax, the occiput presenting, and in the absence of a pain, by carrying my hand into the vagina, I was enabled to get my fingers higher within the pelvis, and make a more accurate examination of it than I otherwise could have done. There was no deformity existing any where, but I could feel the head completely filling the brim of the pelvis, and only a small part coming down, which was the occiput, the greater part remaining above. Her countenance was haggard and wild, her eyes staring, and altogether she had the appearance of a person in a violent fit of mania; her pulse was about 120, skin hot and dry, great thirst, and was constantly getting up to make her water, which she did freely. As the os uteri was not dilated to such a degree as to admit of my assisting her in any way, and as the head was the presenting part, I thought it proper to wait for some time before interfering, and more particularly as it was so difficult to confine her in bed. I may state also that she was permitted frequently to get out of bed, but when up, she could neither stand nor walk, and if not held by an assistant was in danger of falling down. Things continued in this state for a few hours, when I got leave again to make an examination, and found the os uteri only a little more dilated than it was when I examined last: I therefore dispatched my brother to a neighbouring medical friend, whose assistance I wanted; but before his arrival our patient became quiet, and allowed me to do what I pleased to relieve her: she seemed to be completely exhausted, with the strong pains and excitement which she had endured; and finding it was impossible to resort to the use of the long forceps, as the os uteri was not sufficiently dilated to admit of their application, I therefore resolved to

have recourse to the perforator. I had less hesitation in doing so, as our patient informed me she had not felt the movement of her infant for the last twelve hours. There being no time to lose, as she seemed so much exhausted, I introduced the perforator in the space between the os occipitis and the ossa parietalia, being the most depending part of the child's head; when about four pints of clear serous fluid issued out: the bones of the head collapsed, and delivery was effected almost immediately, by the unaided efforts of the uterus: the placenta followed soon afterwards. She was delivered about 1 A.M. on the 5th, just eight hours from the commencement of true uterine action. On visiting her again, at 8 A.M. (the same morning), I found her weak, and complaining of pain in the lower part of the abdomen, which was pretty much swelled, and tender to the touch. Pulse small and wiry, beating 120 in the minute; great thirst; the lochial discharge scanty; and, in short, she was labouring under all the symptoms of puerperal peritonitis of a low kind; and knowing, from what she had already suffered, that she would not be able to stand general depletion, I ordered a dozen and a half of leeches to be applied to the lower part of the abdomen, the belly to be fomented when they came away, and warm cataplasms to be applied afterwards. She was ordered likewise an ounce of castor-oil. In the afternoon (the same day) I found that the leeches had bled well, but the bowels had not been moved, and that the pain and tympanitic state of the abdomen still continued. She was then ordered a scruple of calomel and a grain and a half of opium; likewise to have an enema of an ounce of castor-oil, and an ounce of oil of turpentine. On visiting her again in the evening, I found her much the same as I left her; the bowels had not been relieved: I therefore ordered her to have the enema repeated, and to take some pills of four grains of calomel and half a grain of opium in each, every three hours. Next morning (the 6th) I found her no better, still complaining of pain in the belly, great tenderness on pressure, and swelling of the abdomen; countenance collapsed; pulse small and quick, about 130 in the minute; great thirst and vomiting; skin hot and dry; lochial discharge continuing but scanty. Ordered her to have some warm oil of tur-

pentine to be rubbed into the abdomen, and to continue the pills.

At 1 p.m. (same day) visited her, in company with my friend, Dr. Kilgour, and found her in the same state as at my last visit, vomiting every thing she took into the stomach. Bowels had not been opened; she was therefore ordered a scruple of calomel and two grains of opium. The turpentine had not been rubbed into the abdomen, neither would she hear of a mustard cataplasm being applied, which was ordered. Towards evening a violent purging set in, and she sunk about 10 p.m. the same night.

Autopsy, 12 hours after death.—On opening the cavity of the abdomen, the usual appearances of puerperal peritonitis were found, but the inflammatory action had been mostly confined to that part of the membrane covering the bladder and uterus. The uterus was the size that it usually is about the fourth month of utero-gestation. The peritoneal membrane covering the anterior and posterior surfaces of it, very much inflamed, and of a deep scarlet colour. Upon making a section, the parietes were found to be about an inch thick, and solid; the inner surface covered with dark blood, and containing small coagula, which, when washed out, presented a mottled red appearance; the fallopian tubes and the broad ligaments presented a dark livid colour; the bladder was of the same appearance, but empty.

REMARKS.—In this case, peritonitis had set in on account of the pressure which the neck of the bladder and parts within the brim of the pelvis had suffered during this short but unusually hard labour; and there is not the smallest doubt, in my mind, that had the perforator been resorted to much earlier in this case than was deemed proper by me, under existing circumstances, the poor woman would likely have been saved a great part of the suffering which she endured during labour, and all that she suffered afterwards, and might have been still spared as a blessing to her family. On account of the liquor amnii being discharged before I saw her, the uterus had acted so violently from the commencement of real labour, that a constant pressure was kept up on the presenting part, which prevented me feeling any fluctuation in the head, although I could feel the bones of the fœtal head very wide apart

from each other, and kept me from defining accurately what was the real cause of delay. The case shews plainly the very great necessity that exists, in all cases where the liquor amnii is discharged early, and where there exists a disproportion either in the capacity of the pelvis through which the child has to pass, or in the increased dimensions of the body which has to pass through, to relieve the soft structures within the pelvis from pressure as speedily as possible, to prevent consequences such as we have detailed in this case.

EXTRACTION OF PORTION OF CATHETER FROM BLADDER.

To the Editor of the Medical Gazette.

SIR,

IN YOUR GAZETTE of June 5, a case is related of extraction of a pencil from the bladder; and several cases are upon record in which pieces of catheter, &c. have been, at different periods from their introduction, successfully removed from the bladder and urethra. The case which I now send you for insertion in your valuable hebdomadal, is chiefly remarkable for the length of time which elapsed before the foreign body was extracted.—I am, sir,

Your obedient servant,
T. C. BUCHANAN.

Gloucester, June 22, 1840.

A. B., æt. 40, valet, was admitted under my care into the Gloucester Infirmary, Nov. 24, 1836. He stated that while he was under treatment for stricture of the urethra in the preceding September, as an elastic gum catheter was being withdrawn, it broke, and about three inches of it were left in the passage, near the bladder. After his admission into the Infirmary he was several times sounded, but no foreign body could be detected in the urethra or bladder; and as the patient was then suffering no inconvenience, he was allowed to leave the hospital Dec. 24, with directions to return immediately the catheter gave him any annoyance.

May 23d, 1837. — The patient returned to the Infirmary, and, on being sounded, a foreign body could be felt in the bladder, producing the sensation that may be supposed to be communicated by a soft substance, surrounded

here and there with calcareous deposition. The bladder was at this time in a state of inflammation, and the urethra exceedingly irritable, so that it was judged more prudent to allay these before any operative procedure was resorted to.

June 19th.—The patient was about to be operated on as for lithotomy, but as the foreign body could not then be felt, the operation was not performed.

27th.—On proceeding to sound the patient, part of the catheter was felt in the prostatic portion of the urethra. The man was now recommended to have the catheter at once removed by operation, but he objected, and earnestly begged to be relieved by other means if possible. The plan of treatment, therefore, consisted in gradually dilating the urethra with bougies, the patient being directed to sit immediately after over warm water, and to retain his urine as long as he could, with the hope that the *vis a tergo* during its evacuation would propel the catheter forward. The urethra, however, was occasionally so obstructed, that the introduction of a small elastic catheter was necessary to draw off his urine till July 29th, when the piece of catheter appeared to have advanced as far as the bulb of the urethra, and the urine could be evacuated by the natural efforts. A small quantity of pus had, for some time, passed daily through the penis, but the man seemed to suffer very little irritation.

Sept. 10th. — Three-quarters of an inch of elastic gum catheter, as large as a No. 6 silver one, rough, and with some of the gummy part removed, were extracted, by passing into the interior a small elastic catheter, and then gradually drawing it forward, an attempt with forceps having previously failed. Another piece of catheter could be felt in the canal, but could not then be extracted, nor till Oct. 15th, when an inch and a half was removed in the following manner:—A small aperture was made at the very extremity of a small elastic catheter; a full-sized stilette was next passed down through the catheter, and made to protrude through the aperture at its extremity; the end of the stilette was then turned up, so as to form a little hook, which was drawn up close to the end of the catheter. The catheter was then introduced down the urethra, into the interior of the impacted piece, and the stilette was gently pushed

on, and moved about, so as to fix its little hook into the side of the impacted portion, and, after a short time, a sufficient hold having been obtained, the piece was drawn out. In the evening another piece, the same length as the former, being the eyed or vesical extremity of the catheter, was also extracted in the same manner. The testicle was swelled for a few days afterwards; but the swelling gradually subsided, and the patient was shortly discharged, completely cured of his strictures, and suffering no injurious consequences from the detention, in his bladder and urethra, of more than three inches of elastic gum catheter, for upwards of twelve months.

CASES ILLUSTRATIVE
OF THE
POISONOUS AND INJURIOUS EFFECTS OF THE HYDRIODATE OF POTASH AND IODIDE OF STARCH.

BY J. ADAIR LAWRIE, M.D.

Surgeon, Glasgow Royal Infirmary; Glasgow Lock Hospital, &c. &c.

I HAVE for some time been aware that the preparations of iodine produce effects on the mucous membranes of the eyes and air passages not hitherto, I believe, noticed. Fatal consequences having in two instances ensued, I think it my duty to make the details public. I shall give the cases in the order in which they occurred in private and hospital practice.

CASE I.—Mr. —, November 1838. Had been for some time under my care for secondary syphilis, affecting the skin, mouth, and throat. Mercury, in various forms and very minute doses, had been tried, but he was so peculiarly susceptible of its influence that I was obliged to lay it aside. I prescribed $2\frac{1}{2}$ grains of the hydriodate of potash daily.

He only took three doses ($7\frac{1}{2}$ grains). The last, which he swallowed immediately before going to bed, left a disagreeable dryness and irritation in his throat. He awoke during the night, with great difficulty of breathing and loss of voice. I saw him early in the morning, with all the symptoms of severe spasmodic croup. Immediate counter-irritation to the throat, warmth, and sulphuric ether with morphia, gave instant relief. The symptoms passed

off in the course of the day, and did not return. This gentleman had never had any similar attacks, and is now in good health. He felt certain that the hydriodate was the cause, and declined continuing it.

CASE II.—Mr. —, January 1839, was under treatment for the sequela of an inflammatory pulmonary attack. I prescribed hydriodate of potash in a form which I very frequently employ.

R Potass. Hydriodat. ʒj.; Infus. Quass. lb. j. solve; S. æger, ʒj. bis in dies.

He had not taken one-half of the mixture in the above dose, when I was sent for to see him during the night. He said he had been suddenly seized with excruciating headache, which he likened to a wedge driven from between his eyes back to the base of his skull; acute pain in his eyes, with the most profuse secretion of tears I ever witnessed, and intense pain in his side, which was swollen, and from which clear serous fluid ran in a continuous stream. I have known this gentleman from his boyhood, and have met with few men of greater courage or power of enduring pain, and I am certain his suffering must have been exquisite. I immediately gave a saline purgative, and applied leeches to the mucous membrane of the nostrils. The leeches bled freely, the relief was almost instantaneous, and next morning the symptoms had disappeared. He was very anxious to continue his "biters," having felt his appetite much increased during their employment, but to this I would not agree. His general health is now good.

CASE III. occurred in the Infirmary. —, admitted into Ward 12, May 10, 1839, for a cancerous ulcer towards the root of the tongue.

11th.—He was ordered ʒj. of the iodide of starch (each drachm containing gr. j. of iodine) morning and mid-day, and eight grains extract of hyoscyamus at bed-time.

16th.—Felt unwell yesterday, without any local ailment, and was directed to take half the quantity of the starch. Early this morning was seized with dyspnœa, which is now very urgent. Countenance sallow and anxious; pulse intermittent on right side of neck, extending downwards from angle of jaw. There is considerable firm circumscribed swelling, apparently not inter-

fering with the larynx or trachea. To this 12 leeches have been applied. On right side of chest percussion is dull, especially posteriorly. Respiratory murmur throughout feeble, and in front there is loud mucous rale. Left side is similarly, but less severely, affected. The medical attendants being in the house at the time, I requested their opinion as to the propriety of tracheotomy. The state of the lungs appeared to them to forbid its employment, and an emetic was recommended, which acted freely, and brought away a considerable quantity of viscid mucus, with relief. In the evening his pulse flagged, and he was ordered wine. At 10 p.m. the dyspnœa increased, and at midnight he died suddenly. The relations obstinately refused to allow his body to be opened.

CASE IV.—Robert Boag, æt. 49, Ward 12, was admitted January 13th, 1840, for phagedæna of the veins; mild measures were tried for some days, but the ulcer continuing to extend was freely and repeatedly cauterized with strong nitric acid, and he was ordered ʒss. of the hydriodate three times daily: the sore immediately improved, the sloughing ceased, and it healed rapidly.

Jan. 8th.—Has taken ʒviiss. of the hydriodate; complains of pain in both eyes, hoarseness, pain in his chest, cough, and slight difficulty of breathing: the eyes exhibit acute conjunctival congestion, submucous infiltration, and contracted pupils; and the characters of the respiration are those of the subacute bronchitis; urine impregnated with iodine: the hydriodate was immediately omitted, the symptoms gradually subsided, and on the 15th he was dismissed cured.

CASE V.—E. L. æt. 30, was admitted into the Lock Hospital, May 22d, 1840, for sinuses after buboes, and secondary ulcers on thighs; she was ordered the infusion of quassia with hydriodate, as for Case Second.

May 31st.—A profuse papular eruption has appeared on face; sores improved.

Omitt. Hydriod.

June 7th.—Soon after last report eruption disappeared, and hydriodate was repeated; eruption almost immediately returned, and is now profuse.

Omitt. Hydriod.

June 8th.—Complains of sore throat,

but no redness or swelling discoverable.

June 9th.—During the night was suddenly seized with acute dyspnoea and hoarseness; pain on pressing trachea, and swelling and pain inside of right submaxillary gland. Pulse full, 103; she was immediately bled to faintness, 12 leeches were applied to larynx, and tartar emetic in full doses given internally. I saw her at eleven forenoon, and immediately determined on opening the trachea, and asked the assistance of Dr. A. Buchanan. On his arrival the symptoms appearing somewhat alleviated, we agreed to delay for an hour or two, and she was left in charge of Mr. Roe, the clerk of the Hospital, with directions to send for me the moment the dyspnoea became in the least aggravated. At three o'clock, about an hour and a half after I had left the hospital, she died almost instantaneously.

Inspection.—The right submaxillary gland was enlarged, with incipient purulent infiltration into the surrounding cellular tissue, especially towards larynx and trachea. The mucous membrane of the upper part of the larynx, rima glottidis, and epiglottis, oedematous. The mucous membrane of the trachea and bronchial tubes generally was nearly natural; the right lung posteriorly was heavy, and acutely congested; the left was similarly, but less severely affected: there was no exudation of lymph from the mucous membrane of the inflamed parts.

There can be no doubt that my first impression, as to the necessity of immediate tracheotomy, was correct, and probably the patient was lost by the delay; at the same time I was not prepared for so very rapid a termination. The patient died within twelve hours from the first accession of the symptoms, and in despite of very active treatment.

I think I am justified in concluding that the above train of symptoms was caused by the iodides; I believe the observations are new; and my colleague, Dr. A. Buchanan, whose papers, in the *MEDICAL GAZETTE* (1836,) bear honourable testimony to the ability with which he has investigated this subject, tells me that he has never met with any such accidents; and I am not aware of any published statements containing similar cases.

Besides these more acute and dangerous effects, I may shortly allude to others, some of which have been frequently observed;—

First, an extremely disagreeable taste in the mouth: this is very frequently complained of, I have myself experienced it: I took the hydriodate some months ago as a tonic; it caused dryness in the throat, and so persistent and unpleasant a taste in the mouth, that I was glad to omit it: the taste continued for many days after the medicine had been given up.

Secondly, cutaneous eruptions. Dr. Buchanan (*MEDICAL GAZETTE*, October 1836,) says, "Dr. Lawrie has remarked that it is only in cases of syphilis that any eruption shews itself under the use of iodine." More extended experience has shewn me that I was wrong in this limitation: I have very frequently met with a papular eruption, where there was no possibility of venereal taint.

Thirdly, intense headache.

CASE VI.—John Carnot, æt. 50, admitted with extensive ulceration of the right hip. Feb. 14th, 1840. Ordered

Potas. Hydriod. ℥j.

15.—Since yesterday (almost immediately after taking medicine) intense headache, and to-day slight salivation and sore throat.

Omitt. Hydriod.

CASE VII.—Mr. J.—Chronic enlargement of right testicle from an injury. Among other remedies I tried gr. v. of the hydriodate twice daily. In two days he complained of severe headache; the dose was reduced to gr. iiss. The headache continued; the medicine was omitted, and the headache immediately left him.

4. Salivation.—This I have met with, but not so frequently as I expected.

From the above cases it would appear that the hydriodate of potash and iodide of starch are dangerous and uncertain medicines. I am, in my own mind, quite satisfied that they were the causes of death in Cases 3d and 5th. Their uncertainty, in a remedial point of view, is even more to be lamented than their danger. If they were unsafe in large doses, and safe in small, or if the disease for which they are exhibited, or the constitution of our patient, had any definite influence on their poisonous effect, they might be used with comparative impunity. As yet, however, I know of no criterion by which we can judge beforehand of their probable effect; that the quantity exhibited is no guide, I am very certain. Case 3d had only taken

one grain of the solid iodine twice daily for five days, when he died, while many of Dr. A. Buchanan's patients take *seventy-two* grains of iodine daily, in the same form, without any bad effects, for days and weeks together. Case 5th took five grains twice daily for a week, when she died; while Wm. M'Symont, æt. 50, Ward 7, with gangrene of the penis, took 3j. daily for eleven days, with apparently great benefit to his disease, and not one of its injurious effects. I have given it in double this dose, and known half an ounce given daily with impunity. I very much regret this danger and uncertainty. I consider hydriodate of potash as by far the best of our recent remedies, and have prescribed it more frequently than any other medicine. In future, however, I shall be more cautious in its employment. Every patient for whom it is prescribed should be frequently seen by his medical attendant, and should be warned to omit it whenever any of its constitutional effects appear. Case 5th teaches us to omit it when the papular eruption is profuse, and not to resume it. Swelling of the neck, hoarseness, and dyspnœa (Cases 3d and 5th), are most dangerous symptoms. For them I believe there is no remedy but tracheotomy, early performed, and on it I would place great reliance. Case 5th teaches us that delay is fatal; and I would not in any future case allow the state of the bronchial mucous membrane to deter me from its performance.

If the above observations are correct, it would further appear that these iodides exert their poisonous influence on the mucous membranes of the air passages, not as direct irritants, but indirectly through the circulation, in the form of acute inflammation. I have never seen them act as irritants to the gastro-intestinal mucous membranes, nor have I ever seen them produce emaciation, atrophy of the mammæ and testicle, hectic, and those other symptoms described by various writers under the name Iodinia.

15, Moore Place, Glasgow,
June 25, 1840.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégér.”—D'ALEMBERT.

Odontography, or a Treatise on the Comparative Anatomy of the Teeth; their physiological relations, mode of development, and microscopic structure in the vertebrate Animals. Illustrated by upwards of 159 plates. By RICHARD OWEN, F.R.S., &c. Part I., containing seven sheets of letter-press, and fifty plates, from drawings by Mr. T. Dinkel, and engraved by Mr. L. Aldous. Baillière, 1840.

[2d Article.]

WE cannot but congratulate our readers and ourselves, on the various excellent results which are likely to flow from our late review of the “*Odontography*” of Mr. Owen. No sooner had that gentleman perused it, than he indites a very peremptory epistle to Professor Phillips, the Secretary of the British Association, of which the object appears to be, to put a stop for ever to the practice of modifying, either by addition or omission, the reports of papers read at the British Association. As Mr. Owen's good will and pleasure are here in perfect accordance with right and justice, we sincerely hope that they will be implicitly obeyed. We were not previously aware that such an abuse existed, and Mr. Owen has certainly the incontestable merit of having first called public attention to it. Mr. Nasmyth, however, in his letter of last week, has shown the evil to be so glaring, and so evidently unjust in its consequences, that we can scarcely consider any terms in which it is censured and denounced as too violent. We therefore second his appeal with all our heart, and wish him every success in his laudable exertions to remedy abuses, which certainly no person is more capable of pointing out, and of tracing back to their motives. We look forward with confident pleasure to the appearance of a new edition of the Archives of the Association, to be published under the auspices of Professor Owen. Doubtless, as he has been pleased to request Mr. Phillips to restore, in Mr. Nasmyth's abstracts, certain passages from the report of the Literary Gazette, which it suits him to

presume have been omitted with a fraudulent intention, he will not merely request, but peremptorily enjoin that gentleman to strike out of the abstract of a paper of his, entitled "On the Structure of the Teeth, and the Resemblance of Ivory to Bone," &c., read in August, 1838, certain passages which are not only wanting in the reports published in the weekly journals at the time, but which actually could not have been written until more than six months after they are represented as having been read!!

Such a revision of the Transactions, however, would not in the slightest degree affect the charge which, in our article on his Odontography, we brought against Mr. Owen. There is no necessity, whatever, for our flying to the "Transactions" for evidence against him. In a letter published last week in this journal, we observe that Mr. Nasmyth claims some allowance for the inaccuracies which unavoidably creep into reports of the papers read at the British Association, made so hastily and under such disadvantageous circumstances, as those in the Literary Gazette and Athenæum: we think that there was no need for him to have done this; at any rate we have compared the corrected edition of his paper in the "Transactions" with the uncorrected one in the weekly journals, and find that there is really no essential difference between them, with respect to the matter they contain; in point of form, we need not say, that Mr. Nasmyth has taken care that his own report should be more correct, definite, and concise, than the others. We shall therefore proceed, with merely the Literary Gazette and Athenæum in our hand, to repel all Mr. Owen's insinuations; to confirm, indisputably we think, the charge we did not at first bring against him, without due consideration of all the bearings of the question, and we shall, at the same time, adduce fresh evidence, which is equally, if not more conclusive, than that which we have already published. Our readers will thus perceive, that Mr. Owen's letter to his secretary, to put a stop to proceedings which in this case had never commenced, as well as a considerable part of his address to ourselves (in which he is at the pains of imagining a case that does not exist), have no reference to the point at issue, and would, indeed, be utterly superfluous and fruitless, were it not

that they may possibly contribute to the suppression of the odious practice of interpolation, which was so flagitiously carried on in 1839. However, leaving Professor Owen to prosecute this interesting subject, we proceed at once to address ourselves to the immediate question.

In reply to our review, Mr. Owen comes forward with a bold face, and says that he, on the 16th of December of last year, was the first physiologist to teach that the ivory of the tooth is formed by the transition of the pulp into an ossified state, and not by the simple secretion of ossific matter on the surface of the pulp—the old theory of the process, which previous physiologists, including, he says, Mr. Nasmyth, had adopted. This new light, according to Mr. Owen, first shone upon the French Institute on the 16th of December last, from a memoir of his entitled "*Recherches sur la structure et la formation des dents des squaloides, et application des faits observés à une nouvelle théorie du développement des dents.*" Now let us see how these assertions square with the tenour and details of the reports of Mr. Nasmyth's papers, published three months previously, viz. on September 15th and 21st, 1839. Mr. Owen's whole position rests upon the assumption that Mr. Nasmyth believes the ivory to be formed by ossific secretion from, and not by an ossific transformation of, the pulp. Now what say the following passages?

"Mr. N. next proceeded to inquire *how the transition into ivory is effected?*" (Lit. Gaz. No. 1183, p. 597.) "A comparison between the superincumbent perfect ivory and the formative surface of the pulp beneath is always easy, because portions of the former at an early stage, at any rate, remain adherent to the latter, and fragments of the dental bone are strewn over it, more especially in human teeth. The cellular conformation of these fragments is always evident; and in size and appearance they are perfectly accordant with the *cellules of the pulp.*" (Lit. Gaz. p. 598.) It will scarcely be believed that Mr. Owen, who complains so dolorously of mutilated and unfair quotations, should actually have cited a part of the above passage, viz. as far as the semicolon, as a complete statement, and as shewing that Mr. Nasmyth main-

tains that the ivory is secreted on the surface of the pulp, instead of being constituted by ossific matter deposited in its cells, which the conclusion of the sentence proves to be Mr. N.'s opinion. We quite agree with Mr. Owen that such tricks are indeed stale, and ought to be discarded from all legitimate controversy. By the formative surface of the pulp, Mr. Nasmyth evidently does not mean a surface from which a mass of ossific matter exudes, or he would not go on to say that the cells of the ivory correspond in size and appearance with the cells of the pulp: he means that the surface of the pulp undergoes a certain change previous to the formation of ivory by the deposition of ossific matter in its cells; and this change, which he has elsewhere fully described, he distinguishes as formative. Mr. Owen transmits his order to Professor Phillips, to see whether the word "formative," occurring in the report in the Literary Gazette, is retained in the abstract, presuming, of course, that it is omitted. We beg to inform him, that on turning to page 9 of Mr. Nasmyth's abstract, he will find a distinct description of "the formative surface of the pulp."

To proceed further with our evidence that Mr. Owen's memoir of Dec. 16th is not, as he would have us believe, the first announcement of the "*nouvelle theorie*" that the ivory is formed by the transition of the pulp to an ossified state. At page 598 of the Literary Gazette for September 21, we find Mr. Nasmyth stating that, at an early stage of ossification, "*the different layers of cells will be seen, and the transition into ivory may be observed.*" A little further on he observes, that "*the manner in which the osseous matter is deposited in the cells of the interfibrous substance, he had not been able to discover.*" In the Athenæum for Sept. 14, 1839, p. 707, Mr. N. says, "*The cellules of the fragments of the ivory, which are found scattered on the pulp, resemble exactly in size and appearance the cellules of the latter when in a state of transition.*"

Surely we need proceed no further. We must by this time have satisfied every candid and impartial mind. Mr. Owen may carp at the phrase "formative surface"—may make objections to the terms "deposition" and "layer," &c.—may try to prove again and again

to Professor Phillips the necessity for the restitution or omission of this or the other expression, but he will never succeed in convincing a single rational being that Mr. Nasmyth, in the papers from which we have quoted above, teaches the old doctrine of secretion or exudation of the ivory from the bulb, in contra-distinction to Mr. Owen's pretended "*nouvelle theorie*" that the ivory is formed by the transition of the pulp to an ossified state. As we have commenced the chain of evidence, however, we will not omit any of the links, though all may not be absolutely necessary to our argument. Not only has Mr. Nasmyth, as the above quotations shew, argued the transition of the cells of the pulp into the cells of the ivory, but he has done the same with respect to the fibres. It appeared to him, he says, that the fibres of the ivory are nothing else but the frame-work of the reticulations (which he has described as being presented by the surface of the pulp in its formative or transitive condition): at any rate, he continues, "*The diameter of these fibres of the reticulations is precisely that of the fibres of the ivory. The fibres of the ivory are frequently very spirally curved, like those of the pulp.*" (Lit. Gaz. p. 598.) Do not all these observations tend to establish the theory of transition? Can they by any ordinary distortion be interpreted in favour of a doctrine the very opposite to that of transition? Is Mr. Nasmyth to be rudely dragged before Professor Phillips, and made to do penance at the instance of the great ante-interpolator, Owen, for having dared to insert in his abstract that the ivory is neither more nor less than the ossified pulp? We confidently leave these questions to be answered by any one who has devoted half an hour to the perusal of the reports of Mr. Nasmyth's papers.

Mr. Owen asserts that all Mr. N.'s observations go to confirm previous researches—to support the old view of the formation of the ivory. If Mr. Nasmyth, who, as the author of these observations, ought, with all due deference to Mr. O., to have some knowledge of their bearing and tendency, is to be credited, they are to be viewed in an exactly opposite light. In the Literary Gazette for Sept. 21, p. 598, we find the following passages:—"He allowed that these views

of the formation and structure of the teeth are both *bold* and *novel*. He fully recognized and respected the authorities ranged in support of *very different* theories, though he still ventured to think that, were not his limits confined, he could easily show how what he held to be fallacies and incongruities have arisen." We are afraid this cannot but tell against the novelty of Mr. Owen's "theorie" of the 16th of December.

No statement, however cautiously and leisurely drawn up, of recent complex microscopical investigations, in a most delicate and difficult department of anatomy, can be rendered proof against all cavils and quibbles, especially when started by a gentleman so versed in "physiological subtleties" as Mr. Owen, and followed out on one single point through an epistle of eleven columns of letter-press. How much more exposed to them, therefore, must be reports drawn up like those of the *Literary Gazette*! But it is extremely remarkable, and Mr. Nasmyth ought to esteem himself very fortunate in his reporter, that even in that journal, Mr. Owen can only fix upon one passage on which, by the aid of unfair juxtaposition (a practice stale at the commencement of his letter, but, as we shall show, very sweet before he reaches the end), to found, with any plausibility, the charge of inconsistency against Mr. Nasmyth. And even in this case, the discrepancy he has so exultingly detected is merely apparent—it is in the style and not in the matter—and will be dissipated by a simple explanation, as completely as all the other counts in Mr. Owen's charge have already melted into air. The tenour of Mr. Nasmyth's views has been sufficiently shown in the extracts given above. The theory of transition is expressed or implied throughout the whole paper. When, therefore, towards the end, the reporter says, "Schwann regards the dental substance as the ossified pulp, whilst Mr. Nasmyth's observations lead him to conclude that the cells of the ivory are altogether a distinct formation"—the natural inference is, that he refers to some peculiar theory of Schwann, from which Mr. N. differs. And this, though Mr. Owen finds it convenient to omit all mention of it, was actually the case. "Schwann acknowledges," Mr. N. goes on to say, "that he is ignorant of the

process of transition, and he regards *the dental pulp as a simple cartilage*." This Mr. Nasmyth denies; he does not believe, with Schwann, that the pulp is converted into ivory in the same way that cartilage is converted into bone; to the view of its ossification, therefore, in Schwann's sense of the word, he is altogether opposed, believing that a distinct formative process takes place at the surface of the pulp prior to the conversion of its cells into the cells of ivory. In the report published in the *Athenæum*, which was furnished, it appears, by Mr. N. himself (see his letter of last week), we find the following notice of this subject:—"Mr. Nasmyth concluded his paper by a notice of Schwann's work on the cellular character of primary tissues, dwelling on his views of the cellular organization of the pulp, from which his own were essentially different."

Indeed, the attempt to deduce from this isolated and misquoted phrase of the reporter of the *Literary Gazette*, on a controversial point, in opposition to the whole tenour of Mr. N.'s paper, that that gentleman is in favour of the old view of the formation of the ivory by exudation, is the very height of absurdity, or at any rate, to use Mr. Owen's own words, of "physiological subtlety." We cannot tax the patience of our readers by discussing whether the reporter would have been more correct in making Mr. Nasmyth speak of the deposition of ossific matter in the cells of the surface rather than on the surface of the pulp, for having already quoted sufficiently from the report of Mr. Nasmyth's paper to convince every right-minded person of its real spirit and tendency, we shall leave this, the last mighty matter of detail which Mr. Owen has touched upon, to be discussed in another letter from him to the Secretary of the Association.

There are phrases in Mr. Owen's letter, from which we might infer that he is in favour of the old doctrine of dentification with quite as much justice as he has made that assertion with regard to Mr. Nasmyth: for instance, he says that his observations were a "subversion of the prevalent doctrine that the ossific matter of the tooth was deposited in thin layers on the surface of the pulp, a doctrine based upon *the well-known facility with which these layers can be detached*." (*MED. GAZ.* No. 655, p. 504.) At

p. 784 of the *Comptes Rendus*, also, he speaks of "la facilité avec laquelle on peut separer du bulbe sous-jacent la portion de la dent déjà solidifiée." From both these passages, when isolated, it might be inferred that Mr. Owen was opposed to the theory of transition: at all events, the subject has not been attentively investigated till of late, and hence is not so easily described as matters of ordinary anatomical investigation; it is, moreover, surrounded by no common difficulties, and Mr. Owen should have borne this in mind, and made allowance accordingly, instead of dilating on apparent contradictions of the reporter to the *Literary Gazette*; mutilating some of his passages, and attempting to pervert the sense of the whole report.

The researches of Mr. Nasmyth on the structure of the teeth have evidently been much more extensive and various than those of Mr. Owen, whose ignorance of some parts of the subject is such as to create no little astonishment; for instance, he confounds the well-known cells or corpuscles of the teeth, described by Retzius, with the peculiar cellular structure of the interfibrous substance, as described by Mr. Nasmyth: *but they are totally distinct from each other*, as every reader of the reports of Mr. N.'s papers in the *Lit. Gazette* and *Athenæum* will at once perceive. Hence, Mr. Owen's officious observation to Prof. Phillips (*MED. GAZ.* p. 505, note,) that Mr. Nasmyth's account of the discovery of the cellular structure of the interfibrous substance of the ivory should be omitted in the *Transactions*, in justice to Retzius, who singularly enough has never especially referred to the interfibrous substance at all, is neither more nor less than ridiculous. We advise Mr. Owen, who pounces so predatorially upon Mr. Nasmyth's papers, cutting away some parts, claiming the lion's share for himself, and offering a portion of the booty to Retzius, to wait until the Swedish Professor asks him for what belongs neither to one nor the other—a claim to a discovery which we are sure Retzius would be ashamed to make, though Mr. Owen would evidently be too happy to award it to him.

By no means can we excuse Mr. Owen's silence respecting Mr. N.'s researches, in his communication to the French Institute: even supposing the reports in the *Literary Gazette*

and *Athenæum* to have been not altogether clear to him, there was evidently sufficient allusion in them to the theory of transition, to demand a notice of them in a communication which was devoted to the propounding of a theory on that subject. And Mr. Owen's conduct, we think, admits still less of palliation, when it is recollected that he is an officer of the College of which Mr. Nasmyth is a member, and one of the Council of the British Association, of which Mr. N. is a fellow; and therefore should have been particularly careful not to pass over himself the claims to which that gentleman's "able" researches (for thus Mr. Owen has himself characterized them) had so justly entitled him. The truth is, however, that Mr. N.'s papers contain a mass of facts, the fruits of actual, careful, and extensive investigation, which, as they are both new, and established on indisputable evidence, cannot be diminished in value by the progress of time, whatever additional light may hereafter be thrown on the subject, and however it may suit the publishers of new theories to pass them over in silence.

It is in vain for Mr. Owen to deny the analogy which exists between many parts of his *Memoir* of December 16th, and the report of Mr. Nasmyth's paper, published September 21st; an analogy which cannot fail to strike even the most cursory reader. Let us, for instance, compare their respective microscopic observations on the structure of the pulp. "The unossified pulp," says Mr. Owen, in the *Comptes Rendus* for December 16th, "when examined under a strong magnifying power, consists of semiopaque polyhedral granules, or cells, suspended in a clear matrix, and the whole is enclosed in a tough transparent membrane which forms the outer surface of the pulp."

"On examining the internal structure of the pulp generally," says Mr. Nasmyth, in the *Literary Gazette* for Sept 25th, "the number of minute cells presenting themselves in a vesicular form is very remarkable; they constitute, indeed, the principal portion of its bulk. Those vesicles vary in size, from the smallest perceptible microscopic appearance, probably the ten-thousandth part of an inch in diameter to one-eighth of an inch, and are evidently disposed in different layers throughout

the body of the pulp." The outer surface of the pulp Mr. N. has more minutely described, as presenting a reticular character. We think that it would have been much better for Mr. Owen to have stated that he was ignorant of Mr. Nasmyth's previous researches, as he has done of Schwann's, than to have had recourse to his present defence.

As we have here mentioned the name of Schwann, we must observe, that, in his *Odontography*, Mr. Owen states, that at the time of the publication of that work, he was in ignorance of Schwann's researches on the development of the teeth; but he places himself in a very awkward dilemma by such a statement, inasmuch as Mr. Nasmyth, in one of his papers read at Birmingham, gave a full account of Schwann's labours on this subject, as is mentioned in both the *Literary Gazette* and *Athenæum*. In the former journal the account is reported at great length.

In conclusion, we beg leave to tender a word of advice to Mr. Owen, suggested by the manner in which he has approached, and seems inclined to carry on, this discussion. As if conscious of the weakness of his cause, he resorts at once to angry words, and such reckless abuse, as no prudent controversialist, much less a man strong in the consciousness of truth and in the justice of his position, would ever have recourse to. Instead of at once meeting the charge brought against him, he, in a great measure, diverts the attention of the reader from the real point at issue, by writing a long desultory letter to Prof. Phillips, on a subject, which, as we have shewn, has really nothing to do with the question; by bringing accusations against Mr. Nasmyth, all of which are groundless, and one of which not only misses its aim, but recoils with concentrated force on its author; whilst another (we allude to the pretended injustice to Retzius) would certainly cover him with shame for the ignorance of the subject on which alone it can have been founded, were it not that the multifarious nature of his pursuits may, in some degree, be pleaded as an excuse for his inaccuracies in a department of anatomy to which he can only have devoted a part of his attention, and for a very limited time. His influence and his reputation are both summoned to aid him in the struggle:

he omits none of the offensive and defensive manœuvres of unscrupulous literary warfare; and we see him resolved, if possible, to crush his adversary at all hazards, in order that a salutary warning may be held out to any one who may hereafter be tempted to thwart him in his career. To facilitate his escape from well-merited reproaches, he represents himself as an injured and long-suffering individual; he complains bitterly of stale juxtaposition and mutilation, and practises both in the most unscrupulous manner himself. Nay, he does more. Great as is his reputation, lofty as is his position, he does not hesitate to descend to making false quotations, in order to give an air of greater plausibility to his defence. At p. 507 of the last week's number of this journal, he manufactures what he is pleased to call Mr. Nasmyth's *emphatic statement* of September 1839, "that so far from being the ossified pulp, it (the dental substance) was altogether a distinct formation." In making this fabrication, he appears to have been assisted by a friend; and in order to give it greater weight, he takes the trouble to inform us that the character of that friend "is the very antipodes of impudence and duplicity." Now of this passage, which he gives as quoted from the *Literary Gazette*, p. 598, only the *last four words* will be found, on reference to that journal, to be correctly copied: *all the first part of the passage is the composition of Mr. Owen*. Mr. Nasmyth, by this perversion of his report, is made to say that the dental substance is altogether a distinct formation; whereas he never mentions the dental substance at all, and his real meaning evidently is, as we have shewn above, that the cells of the ivory have undergone a distinct formative process in their transition from the cells of the pulp. Such unfair and unworthy tactics must inevitably defeat the purpose for which they were adopted. Mr. Owen's unscrupulous violence, far from concealing, as he seems to calculate it may do, the weakness of his arguments, will only still further damage his cause in the eyes of every dispassionate reader.

MEDICAL GAZETTE.

Friday, July 3, 1840.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recusio."

CICERO.

MEDICAL REFORM IN IRELAND.

Our readers are aware, that on the perplexing subject of medical reform, we have always endeavoured to keep the just medium between the eager innovator and the sluggish conservative. The former imagines that evils inherent in human nature, or, at any rate, firmly entwined with the very frame-work of society, can be suddenly removed by a mere legislative enactment; the latter cries out, "whatever is, is right!" and would shrink from correcting the most notorious abuses, till reform comes, as Lord Chatham said, "with a vengeance, from without."

It is thus that while we look with a natural distrust on the non-faculty scheme of our English agitators, we commend the improved examinations of our medical corporate bodies; and it will not be too bold to claim our share in the great and indispensable reform which took place in the College of Physicians. Our Irish brethren, however, have grown impatient at these slow improvements; and, disdaining a bit-by-bit reform, aspire at once to a medical millennium.

It is now rather more than twelve months since we gave an account of the first assembling of the Medical Association of Ireland. Their first anniversary took place on the 27th of May. As on the former occasion, Mr. Carmichael's speech was the first and best of the day.

The people, said this eminent surgeon, have not yet come forward to petition parliament in favour of medical reform; yet it is their interest to do so, because

many men who call themselves physicians and surgeons are incompetent to the performance of their duties. Meantime, there are eighteen chartered corporations or colleges in the United Kingdom, empowered to grant licenses to practise; and these, instead of trying to encourage a maximum of knowledge in their candidates, try only to obtain a maximum of diploma fees for themselves; or, in the words of the ingenious President of the meeting, "exert a miserable rivalry, only in the accumulation of money." This would be a sad case, indeed, if true, as they say in America. We should almost despair of the reform of a profession whose leading members in the several corners of the British islands vied with each other only in opening the portals of their colleges on the easiest terms—where Aberdeen and Edinburgh, Oxford and Cambridge, London and Dublin, had no emulation save in the cheapness of their respective *asyla ignorantie*! "Come here," cries one, "and for ten pounds we will excuse you all the refinements of anatomy." "Nay," interrupts another, "*we* allow you to transpose the liver, like the imaginary doctor in the *Médecin malgré lui*, for the small charge of nine guineas."

The only example, however, of an examination lowered to meet the public demands, which is given by Mr. Carmichael, is that of the Irish College of Surgeons. It "maintained for many years a high character for the rigour of its examinations, which caused its diploma to be every where respected. But of late years it has been induced to swerve from the high tone it had adopted, and lower its examination to the level of the Colleges, otherwise it would have scarcely a candidate for its diploma—*Ab uno disce omnes*. (Hear, hear.)"

Never was a quotation more inappropriate, or a "hear, hear!" more indis-

criminative; for whatever the Irish College of Surgeons may have done, increase of severity, not of leniency, has been the general characteristic of the changes made of late years in medical examinations. We wonder that so sharp a man as Mr. Carmichael should not have heard what has been done by the University of Cambridge, and our London Corporations, the College of Physicians, the College of Surgeons, and the Society of Apothecaries. These are among the eighteen licensing bodies he speaks of, and they have all either lengthened the course of study required from their candidates, or made the examination more strict, or effected both these reforms. The University of London, too, is far from forming one at the Dutch auction imagined by Mr. Carmichael, where the eighteen licensing bodies contend to sell their honours to the lowest bidders in point of qualifications. In fact, we believe that several bodies besides those we mentioned, have raised their qualification, and we doubt if any one but the Irish College of Surgeons has lowered it.

Nevertheless, we are ready to admit that many of the eighteen bodies might raise their standard with advantage; and it is possible that some minor seats of knowledge still hanker after doctorial fees, and are unwilling to drive customers away.

Mr. Carmichael's remedy is to have only three licensing bodies, one in each of our three capitals, and to raise the standard of qualification to so high a pitch, as to thin the ranks of the profession. This would be pleasant enough for most of us, but what would be its effects on society? It does not require much foresight to be convinced that it would be an irresistible premium on amateur practice of all kinds; bonesetters, Lady Bountifuls, village wisemen, and uns graduated in Buchan's Domestic Medicine, would all walk an inch the

higher for it. It would be a partial return to the sixteenth century.

The plain truth is, that although we have an over-abundance of medical practitioners, if we measure their superfluity by their remuneration, we have scarcely one too many, if we regard merely the wants of the public. Even in this island there are numerous districts where there is no practitioner within a reasonable distance. Thus in South Wales it often happens that the nearest practitioner is fifteen miles distant; and "old women, or other uneducated persons who are supposed to possess skill, are usually employed in the most tedious cases of fever, &c."*

Nor is it necessary to go as far as Wales to witness a lack of medical advice. In Dr. Skrimshire's work on popular medicine, on which we commented about two years ago,† and which is addressed to his son, a clergyman in the Isle of Ely, he tells him that as he is situated in a populous village, some miles from a medical practitioner, he may expect to be frequently summoned to cases of accident or sudden illness, to consult with the friends of the sufferers, &c. So that even within seventy miles of London it may be usual to consult a gentleman whose knowledge of medicine is derived from a single duodecimo volume!

In Kilkenny, again, as we learn from Dr. Cane's speech at the meeting, there are no less than twenty practising quacks; these are "ignorant, pretending men — regular bone-setters, who earned from £50 to £100 a year each, by practising medicine, though there were many of them who did not know how to read. A great many of the surgical operations of the country are performed by these men," &c.

Now, the expectation is afloat that

* Extract from Mr. Edward Senior's report, in the report of the Poor Law Commissioners, 1840.
† Medical Gazette, August, 1838.

under the new and faultless system the profession and the legislature combined will be able to banish these interloping bone-setters, and also diminish the tale of regular practitioners. Vain hope! for as soon as the supply of surgeons is unequal to the demand, so soon will Kilkenny be invaded by another horde of cheap unlicensed operators. In other words, a fresh tax on the article will be an encouragement to smuggling.

So that here is obviously a social dilemma to be cleared up, not evaded. The medical practitioners of this and other countries are too numerous to be tolerably rewarded, but not too numerous to be employed; the profession would wish its ranks to be thinned, and its recompense increased, but then the battalions of rustic bone-setters will multiply. If, on the other hand, the present unbridled competition continues, medical fees will be lowered to the wages of day-labour.

The qualifications of medical candidates may be safely raised, with advantage both to the public and to practitioners; but it is impossible that this can be done so suddenly and severely as to make any perceptible difference for years to come in the serried ranks of our profession. Thus we agree with Mr. Carmichael, when he suggests that when the examination is on anatomy, a body should be placed before the candidate, and a knife put into his hand, and he should be desired to demonstrate such parts as his examiner may select; and a similar method might be pursued with chemistry and botany.

Another improvement suggested by Mr. Carmichael is the separation of the apothecary from the physician; in other words, he proposes that the prescriber shall not sell the drugs which he orders. This limitation is no doubt advisable; but the creeping in of the contrary custom in Ireland, in the present age, as in England 150 years ago,

is a proof that cheapness is imperiously demanded by the community. Mr. Carmichael says that the apothecary, having ninety-nine times out of a hundred the first possession of the patient, and professing to be as clever as the physician or surgeon, will keep the case; "assumptions like those, on the one hand, and *mistaken notions of economy* on the other, will keep the regularly educated physician and surgeon out of practice," &c. So that, after all, it is a question of economy, or, at any rate, of saving in the first outlay, which is shelving the physicians of Ireland in 1840, as it did those of England in 1690. Mr. Carmichael, indeed, says that the practitioner of five years' standing will not expect to be paid like one of ten years', nor he again like one of twenty; but, we would ask, are the physicians of Ireland ready to take crown fees? with them they are saved; without them they must prepare to follow their brethren in the ruling island.

Mr. Carmichael observes, too, that this mixed practice brings in its train an excess of physic; it "has induced a habit of inordinate dosing;" so that on the continent we are called the physic-taking English.

It is from this superfluity of drugging, he adds, that the homœopathists have perhaps acquired more character in the British dominions than elsewhere. The patient, overwhelmed by kilderkins of white and black draughts, gets well by "*Belladonna, x.*," *i. e.* by taking no medicine at all.

A celebrated practitioner, at a watering place in England, owes his renown to the same judicious plan, according to Mr. Carmichael. "Patients, in general, go to him fairly run by the quantity of medicine they have taken; he prescribes early rising, an early dinner on one plain meat," &c. In short, the patient gets well, the doctor rich and famous. There is some exaggerative

humour in this picture; yet it is doubtlessly founded on facts, and the physician deserves his praise. For though a patient "run down" by medicine will often be benefited by simply omitting all his drugs, yet this resource does not instinctively occur to every one, though, like Columbus's balancing of the egg, it is the easiest of all things when it has been shown.

Our Irish brethren have certainly the advantage of us in the constitution of their assembly. The presidency of Mr. Carmichael has given it a vigour and a vivacity not to be found in the British Medical Association; and the delegates from so many parts of Ireland bestow upon it, in some measure, the complexion of a national convention.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

June 23, 1840.

SIR B. C. BRODIE, BART., IN THE CHAIR.

A Case of Fractured Spine treated by Extension.

By HINCHMAN CROWFOOT, Esq. of Beccles.

THE patient was a coachman, and received the injury by driving a carriage under a gateway obstructed by a beam, by which he was bent almost double. The spinous processes of the 9th and 10th dorsal vertebrae were found, on examination, to be separated from each other much beyond their usual distance, the 9th being apparently forced forwards, whilst the 10th projected backwards. The bladder was paralysed, and there was a total loss of the power of voluntary motion in the lower limbs, with an equally complete abrogation of sensibility. Unwilling to leave the patient to his fate without some decided attempt to relieve him, the author resorted to the use of extension by means of pulleys, by which the deformity of the spinal column was evidently diminished, with the restoration, at the same time, of a small degree of sensibility. Voluntary power, however, was not at all restored. The most active antiphlogistic measures were afterwards pursued for a very considerable time, with the result that, in about eleven months from the accident, the patient was restored to the power of resuming his duty as a coachman.

The author considers the final recovery of the patient to have been chiefly due to the steadily-continued efforts to prevent or subdue inflammatory action in the injured parts.

A Case of Tumor in the Pelvis, impeding Parturition. By J. C. W. LEVER, Esq. Communicated by Dr. MERRIMAN, by whom a Postscript is appended.

The patient who was the subject of the affection here described had been many hours in labour when Mr. Lever was called to see her. Finding a tumor as large as a foetal head occupying the middle of the pelvic cavity, and obstructing the progress of the labour, the author punctured it with a lancet, and gave exit to upwards of a pint of an oily fluid, when the tumor collapsed. The pains continuing, the head of the child rapidly advanced, and birth was effected in two hours from the operation. The case here related bears a close resemblance to some of those described by Dr. Merriman in the tenth volume of the Society's Transactions.

A Third Memoir on some Principles of Pathology in the Nervous System. By DR. MARSHALL HALL.

The first of these memoirs was entitled, "On the Condition of the Irritability of the Muscular Fibre in Paralytic Limbs;" the second, "On the Reflex and Retrograde Actions of the Spinal Marrow."

The present memoir treats of "the Influence of Volition, of Emotion, and of the Vis Nervosa," and completes the account of the sources of emotion as exhibited in the various diseases of the nervous system.

An attack of complete hemiplegia leaves the limbs of the paralysed side, but especially the arm, deprived of voluntary motion; the patient generally carrying that arm, the rest of his days, in a sling. Immoveable by volition, however, the arm is moved energetically on any occasion of emotion—any hurry, alarm, surprise, &c. The source, the seat of volition, is cut off from the affected limb; that of emotion still remains in connection with it: these are therefore different, and it seems probable that that of the former is placed higher up than that of the latter; the two occupying the *cerebrum* of the *medulla oblongata* respectively. But besides the occasional effect of emotion, there is a constant influence of the *vis nervosa*, seated in the spinal marrow, inducing contraction of the fingers and of the wrist of the hemiplegic hand and arm.

These are facts of clinical observation, valuable as facts, and in their relation both to physiology and pathology. Who does not now see the distinction, for ex-

ample, between volition, emotion, and the *vis nervosa*, as sources of muscular motion?

In fact, an attack of decided hemiplegia, severs and dissects, as it were, the cerebral from the true spinal system. The morbid and deleterious effects of emotion, in the latter case, is emphatically set forth; the author affirming that the intrusion of visitors, &c. is frequently the cause of a fatal termination, which might probably have been averted by seclusion in a still dark room, free from the visits of strangers.

The author proceeds to speak of the effects of emotion in cases of stammering, of chorea, of paralysis agitans, &c.; and goes on so far as to suggest that the two former might scarcely manifest themselves if all emotion were excluded. They subside during quiet sleep, to return on the occurrence of dreams or waking. How are these facts to be explained, except on the principle of the removal and re-admitted influence of emotion? It is well known, on the other hand, how emotion aggravates these diseases at other times.

An interesting case is briefly detailed, and illustrated by a drawing, of a patient who could seize and hold a pen by a strong and sustained effort of volition; but when this effect subsided, the pen was drawn into various positions by the involuntary and irregular agency of the *vis nervosa*.

The paper concludes by a brief reference to the influence of *shock* on the nervous system. In the first attack of hemiplegia, the paralytic muscles manifest less irritability than those of the opposite side: a state the very contrary of what is observed in the sequel: *immediately after* the accident by which the spinal marrow is injured, the reflex actions afterwards observed are absent. In some experiments on the circulation of the blood in frogs, if, when the brain and spinal marrow were entirely removed, the circulation still continuing in the web, one foot was suddenly crushed, the circulation instantly ceased in the other. Lastly, a blow on the tibia induces immediate, though momentary, paralysis of the leg. These are examples of the influence of shock, and obviously afford subject for investigation.

ASSOCIATION OF PHYSICIANS,

Dublin, June 1st, 1840.

THE PRESIDENT, DR. ROBERT COLLINS,
IN THE CHAIR.

— —

A note on diseases of the Aortic Valves.

DR. OSBORNE said—Although much has been done towards the elucidation of the pathology and symptoms of the diseases of the heart, yet the subject is far from exhausted. I more willingly offer a small

contribution, although so many from the ranks of the profession in Dublin have made splendid additions, inasmuch as I have followed a different course from theirs, in seeking for symptoms independently of the sounds of the heart; and, also, in applying some geometrical principles to the measurement of the diseased valves.

According to my observations, bounding of the smaller and of the larger arteries are two very different things, occurring under different conditions, and dependent on different causes: bounding of the smaller arteries, as is well seen in the radial artery, is to be observed in most persons in hot weather, or after taking any unusual exercise, and in many is evident at all times, without any such excitement, and without any motion whatever in the larger arteries. The obvious explanation of this phenomenon is, that the wave of blood sent from the heart proceeds onward through the canal, until it arrives at its smaller extremity, where the obstacle presented causes it to impinge on the sides of the vessel, and thus to produce a bounding: whether this explanation be correct or otherwise, the fact is, that this bounding of the radial and other arteries, equally distant from the heart, occurs in perfect health, and (as I have ascertained) may be produced in the majority by using violent exercise, or by external heat. The bounding of the larger arteries, as the brachial, occurs as a permanent symptom only in an open state of the aortic valves. As some doubt appears still to exist as to the connection between bounding of the arteries and imperfection of the aortic valves, I shall here briefly state the facts, which seem to me to establish it, with regard to the larger arteries: first, whenever I had the opportunity of thoroughly examining cases of bounding of large arteries during life, there were found in all indicative of hypertrophy of the heart, in a greater or lesser degree; in fact, by feeling the pulse alone, I am now accustomed to predict those cases in which the bounding of the brachial artery will be found. Secondly, in all cases in which I have the opportunity of examining such cases after death, I find the aortic valves more or less diseased. Thirdly, this bounding, although most frequent in the decline of life, yet is not necessarily a consequence of the changes in the cellular structure, or in the loss of fat surrounding the artery, incident thereto, because in some old persons the arteries, although deserted by the fat, and rendered superficial, yet exhibit no bounding whatever. Fourth, bounding of the larger, as the brachial artery, cannot be produced by exercise in an individual in whom it does not previously exist in some degree, although when so existing it may be greatly increased; and,

fifth, when we instantly compress the upper part of the artery after each pulsation, the lower portion will retain its position, and bounding will be effectually prevented. This experiment requires some practice and dexterity, but deserves to be called an *experimentum crucis*, the result of it being susceptible of only one explanation—that by making the finger perform the office of a valve, and so preventing the passage of the blood backwards towards the heart, the bounding is prevented, and that regurgitation alone is the cause of the bounding. When the same experiment is performed, with reference to the bounding exclusively confined to the smaller arteries, it does not stop the bounding; and hence it follows that it must depend on a different cause.

This necessary connection between bounding of the large arteries, and an open state of the aortic valves, has not been generally admitted, in consequence of the numerous cases in which the valves are reported healthy, although bounding existed during life. That those reports of healthy valves arose from want of sufficient care in their examination, I had been long convinced. To some it appears sufficient to see if there are ossific deposits; to others, to pour water down the artery, and if they can hold it in such a position as to prevent the water from running out, the valves are pronounced healthy, and fit for the performance of their functions; others feel them with their fingers, and if no bony hardness is perceived, they are pronounced all right. I therefore think it useful to enumerate the diseases of those valves which have actually been observed; secondly, some which have not been observed; and, thirdly, to offer an explanation of those cases in which bounding of the large arteries occurs in a transitory manner, and without any organic disease.

Diseases of the aortic valves already described.

1. Ossific concretions preventing the juxtaposition of the valves when in action, or if not projecting, impeding their motions. (N.B. The thrilling vibration propagated through the arteries is always most evident in those cases.)

2. Dislocation causing the valves to occupy a different level.

3. Perforations generally at the base of the valve.

Diseases now first described.

4. *Thickening and shortening.*—This disease is very generally passed over. The healthy transparent appearance of the valve is to be ascertained by a comparison between the valves of the aorta and those of the pulmonary artery, the latter being almost always healthy except in cases

of emphysema of the lungs. When the valves are thickened, they are also contracted, and thus a triangular space is left between them.

5. *Adhesions.*—This is a very rare disease. The figure is taken from a preparation from a patient who died under the usual symptoms complicated with those of emphysema of the lung and adherent mitral valves, both of which diseases were found after death.* This specimen is to me *unique*. It unites permanent patency with permanent contraction. I conjecture that the very rare cases reported of want of a valve were produced by adhesions of the surface of the valve to the aorta.

6. *Elongation and consequent puckering or falling down of the valves.*—In order to appreciate this change, it is necessary, in the first place, to consider the length of the valves required for closing the orifice and preventing the regurgitation of the blood. Let us suppose the transverse section of the aorta to be an exact circle, and that the valves are all of equal dimensions. Then, as they must all meet at the centre, and as they must form straight lines when pressing against each other in action, it follows that each equals two radii of the circle, and that the sum of them all is equal to six radii, or three diameters, which is nearly equivalent to the diameter of the circle; and hence the length of the three valves, taken together, should be equal to the circumference of the aorta.

There is, however, a circumstance to be taken in connexion with this estimate, namely, that the valve which does not subtend the orifice of either coronary artery is always larger than either of the others; consequently the point of meeting of the three valves is beyond the centre, and, therefore, the sum of their sides must be somewhat larger than the circumference of the aorta. In my measurements of healthy hearts, I find this always to be the case, but only within certain limits. In cases in which there was bounding of the large arteries, and hypertrophy of the ventricles, I found the sum of the lengths of the valves to be to the circumference of the aorta as above four to three; while in cases in which there were not those indications of regurgitation, they were only as seven to six.

Elongated valves, although otherwise of healthy appearance, may generally be observed either to fall down in folds, or to project into the canal in consequence of their bases being occupied by structure of cartilaginous or osseous consistence.

In the last place, we consider how

* A figure or diagram occurs here in the MS., as well as in reference to several other diseases; but they are scarcely of a nature to admit of our giving them in wood-cuts.—ED. GAZ.

bounding of the large arteries takes place at times in a transitory manner, and where no organic disease of the valves can be suspected. This is observed after losses of blood, and during tumultuous action of the heart from mental or nervous influences. It must be at once conceded that the bounding in these cases occurs from an open state of the aortic valves, just as in the cases of organic disease; and then the sole difficulty lies in explaining how this open state can be produced for a time, and afterwards cease. This difficulty will subside when we remember the following facts: that the valves are supported by the column of blood entering the ventricle, and that when this is taken away, or becomes deficient, an undue strain must take place on them; that in tumultuous actions of the heart, the whole organ, but especially the ventricular portion, is thrown into unusual positions, as may be perceived by placing the hand over the cardiac region, and that by holding any heart, however healthy, in any position, except the one in which the three aortic valves are at the same level, a fluid may be poured from the aorta into the ventricle. Again, that in those cases of tumultuous action, there is always regurgitation from the heart into the pulmonary vessels, as is evinced by the panting and difficulty of breathing, which can only take place by the mitral valve being held down, and that in this way both the two preceding causes and the last are simultaneously in action.

To conclude, these valves being, as it were, the portals at the gate of life through which the blood issues to supply energy to every part, no disease, however slight, can long exist in them without being followed by serious consequences; the first of these is hypertrophy of the ventricle, causing a tendency to apoplexy; and the second is a defective action in the capillaries, producing Bright's disease of the kidneys, congestion in the liver, and other organs. From the great frequency of disease of those valves in the advanced stages of life, it may be estimated as the climacterical disease of the heart. Standing, as they do, at the base of the arterial system, the slightest failure in their function tends sooner or later either to produce the diseases now mentioned, or to destroy the equilibrium between the two divisions of the circulation, and so, by degrees, to subvert the health of the individual.

DR. LAW concurred with Dr. Osborne on the constancy of the phenomenon of the bounding of the larger arteries, as a sign of imperfection of the aortic valves, as all the instances that he had met with of this particular disease, (and they were not a few) had exhibited this sign. Still, it was far from being confined to this modification

of heart disease, or even to heart diseases. He had observed it in permanent patency of the mitral valve, also in cases of hæmorrhage, in chlorosis, and even in protracted diarrhœa; he considered the phenomenon to depend on an altered relation between the stream of blood and the artery; whether this resulted, as in the case of aortic valve disease, from the impediment to the issue of a full column of blood from the ventricle, owing to the valves so losing their normal organization as not to allow them to apply themselves closely against the sides of the vessel, and also to their admitting the regurgitation of this diminished quantity of blood; or in cases of patulous condition of the mitral valve; then as much, or more, of the blood passed back from the ventricle into the auricle, than proceeded from the ventricle into the aorta; or if this altered relation were the effect of a positive and direct diminution of the mass of the circulating fluid, as in cases of hæmorrhage, or if the diminution were less direct, as in diarrhœa; or again, if the quantity of blood continuing the same, its crisis were less than natural, all these different conditions concurred to produce this change of relation between the stream of blood and its containing vessel, the result of which was, the vessel not being kept in such a state of tension as to prevent a molecular motion between its particles, communicating a sense of vibration or thrilling. This explanation seemed, to Dr. Law, to provide for all the cases. Although Dr. Osborne had entered very fully into the subject of diseases of the aortic valves, and had brought under notice some that had hitherto been overlooked, still Dr. Law did not think that he had sufficiently dwelt upon the different diseased conditions of these valves, as exhibited at the different periods of life; that while the individual, advanced in life, presented the ossific degeneration of them, the younger subjects exhibited their disease as the result of inflammation, whether of a specific character, as rheumatism, or as the effect of cold, which seemed to Dr. Law to be the ordinary work of generation of vegetations, which had formerly been looked upon as venereal. Dr. Law distinguished between the disease of the valve, where the change, whatever it was, took place in the substance of the valve, and when it was a deposit on the surface. In reference to Dr. Osborne's observation of the frequency of hypertrophy of the left ventricle of the heart, as caused by disease of the aortic valves, and of apoplexy, as the consequence of this, Dr. Law believed that the diseased valves, in this case, by breaking the form of the hypertrophical ventricle, actually served as a protection to the brain; and that when disease of the

brain did coexist with diseased aortic valves, it was not apoplexy, the result of the blood driven with unusual impulse to the brain, that occurred, but ramollissement of the organ, from the diseased valves obstructing the course of the blood to it, and thus interrupting its nutrition.

Dr. Law was of opinion, that, in order that an hypertrophied left ventricle produce apoplexy, if, as was most commonly the case, the hypertrophy depended on some obstruction to the circulation, such obstruction must be situated more remote from the heart than the origin of the vessels which convey the blood to the brain. Dr. Law remarked upon the confusion that prevailed upon the subject of cerebral disease, as connected with disease of the heart; that many modifications of disease, very dissimilar in their nature, and equally differing in the treatment they required, were mixed up together, and treated with equally little discrimination. He conceived, without entering very minutely into the subject, that there were four different kinds of disease, which required to be carefully distinguished. 1st. Apoplexy produced by hypertrophy of the left ventricle of the heart. 2d. Ramollissement of the brain, from obstruction to its circulation, such obstruction being placed between the heart and the vessels conveying the blood to the brain. 3d. Congestion of the brain, from narrowing of the left auricular ventricular openings, and consequent congestion of all the vessels placed behind this impediment. 4th. Failure of the brain's action, as the organ of innervation, from the heart's structure undergoing such a change as to unfit it for driving the blood, its proper stimulus, to the brain; as when its muscular structure underwent a fatty degeneration. The sudden death in this case was generally considered an apoplectic seizure, whereas its symptoms entitled it to be regarded as a prolonged syncope. The practical importance of distinguishing between these several modes of disease appeared to Dr. Law too obvious to require of him any lengthened observations.

Dr. Sargent agreed with Dr. Law that death sometimes took place, accompanied by the usual symptoms of apoplexy, where disease of the heart had previously existed, without hypertrophy of the left ventricle; nay, under conditions which might be looked on as the opposite of such disease: as where dilatation of the right ventricle and fatty degeneration of the substance of the heart existed; in which every trace of the true fibrous structure was lost in a greasy "hepatized" condition (if he might use the expression). Dr. S. detailed a case of this kind, where the *rhythm* of the heart was completely lost in a weak

undulatory irregular motion; its *impulse* much diminished, and no "bruit" of any sort to be discovered. The head symptoms occurred prominently amongst the other impaired functions which usually accompany cardiac disease, as referred to by Dr. Osborne, in his paper; the respiratory system was much deranged; orthopnoea, dyspnoea, cough, and frothy expectoration, existed to an alarming degree; yet, after careful and extensive examination by the stethoscope, no severe disease of the lung was detected. After several weeks' treatment, the patient appeared to recover so considerably that daily attendance was deemed unnecessary, though the most unfavourable prognosis was persisted in. The thirty-fifth day from first examination of the case, death took place suddenly, as from apoplexy; and post-mortem examination revealed the above described organic condition of the heart, which appeared pale and macerated: the valves appeared perfectly healthy, as were also the lungs.

RUSSIAN PRACTICE.

[Concluded from page 476.]

Operations performed by Dr. Heine with his osteotome at Cronstadt. Communicated by Dr. Meleschko.

WHEN Dr. Bernhard Heine of Würzburg, was at Petersburg by the desire of the Russian government, he visited the great naval hospital at Cronstadt, where he found the following cases suited for the operation with the osteotome.

1. Andr. Mateen had severely injured his left tibia with a cable on board the Brienne, and had been treated as well as circumstances would allow; but when the ship returned to Cronstadt in the July of the same year, he was transferred to the naval hospital. Meantime an ulcer secreting a large quantity of thin pus had formed upon the tibia. It was of irregular shape, about an inch in size, but not well defined. To this were added feverishness and scorbutic symptoms. On examination with a probe, the periosteum was found to be injured in a circumference of four inches. The first treatment was directed against the scurvy and the fever, both of which were gradually cured by suitable remedies. On this, the wound became somewhat cleaner, and began to granulate; but in spite of incision and proper treatment, it was not possible to prevent necrosis. Dr. Heine found the ulcer in the following state. On the left tibia were seven separate sores lying within the compass of four inches. The external opening common to them all was not very large,

being about half the size of a finger-joint, with thick and callous edges. Lower down, however, the sores were larger, and were at their largest on the surface of the bone, from which point fistulæ ran in all directions; and many of them, though separated above, united into one focus below, as was clearly shown by injections. The bone was easily reached with a probe; and in some places it could be taken hold of with nippers, and the sequestrum could be felt to be somewhat moveable.

After Dr. Heine had made an incision through the skin for the whole length of the ulcer, he drew it aside, and, placing his osteotome on the sequestrum, sawed it through across its whole breadth. A piece of the sequestrum, three inches long, could now be removed; and the remainder of it was then taken out with slight movements of the saw: the whole was rather more than four inches long. The wound was washed out, and lightly bandaged: the operation was followed by traumatic fever, but it was not violent. The wound healed very slowly, as splinters were continually thrown off, and came away by suppuration.

2. Iwan Tarossoff had a very similar affection of the left tibia. The operation was like the last, but performed by Dr. Heine's friend, Dr. Samson. The wound improved but slowly, small splinters being continually thrown off; yet it gradually closed, and the patient began to walk about with a stick, but still had considerable pain in the bone.

3. Hippolytus Iwanoff injured his left fore-arm, in 1834, while furling the sails. Necrosis gradually came on, and Dr. Heine's skilful hand removed, with little difficulty, a sequestrum four inches and a half long. After laying the part bare, he only sawed through the sequestrum in the middle, and then easily took out both pieces. The operation was but slightly painful, and lasted hardly a quarter of an hour. The wound healed proportionably quicker than in the previous cases; the patient, however, is recovering the use of his hand but slowly. The German translator here extols the advantage of the osteotome in removing sequestra, observing that those who have been obliged to operate with hammer and chisel will appreciate the advantages of this excellent instrument.

On the external application of Croton Oil, by Dr. Slonetzki Michailoffski.

In a case of obstinate sciatica, where various internal and external remedies had been employed without advantage by others as well as the author, a cure was soon effected by rubbing in twelve, and afterwards fifteen, drops of croton oil daily,

on each thigh, along the course of the sciatic nerve. On the third day there appeared great redness and a considerable eruption, with obvious relief; and the improvement was so rapid, that, on the fourth day, the patient was able to rise and move about; and though motion was attended with pain, yet this, too, disappeared after a couple more frictions. Some time afterwards the author's own child, eighteen months old, who had been previously healthy, after taking cold, was attacked with an affection of the hip-joint; and, according to the opinion of the best physicians of the place, the true hip-joint disease was to be apprehended, and the most active measures were recommended. But, as leeches and blisters gave no relief, the author resolved to rub four or five drops of croton oil on the hip-joint. This method was followed by obvious improvement in fourteen days, and a cure in six weeks. Although the remedy produced violent redness, yet it did not cause either fever or any other disturbance of the system in the child.

Remedies for Rabies.—Dr. Schorstein has seen eight patients bitten by mad dogs. They were treated in the same way externally. Six recovered under the use of the Tr. Genistæ; the other two by Werlhof's pills against rabies. The receipt is as follows:—

R. Pulv. subt. cantharid. gr. j.; Bellad. fol. pulv., Calomel. aa. gr. ij.; Camphor. gr. iv. M. f. c. mucil. acac. pil. vj.

Three of these pills are to be taken twice a day. The hydrophobic vesicles, described by Maroketti, appeared only in one patient, a girl; and they were cauterized by the author.

Adhesion of long standing.—At the meeting of the society of Russian physicians, on the 19th of February, 1838, a communication was read from Dr. Tarossoff, physician to the Ural mines. A lad, the whole of whose left fore-arm had adhered to his chest, since the age of eleven, in consequence of a burn, came to Dr. Tarossoff at twenty, to be operated on. The shoulder-joint regained its power of motion but slowly.

On indigo in intermittent fever.—Dr. Schorstein found the following compound of advantage in spring intermittents:—

R. Indic., Magn. Carb., Flor. Chamom., aa. gr. v. M. f. pulv.

A powder to be given every hour during the apyrexia.

New mode of scarifying with the leaves of the Elymus arenarius.—Dr. Pehnikoff first convinced himself of the benefit obtained by using the rough side of the leaves of this plant, to scarify old ulcers of dirty appearance, and secreting bad pus. He then

began to use this remedy in inflammation of the conjunctiva, purulent ophthalmia, pannus, and pterygium; particularly in inflammation of the conjunctiva, and frequently with results approaching the miraculous. The bleeding is far more considerable than after leeches, or scarification of the conjunctiva with a lancet, and at the same time the pain is so remarkably diminished by it, that on the following day the patients commonly ask for a repetition of the operation, which is generally requisite for four or five days. Fresh leaves are the best, and from June to August is the best time for their application; but dried leaves, when soaked, do good service. Dr. Magaziner, who had to inspect the hospital, attended by Dr. Pehtnikoff, attests the advantage of these scarifications in No. 5 of the Journal.

Hooping-cough.—Dr. Michailoffsky Slo nezki has seen much advantage from linseed in this disease; either the infusion made into a syrup with sugar, or the seeds roasted and prepared like coffee. The latter is particularly good in the later stages of the disease. The German translator has been assured by Swedish families that this remedy is also much esteemed among the people in their country.

Practical Observations by Dr. Bajanoff, physician to the Bomberski Military Hospital.

1. *Hæmatemesis in a new-born child.*—A girl, five days old, vomited blood; and the vomiting returned the next morning, coagulated blood being thrown up ten times. In the evening the child vomited again, but less. The body was swelled, and much flatus was discharged, with perfectly black blood, just as in *melæna*, by stool. The author had previously given the emulsion of bitter almonds, and he now ordered a tea-spoonful of alum whey every two hours, and the abdomen to be rubbed with the camphorated oil of hyoscynamus. At three in the following afternoon, the patient again vomited much coagulated blood, took whey for two days more, and recovered perfectly. The Russian doctor asserts that the child had lost near three pounds of blood, but of this the German translator hints his disbelief.

2. *Hemorrhage from the eyes.*—This recurred several times from the veins of the albuginea, in a very old military chief of the Don Cossacks, without disturbing his general health.

3. *Affections of the urinary organs in intermittent fevers* were frequently observed by the author in Irematia. (Was there not at the same time an affection of the spinal nerves?)

4. *Riding on horseback in intermittent fever* was tried by many in that country, but did harm instead of good.

Vomiting cured by raw sourcrouit.—Neither internal nor external remedies had been of any avail, and the patient earnestly begged for something acid, on which Dr. Figurin prescribed sourcrouit. She took about a table-spoonful at a time, and discontinued her medicine. The vomiting recurred only once; on the following days she ate the sourcrouit again with pleasure, and with the most satisfactory result.

Case of iritis, keratitis, a deep ulcer of the left cornea, hypopyon, and purulent ophthalmia of both eyes, by Dr. Sarenko, director of the Orange Hospital.—The author cured this desperate case in six weeks, with the ordinary remedies. His treatment was at first usually complicated. Thus, on the second day he prescribed a purgative; a table-spoonful of the camphorated infusion of arnica flowers every hour; five leeches to each temple; and to the eyes, 1, a solution of lapis divinus, twice a day; 2, the tinct. opii croc. thrice a day; 3, the pus to be frequently washed off the eyes with decoction of mallows; 4, *sacculi aromatici*; 5, the eyelids to be touched with an ointment of white precipitate, of the strength of twenty-four grains to an ounce of fresh butter. The German translator thinks the quantity of white precipitate extraordinary great. In the London formula, however, the quantity is a drachm to an ounce and a half. Would this be too strong for the eyes?

Professor Bujalski's method of curing Carbuncles.—The carbuncle is not to be cut into, but the whole ulcer, and the reddened part surrounding it, is to be covered with a poultice made of bread and cold Goulard water. This is to be changed from four to six times in the twenty-four hours, is to be used day and night, and is to be continued when the carbuncle breaks up. When it is changed the pus can easily be squeezed out; the destroyed cellular substance may be drawn out as far as possible with the forceps, and cut off with scissors. When all the suppurating part is got rid of, the swelling sinks, and the redness disappears; the poultices are then to be discontinued, and the spot is to be dressed with the Ceratum Saturni, or some ointment.

In villages, where Goulard water is not to be had, a fifth or sixth part of strong vinegar is to be mixed with fresh water, and the dough of black bread, or leaven, with the addition of vinegar; this is the whole external treatment. The professor does not recommend an incision, even if there is an accumulation of pus; nor are leeches to be applied to the carbuncle, to diminish its size, as it will certainly enlarge over the places where the leeches were put on. After a crucial incision has been made, the dressing a carbuncle with an

ointment sharpened with powdered cantharides, or red preeipitate, is a very rough sort of treatment.

As carbuncles arise from constitutional causes, their internal treatment is important, but not the external. Dr. Bujalski says, that for more than twenty years he has not cut a single carbuncle, either in hospital or private practice, and has not lost a single patient. Petersburg contains many whom he has cured of carbuncle.

On this the German translator observes, that the extensive hospital and private practice of the celebrated author of the *Tables of the Arteries*, makes this simple method of treatment well worthy of consideration. Yet he has not ventured to adopt it, but has begun of late, instead of the crucial division, to make two long parallel incisions, leaving a space between them of half or three quarters of an inch, or a whole one, according to the size of the swelling. The knife is to be held somewhat obliquely, with the point turned a little to the centre of the carbuncle, which will empty itself very well by these incisions. The rectangular flaps made by the crucial incisions are apt to unite unevenly, causing great pain to the patient for a long time—an inconvenience which is avoided by this method. Even if a part out of the middle of the long flap of skin, formed by the two incisions, should be lost by a spontaneous breaking-up, nay, even if the flap should be severed in two, still the parts will heal with a more favourable surface than the four-corner flaps of the crucial incision.

Cure of an Epidemic Hemoptysis, by the Lichen pulmonarius, or Lobaria pulmonaria.—Mr. Lesskoff, a landed proprietor, states, that an infusion of this plant was drunk both by gentry and peasants, in the village of Krai, situated in the circle of Belozersk, and government of Novgorod; and it was so serviceable, that no one died after its use, though the disease was very fatal before. On this the German translator observes, that the recovery might depend on the diminished violence of the epidemic.

PRIZES—COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

IN the GAZETTE of last week, I observe a letter from a correspondent signed Δ, suggesting some improvements in relation to the delivery of the College Prizes.

I think it but due to the president and council of the College of Surgeons to state that not only was the last Jacksonian prize "awarded in person" by the presi-

dent of the council in full assembly, but in a manner well calculated to render the prize not only a gratifying distinction, but an object of ambition to any member of the profession. A testimonial, on parchment, was delivered at the same time, recording the successful candidate's name, and the title of the essay, signed by the president. It is evident, therefore, that the suggestions are superfluous, being only in strict conformity with the practice already in force.—I am, sir,

Your obedient servant,

RUTHERFORD ALCOCK.

13, Park Place, St. James's,

Winds, W. and S W.

Except the 24th, generally cloudy. Rain fell on the 25th, 26th, 29th, and following day.

Rain fallen, .115 of an inch.

CHARLES HENRY ADAMS.

NOTICES.

The cases alluded to by Dr. H. will be very acceptable.

We regret that we cannot insert the letters from Walworth. No good would in our opinion result from their publication.

WILSON & OGILVY, 57, Skinner Street, London.

Showing the Number of Deaths from all Causes, registered in the Four Weeks ending June 20, 1840.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISLOCATIONS, *continued.*

HUMERUS — RADIUS and ULNA at the
ELBOW — either separately. WRIST —
CARPUS.

HUMERUS, *continued.*

It is not in the present day possible to deny the existence of dislocation *backwards*; that is to say, where the head of the humerus passes between the inferior angle of the acromion and the head of the triceps. It is usually produced by a fall on the elbow, which is directed forwards and upwards. The head of the humerus, carried backwards and a little downwards, destroys the capsule at that point, and is borne towards the base of the acromion; this is the most frequent, the *sub-acromial* variety: or passing further backwards, it rests under the spine of the scapula in the *infra-spinatus fossa*; this is the *sub-spinatal* luxation.

Symptoms.—When we examine a thin person, suffering from dislocation *backward*, we find the roundness of the shoulder wanting, and in its place an evident depression; the edges of the acromion are easily felt, and there is no hard tumor or projection in front of the joint, or in the axilla. If we press firmly there, we may feel the inferior border of the glenoid cavity. Below the commencement of the spine of the scapula, where the acromion arises, is a very prominent round hard

tumor. Sir A. Cooper's observations shew that the arm hangs at the side; in Sedillot's case the arm was directed forwards, crossing obliquely the vertical direction of the body. Rotation of the limb causes the tumor to move. In the case observed by Sedillot, the arm, measured from the summit of the olecranon to the external border of the acromion, was an inch longer than that of the opposite side. Supination of the hand was impossible, because the humerus was forcibly rotated inwards; the highest degree of supination of the radius scarcely enabled the patient to bring the palm forwards, whilst pronation was always exaggerated. The whole limb was wasted (a third less than that of the opposite side), habitually cold, and the patient could make no use of it.

Diagnosis.—Some signs are common to backward dislocation, and fracture of the surgical neck. *External depression of the shoulder* is immediately below the acromion in luxation; lower down in fracture. *Tumor in the axilla* in luxation is rounded, and voluminous; in fracture, irregular and small. In both cases *the elbow is removed from the side*, and no voluntary motion can be executed; but in fracture the arm can easily be brought to the side; only incompletely, and with much pain, in luxation. In downward luxation the limb is *always elongated*; it is always a little shortened in fracture. The *reduction* of fracture is easy; that of dislocation is difficult: in fracture the displacement is reproduced; in luxation it is not. Subclavicular, or upward dislocations, are more easily confounded with a fracture of the neck, because it is in this species of luxation that there is shortening, as in fracture, whilst in the other varieties there is always elongation. In admitting with Malgaigne that, never, in luxation of the head of the humerus, is there shortening, we singularly facilitate the diagnosis, because in fracture there is always shortening; it is only then neces-

sary to measure the limb, to know whether it is luxated or fractured.

Dupuytren, in his *Clinical Lectures*, insisted much upon the diagnosis of these luxations. Every individual affected with luxation or fracture has fallen on the side corresponding to the injury—(this is not strictly correct)—and the patient always believes that he fell upon the point where he feels pain. When called to a luxation, the fall having been broken by the palm of the hand, this part is dirty, ecchymosed, or excoriated. We discover in fracture that there was a fall on the shoulder, that the hand bears no mark of violence; but that we find those marks upon the clothes or upon the skin of the shoulder. In luxation, the pain is owing to the destruction of the capsule and surrounding parts, and if there be ecchymosis, it is at the internal or anterior surface of the arm; in fracture, instead of being rare, as in luxation, ecchymosis is almost constant, it is on the cushion of the shoulder that it exists. An ecchymosis or excoriation at the internal and inferior part of the arm is, in case of doubt, an important index of luxation.

The nervous and vascular plexus of the arm is sometimes compressed; from thence arise œdema, cramps, paralysis of the arm, or of the deltoid, only when the circumflex nerve is compressed or destroyed. It is only because the relations of the head of the humerus with those organs are ill appreciated, that persons are surprised that such symptoms are not more frequent: the fact is, the form of the head of the bone, and that of the nerves and vessels, facilitates that gliding which prevents compression. Paralysis of the deltoid is not, however, very rare: it may be dissipated by blisters or moxas, if the nerve has only been contused: but when it has been destroyed the chances of re-establishing the functions of this elevator of the arm are much lessened.

Post-mortem inspections.—The examinations made after recent luxations have presented the following lesions. *Bones*: very unfrequently, fracture of the anterior border of the glenoid cavity; still more rarely, fracture of the posterior border. Sometimes the greater tuberosity of the humerus is, as it were, torn off by the tendons of the supra and infra-spinati and the teres minor. *The capsule*, destroyed in the direction of the luxation, consequently most commonly at the anterior border of the glenoid cavity, between the subscapularis and triceps, the laceration is always large enough for the head of the bone to pass easily outwards. *Tendons*: that of the long head of the biceps is rarely ruptured, but its gutter is often destroyed; if not, the tendon must be curved to follow the humerus, con-

sequently there are tension of the biceps and flexion of the forearm. The tendons of the sub-scapularis, the supra and infra-spinati, and teres minor, are sometimes ruptured. *Muscles*: the sub-scapularis is ordinarily relaxed, sometimes contused, sometimes destroyed; the head of the bone may pass between its fibres, and be applied upon the serratus magnus. *Principal vessels and nerves* are not commonly seriously injured: in the greater number of cases the head of the bone passes towards the chest behind them. *The cellular tissue* is more or less infiltrated with blood; if the luxation be old it is thickened and condensed.

A dislocation may be simple or complicated; may be complicated by fracture of the glenoid cavity (Flaubert) or of the humerus. The capsular ligament is ordinarily destroyed, and the tendons injured or displaced. Marx states a case where the bicipital groove was destroyed, and the tendon thrown in front of the head of the bone, crossing the tendon of the sub-scapularis. It may be complicated with other fractures.

Treatment.—The treatment consists in reducing the displacement as quickly as possible; even the complication of fracture of the humerus would not prevent our endeavouring to reduce it, if the superior fragment were sufficiently long; but then the reduction can only be accomplished by making, with the hand, extension on the superior fragment. Attempts at immediate reduction would be contra-indicated, if decided inflammatory action had followed the injury; no doubt the best way of lessening that action would be by reducing the displacement, but as this could not be done without violence, it should not be attempted. If the luxation be recent, we at once proceed to reduction; in a few minutes after the accident it is sometimes so easy that the surgeon can, alone, accomplish it; but if the patient be very robust, if he have a very excitable nervous system, and strong spasmodic action be developed, a large bleeding, tartar emetic, intoxication, or narcotics, may be necessary. During the attempts it is wise to address startling questions to the patient, for the purpose of distracting his attention from the immediate business of the moment, for by this means muscular relaxation is often obtained. In luxations of the shoulder, during attempts to reduce it, it is always desirable to prevent the patient from resting his feet on the ground; they should be kept in a horizontal position: this is an advantage which is obtained in the method of Hippocrates and Cooper, by placing the patient on his back, and the heel in his axilla. If the luxation be old, bleeding and bathing are good preliminary means.

An important question still remains to

be decided, before we proceed to act — is there a time beyond which we ought to abandon all attempts at reduction? Without entering at large upon the discussion, or pointing out the many serious accidents which have attended upon violent and prolonged attempts to reduce old luxation, it may be sufficient to say, that many luxations of the arm have been reduced by the eighteenth day, the twenty-second, the thirty-second, the thirty-seventh, the forty-first, the forty-fifth, the forty-ninth, the fifty-first, the sixtieth, the eighty-second, the ninetieth, the ninety-eighth day, at the end of a year (Sedillot): and even a longer period (Malgaigne).

We cannot, here, point out in detail the many methods which have been employed to accomplish the reduction of dislocation of the shoulder; the end of all should be, to make counter-extension on the scapula, to render this bone as fixed as possible, whilst extension made upon the arm should bring the head of the bone on a level with the glenoid cavity, at the same time that a proper direction is given to the shaft of the humerus. The mode of reduction most commonly followed is to seat the patient on a chair, to pass a reel towel or any similar contrivance around the chest, just below the head of the displaced bone; the towel or girth is then fixed to a ring in the wall, or entrusted to two assistants; the wrist being previously protected, another towel is carried around it, the ends crossing on the palmar surface. The surgeon stands on the outer side of the limb while extension and counter-extension are properly made, that is, gradually, and without shock; when carried sufficiently far, the time comes for distracting the patient's attention. When this plan is pursued, the direction of extension must vary with the displacement; if it be axillary, the efforts should be made directly downwards and outwards, the surgeon assisting in directing the head of the bone upwards and a little outwards; at the same moment the assistants should bring the limb downwards and a little forwards. If the luxation be sub-scapular or sub-clavicular, the extension is directed at first outwards, so as to bring the head of the humerus to the level of the lower part of the glenoid cavity: then we proceed as in the former case. If the luxation be directly inwards, extension must be made at first horizontally outwards and a little backwards; the wrist is then brought forwards and downwards; and during this time the surgeon brings the elbow forward, and the upper part of the humerus backwards. If the primary displacement be backwards, an opposite course should be taken; extension should be made at first outwards, then downwards, and a little backwards.

In case of a recent axillary luxation, the surgeon may sometimes reduce it alone; he seizes the elbow, extends it suddenly, whilst with the left hand in the axilla he pushes the head of the humerus upwards and outwards. If he pursue the plan of Hippocrates and Sir A. Cooper, he may often succeed without assistance. The patient lies on his back, the surgeon also lies down, but in the opposite direction; he grasps with both hands the wrist of the luxated arm, he places the heel in the axilla, upon the head of the bone, which he pushes upwards and outwards. Here the counter-extension is made, either by the contraction of the rhomboideus and trapezius, or by the heel itself, which maintains in place the inferior angle of the scapula; this method is often used when no assistants are near. Nearly a century ago, White proposed a method of reducing downward and forward dislocations, which has been very little used, but is still a successful method, and has been of late revived by French surgeons; it consists in raising the arm over the head, until it is parallel with the trunk, and then making extension on it: counter-extension is made by acting upon the acromion and spine of the scapula. When the surgeon thinks sufficient extension has been made, he forces up the head of the humerus into the glenoid cavity.

The mode I employ has never hitherto failed me: it was the mode usually employed at the Bristol Infirmary during my pupillage; and one person, without assistants, will rarely fail to reduce a dislocated shoulder by this means. The patient is placed upon a chair, of such a height as will not permit the feet to reach the ground. In this chair he sits sideways. The back of the chair should be high enough to reach unto the axilla; if it be too high, the patient can be raised by placing pillows under him. The back of the chair should be padded so as not to hurt the axilla. The arm is now placed over the back of the chair. A reel-towel is passed round the arm, just above the elbow, in a slip-noose. With the end of the towel you make a stirrup, into which you put your foot, and begin to make steady pressure, in such a direction as may be necessary: both your hands are unencumbered, to manipulate as may be found most advantageous. In this simple way you may reduce any recent dislocation without assistance, and with no other apparatus than may be procured in every house.

If the dislocation be old, and you have reason to believe adhesion to be formed, you may want more force, and it may be necessary to have recourse to pulleys. They are often recklessly used, without considering the intensity of the force employed.

For the purpose of overcoming this defect, Sedillot invented a "dynamometer," which he considered a safety valve; but how can you by this means estimate the force necessary to be employed in each case, one man having much, another little muscular power? These are matters which can usually be best regulated by the intelligence of the surgeon.

In many cases, at the moment of reduction, a snap or jolt is heard; it results from the articular surfaces coming suddenly together under muscular contraction. It does not usually happen, unless at the moment extension has ceased; it is very rarely heard when pullies are used. After reduction, the shoulder resumes its roundness, and the elbow can readily be brought to the side. In this position, with the arm well supported, the limb must be maintained for not less than a month, to give time for the articular capsule to heal.

If, after reduction, you measure the two arms, you find a slight elongation of the injured one. By some persons this is supposed to be owing to the interposition of a portion of the capsular ligament between the articular surface; by others, to tumefaction of the cartilages: by some, to paralysis of the deltoid. This paralysis of the deltoid is not an unfrequent accident in luxation of the humerus. The dragging of the circumflex nerve may readily be supposed to account for it; the violent efforts sometimes made in reduction may also account for it. Paralysis of the whole limb sometimes occurs: in a few cases it has yielded to treatment, in others it has resisted all the means employed. It is a consequence of considerable injury to the brachial plexus. Laceration of the humeral artery has followed violent attempts at reduction. Desault occasioned it in reducing a dislocation six weeks old: a considerable tumor suddenly supervened under the pectoralis major, and soon filled the whole axilla. There may be œdema of the whole limb, caused by pressure of the head of the bone on the veins and lymphatics, but it usually yields upon reduction, and the application of a roller.

In these tendon-cutting days, other modes of reduction have been attempted. Weinhold, finding resistance on the part of the pectoralis major, cut through its tendon. (Zwanzig, de luxatione humeri et incisione aponeurosis musculi pectoralis ad cur. luxat. inveterat. Halæ, 1819.) The example has not been lost sight of. A few months ago, Dieffenbach, in an old case of dislocated humerus, finding, upon extension, that the muscles resisted, cut, subcutaneously, nearly all the tendons around the joint, reduced the limb, and the marvellous sequel is—it is said the case did well!

ELBOW JOINT.

By this term is usually understood a displacement of both bones of the forearm upon the humerus. But the radius may be alone dislocated, so as to lose its connection with the head of the humerus and the sigmoid cavity of the ulna.

The ulna appears to be scarcely susceptible of more than one kind of isolated displacement: in fact, the examples of it on record, with the exception of the case mentioned by Sir A. Cooper, are wanting in the details necessary to convince us of their reality. Indeed, when we regard the arrangement of the articular surfaces and ligaments, together with the nature of the motion at the joint, the difficulty of an isolated displacement of the ulna must be at once apparent.

In considering dislocation at the elbow joint, we shall first speak of the simultaneous displacement of both bones upon the humerus; second, of the displacement of the radius upon the humerus and the ulna; third, displacement of the ulna alone.

The situation of the elbow joint, between two comparatively long levers, (which may acquire, at their extremities, a very energetic power,) and much exposed to direct violence, dislocation must have been very frequent, did not many circumstances concur to prevent it: such as the extent of the articulating surfaces; the great strength of the olecranon; the power of the anterior and lateral ligaments, and of the muscular and aponeurotic masses, placed in front and at the sides of the articulation. There is yet another circumstance which explains the infrequency of dislocation at this joint; it is, that most of the causes which tend to produce the separation of the articular surfaces very commonly occasion fracture of one or more bones of the arm. For instance, in the case of a violent fall on the palm of the hand, a fracture of the radius alone, or of the radius and ulna, will deaden the violence of the shock, and prevent the displacement we are considering.

As in all hinge-joints, displacement at the elbow may occur in four directions—outwards, inwards, backwards, and forwards. But all are not equally frequent; the lateral displacements are opposed by the prominences and depressions which are presented by the humerus. The forward luxation is prevented by the projection of the olecranon, and can only be produced by a previous fracture of this process, or a great injury to, and destruction of, the soft parts. The backward displacement is the most commonly seen.

Backwards.—In this displacement, the superior extremities of the radius and ulna

pass behind the inferior extremity of the humerus. It is usually produced when, during a fall upon the hand, the forearm is found extended upon the arm. The weight of the body, increased by the impetus of the fall, is transmitted through the humerus to the forearm. If, under these circumstances, the two bones of the forearm obtain a solid support upon the soil, either directly or through the intermedium of the hand, their superior extremity, forming a plane inclined forwards and downwards, decomposes the action of the humerus, and transforms it into two powers, one acting in the direction of the axis of the limb, and tending to press the bones one against the other, whilst the other, perpendicular to the first, directs the extremity of the humerus forwards. Now, if this be strong enough to surmount the resistance opposed to the articular surfaces of this bone, by the border of the articular cavity of the radius, the coronoid process of the ulna, the anterior ligaments, the brachialis anticus, and biceps muscles, the humerus will necessarily glide from behind forwards, and descend in front of the bones of the forearm. Many surgeons are of opinion that this mechanism is the only one by which a backward luxation can happen. There can, however, I think, be no question, that in certain movements of forced extension, during which the forearm tends to form an angle projecting forward, a backward luxation may occur. If, then, the olecranon be not fractured, the humerus, transformed into a lever of the first kind, finds a point of support on the anterior-superior border of this process, and its inferior extremity, which represents the arm of the lever of resistance, acts as much more powerfully upon the anterior ligaments, and the brachialis anticus, and biceps muscles, to push them forwards, as the superior extremity of the bone, or the arm of the lever of the power, has itself greater length.

Whatever be the mechanism of this luxation, it is admitted to be always complete; because it does not seem possible that the rounded articular surfaces of the humerus should rest upon the edges of the radius and ulna, without passing farther, either forwards or backwards; in the one case making the luxation complete, in the other returning to its proper place. Though, as a general rule, such an admission may be made, yet it is certain that an incomplete luxation may occur even in an orbicular articulation; and we cannot, therefore, reject the possibility of such an occurrence at the elbow joint. In that case the inferior extremity of the humerus ruptures or violently distends the fibrous bands which strengthen the anterior part of the

joint, and raises or destroys the brachialis anticus and biceps muscles. The superior extremities of the bones of the forearm pass obliquely upwards between the posterior surface of the humerus and the triceps; and the border of the coronoid process is forced into the olecranon cavity of the humerus. The lateral ligaments and tendons, attached to the tuberosities of the humerus, are distended or destroyed. S. Cooper thinks the lateral ligaments are always destroyed. The annular ligament of the radius may remain uninjured, if the relation of the radius to the ulna be unchanged: this is shown by a dissection of Sir A. Cooper's. Petit (*Mal. des Os*) describes a case in which the brachialis anticus and biceps were ruptured, the extremity of the biceps escaping through a wound in the integument; the reduction was easily obtained, and the patient cured in six weeks. (See A. Cooper, S. Cooper, Abernethy, and others.) So far as I know there are only two instances on record, strange as it may appear, in which the brachial artery and the median nerve have been destroyed by this displacement. A more frequent complication is the fracture of one or more of the bones of the elbow.

In this luxation, the forearm, seen in front, appears shortened; it is flexed at an obtuse angle upon the arm, and any movement of flexion or extension can with difficulty be produced. This is owing to the state of tension in which the brachialis and biceps are maintained by the humerus, and to the biceps being removed from its proper course, by the projection backwards of the olecranon. We feel the olecranon above the tuberosities of the humerus. If the tumefaction be not great we can, occasionally, feel the extremity of the humerus projecting at the bend of the arm. If the patient be stout or fat these signs become much less evident. This is also the case where there is much tumefaction. It is in these cases that luxations are mistaken for contusions and fractures, and *vice versa*. This error is much more easily fallen into when a transverse fracture of the humerus is followed by a displacement forward of the superior fragment. In these cases all the signs of luxation may exist; and in the *Leçons Orales* of Dupuytren, (tom. iii. p. 396,) are examples of errors in diagnosis in such cases. Here, also, we find a mode of avoiding this error: "Seize a fragment in each hand, the thumb applied in front, and directed towards the fracture, and then attempt the reduction." This simple effort without any other means most frequently suffices, especially within the first thirty-six hours which follow the accident; the reduction thus perfectly operated, move the forearm backwards; if

there be luxation, the reduction persists; if there be fracture, the displacement will immediately re-appear. This sign, though unquestionably a good one, is certainly not so infallible as Dupuytren believed it to be. Berard saw a person who was killed by throwing himself from a second floor. The left elbow was the seat of considerable deformity; similar, in all respects, to that which is observed in luxation. Reduction was attempted and accomplished without much difficulty, though a cadaveric rigidity existed. A moderate pressure upon the forearm and arm, in opposite directions, was sufficient to produce a new displacement, which was accompanied by a slight crepitation. These manœuvres of reduction and luxation were reproduced several times with the same result. In this case it turned out that there was luxation in the forearm backwards; fracture of a part of the coronoid process of the ulna; fracture of a portion of the radius. Malgaigne says, whatever may be the projection of the olecranon, it is never further removed from the humeral tuberosities than in the natural state, if there be fracture; if there be luxation, the case is very different.

A dislocation backwards at the elbow, simple, and discovered early, is not a very serious accident; if it be mistaken, it soon ceases to be reducible. Hurteaux (Thèse, No. 255, p. 35, 1834,) states a case in which reduction was accomplished after twenty days. Boyer succeeded in a child of ten years in effecting a reduction at the end of six weeks. Sir A. Cooper has succeeded after several weeks. Leveille assisted Desault in a reduction after two months. But upon these exceptional successes we cannot count; usually the displacement will remain permanent. After a time flexion and extension increase, but they never attain the same freedom as before the injury; pronation and supination are almost abolished. Sometimes singular changes occur at the part when a luxation remains unreduced. In Beclard's museum was a specimen in which the unchanged articular surface of the humerus was received into an accidental cavity; and osseous productions were developed around the radius and ulna.

Though the projection of the head of the humerus through the skin be a serious complication, yet, in the case of Petit, and others of a similar character, the reduction was effected without the development of serious symptoms, and without altering the functions of the part. If the median nerve or brachial artery be destroyed, matters would assume a serious aspect: Boyer speaks of gangrene as the result. However, Abernethy used to mention a case of

this kind, in which the limb was preserved.

Treatment.—Soon after the occurrence of the accident this luxation is easily reduced; in fact, now and then a slight extension made upon the wrist, at the same time pushing the olecranon downwards and forwards, has proved sufficient for the purpose. If this be insufficient, the patient should be seated on a chair, the arm removed from the side, and directed obliquely forward; an assistant grasps the arm near the axilla, without compressing the biceps or triceps; another assistant gradually makes extension at the wrist; the surgeon, placed at the outside of the elbow, makes pressure in the bend with his fingers, whilst his thumbs press the olecranon downwards and forwards: and when this process arrives below the tuberosities of the humerus, he makes pressure almost directly forward, whilst the assistant who has been making extension flexes the arm. Sir A. Cooper advises a different course; the patient sits on a chair, the surgeon places his knee at the outside of the joint, and grasping the wrist, he draws upon the arm; at the same time he presses with the knee against the radius and ulna, so as to separate them from the humerus; the coronoid process is thus pushed from the posterior cavity of the humerus, and while this pressure is exercised upon the elbow, the arm being gradually extended, the reduction is accomplished.

When the dislocation is reduced, the motion of the forearm becomes easy; in the state of flexion the olecranon is found directly below the tuberosities of the humerus, about an inch removed from them. The joint should be enveloped with wet compresses, and the arm sustained in a sling: at the end of a week or ten days the joint should be gently used, so as to prevent ankylosis: the soft parts sometimes continue painful for several weeks. When the annular ligament has been destroyed, the radius retains a tendency to displacement for some time; and occasionally it is necessary to apply a bandage around the upper part of the forearm.

If there be much contusion, it may be necessary to defer the attempts at reduction, until by energetic local and general means the inflammatory action is subdued. In cases where the extremity of the humerus has injured or destroyed the soft parts, and projected through the skin, we must proceed to reduce, according to the mode I have described; the parts must then be kept perfectly quiet, and inflammation prevented by appropriate treatment. If the artery be ruptured, the brachial must be tied; in the first place, if there be at the same time great injury to the median nerve, it may be more

prudent at once to practise amputation of the arm than to expose the patient to the chance of gangrene. However, the cases on record are too few to enable us to erect a principle in this respect; and it must be remembered that in Abernethy's case the limb was saved.

Supposing reduction to be impossible (and such a case is mentioned by S. Cooper, as having occurred to Evans) a resection of the protruding portion of the humerus may be practised, and the patient may recover the complete use of the arm. Again, reduction may be accomplished, and may be followed by so much inflammatory action and tumefaction as to threaten gangrene; in such a case Frera caused a new displacement; resected a portion of the humerus: after three weeks the arm was saved, but it was ankylosed.

Dislocation forwards.—In this case the humerus passes down behind the radius and ulna. This displacement can scarcely happen without a previous fracture of the olecranon; still Delpech describes one case; the destruction of the soft parts was so great, that he said this fact was more calculated to confirm than to destroy the principle. I know no case of luxation accompanied with fracture of the olecranon, though much has been theoretically written on the subject. All I shall say, therefore, is, that when the reduction is effected the part should be treated in the same way that we shall recommend in treating of fracture of the olecranon.

A complete lateral dislocation of the bones of the forearm upon the humerus is very rare, partly owing to the considerable inequalities presented by the articular surfaces, and partly to the strength and thickness of the lateral muscles; it can only happen by two opposite lateral forces acting upon the arm and forearm at the same time. Petit describes two cases, (*Mal. des Os*, p. 239): the injury to the soft parts was so great that almost unlimited mobility was present. The lateral ligaments and the muscles attached to the tuberosities were destroyed; the limb was shortened by the bones riding. It is said that the shortening is less considerable when the luxation is inwards, the riding being prevented to the same extent by the greater projection of the internal tuberosity of the humerus.

When this kind of luxation is incomplete there is an increase in the length of the transverse diameter of the articulation; the forearm cannot be completely flexed; pronation and supination are almost impossible; the biceps, brachialis anticus, and triceps, have their course changed.

If the luxation be *inwards*, the muscles attached to the epitrochleus are raised and tense, and they bring the hand into a state of flexion and adduction: the muscles

attached to the epicondyle are removed from the radius at their superior extremity, forming a relief under the skin; the articular cavity of the radius corresponds to the pulley of the humerus: the small head of this bone may be felt through the soft parts.

In the *outward* luxation it is the articular cavity of the ulna which receives the small head of the humerus, while the radius and epitrochleus project; the muscles of the forearm and the inclination of the head present a disposition inverse to the former case. Lateral luxation, whether outwards or inwards, is a more serious accident than a luxation backward, because the injury to the soft parts is much greater. The inward seems to be more serious than the outward displacement, probably in consequence of the almost inevitable destruction of the ulnar nerve: but this opinion is based upon theory rather than fact. Supposing in lateral luxation the displacement to remain undiscovered, a greater latitude of motion is acquired than in the backward displacement.

Treatment.—Reduction is effected by means of moderate extension and counter-extension: whilst the arm is a little flexed, we push gently in opposite directions the humerus and the bones of the forearm. An examination should be carefully made to ascertain whether the radius have abandoned the sigmoid cavity of the ulna. Sir A. Cooper advises that, in each of these luxations, reduction may be obtained by extending the arm upon the knee: when recent, he thinks extension may be sufficient for the purpose; the biceps and triceps then bringing the articular surfaces in contact. In cases of lateral luxation, acute inflammation is always to be apprehended, and must be energetically combated. It is a safe plan to place the elbow in a gutter to insure quiet, and to apply lotions.

RADIUS.

The radius may abandon the sigmoid cavity at the superior extremity of the ulna; but the unfrequency of the occurrence caused erroneous ideas to be entertained about it up to the time of Durerney, (1751, *Traité des Mal. des Os*.) The superior extremity of the radius may be displaced backwards or forwards; the backward luxation is most frequent: it is almost always produced by a forced pronation: it may be occasioned by direct violence impressed upon the superior extremity of the bone, forcing it directly backwards to the outside of the olecranon. Boyer saw two cases. In Sandifort's 103d plate are two other cases, with ankylosis of the radius and ulna. Dupuytren also mentioned two cases which occurred in

his practice. Sir A. Cooper dissected a case of unreduced luxation of the radius: the head was found behind the external condyle; the anterior part of the coronary ligament was ruptured, as well as the oblique ligament, and the capsule was partially destroyed.

In this luxation the forearm is semi-flexed, the hand is prone, all attempts to produce supination are very painful, the biceps is tense, a depression is felt below the lesser head of the humerus, and the superior extremity of the radius projects at the posterior part of that eminence.

Treatment.—Reduction is accomplished by pushing the head of the radius from behind, forwards, whilst two assistants make extension. The assistant who is charged with extension, should, as the muscles yield, produce gradually as great an extent of supination as is practicable. The restoration of the natural form of the articulation, the possibility of producing easy extension and supination, are evidence that the reduction is complete. When the reduction is accomplished, pronation must be carefully prevented, and all motion should be avoided for a fortnight or three weeks; a compress should be placed behind the superior extremity of the radius, another along the arm and the upper part of the forearm, and secured there; the forearm should be slightly flexed, and the hand supine; an elbowed splint, extending from the palm of the hand to the lower third of the arm, should be applied.

The forward luxation of the radius upon the ulna is very rare; it happens when the hand is violently supinated, or when the superior part of the radius is forcibly pushed forward. It may happen, Sir A. Cooper thinks, in falling upon the palm, the forearm being extended upon the arm.

In this displacement, pronation is impossible; a very perceptible hollow exists behind the head of the radius. S. Cooper says that the superior extremity of the radius is carried in front of the external tuberosity of the humerus, upon the coronoid process of the ulna. Sir A. Cooper says the forearm is flexed, but cannot be carried to a right angle, nor completely extended. If we flex briskly, the head of the radius rubs against the anterior part of the humerus; the hand is prone; and if we attempt to rotate it, we feel the head of the radius move at the anterior part of the elbow; the annular and oblique ligaments, as well as the anterior part of the capsule, are distended and twisted.

Treatment.—To reduce this displacement the surgeon ought, whilst extension and counter-extension are making, gradually push the head of the radius backwards. When reduced, a bandage should be ap-

plied with moderate firmness, the forearm flexed, and the hand placed midway between pronation and supination. But reduction is sometimes very difficult: in two cases seen by Sir A. Cooper, it was impossible to reduce the radius; a third was not accomplished until the patient had fainted. In a fourth case, the patient was placed on a sofa, over the back of which the arm was passed; extension was then made, without the necessity of counter-extension, by grasping the humerus; the reduction was easily accomplished. Extension should be made on the radius only, the hand being supine.

It has been a matter of question whether those gradual displacements backwards of the head of the radius, which occasionally occur, should be considered in the general subject of luxation, or whether they should be considered as consequences of organic disease of the ligamentary tissues, in relation with the superior portion of this bone. Boyer believed it to be often produced by the forced pronation which nurses too often impress upon the arms of children, by raising them suddenly from the ground, by holding the wrist: but it may happen from contusions which have not elongated the ligaments. Sometimes we cannot refer it to any external cause. Usually, in these cases, we can distinguish tumefaction around the superior extremity of the bone; this swelling is painful, the hand remains prone, the fore-arm semi-flexed; gradually the head of the radius projects back more and more. Sometimes the affection is dissipated and motion resumed; sometimes it lasts long, the radius remaining displaced; then supination is impossible, and the radius may ankylose with the ulna; the inflammation may terminate in abscess or caries. To this disease the ordinary means of treating luxations are clearly inapplicable; leeching, quiet, blistering, are the appropriate means of treatment. As soon as the inflammation has somewhat subsided, an angular splint to the bend will serve to counterbalance the too powerful action of the flexors and pronators.

Sir A. Cooper states that the ulna is sometimes luxated backwards upon the humerus, without carrying with it the radius. The character of the limb is much changed by the turning inwards of the forearm and the hand; the olecranon projects backwards; extension of the arm is impracticable, unless the force applied be sufficient to reduce the luxation. This accident is not easily detected; the signs are projection of the ulna, and the inward rotation of the forearm. In the museum of St. Thomas's Hospital is a good specimen of this accident—a long time had elapsed before reduction was effected. The

coronoid process of the ulna was received into the posterior or olecranon fossa of the humerus; the radius rested against the external condyle, and had formed a small cavity, which received the head and allowed of its rotation. This accident was caused by a violent shock upon the inferior extremity of the ulna, by which this bone was suddenly forced upwards and backwards. Luxation of the ulna alone is more easily reduced than when both bones are implicated. The reduction is best accomplished by flexing the forearm over the knee, and drawing the forearm downwards: the reduction is then easy.

THE RADIO-CARPAL ARTICULATION.

Dislocation of the wrist was formerly considered to be very common: standard works contain descriptions of backward, forward, and lateral luxations, and yet, says Dupuytren (*Leçons Orales*, tom. 4, p. 162) there does not exist a single undoubted observation of this injury. His dissections and observations led him to regard the greater part of the pretended luxations as fractures of the inferior extremity of the radius. Pouteau and Desault had also detected this error in diagnosis. Dupuytren was not strictly correct in his opinion, though nearly so. Sir A. Cooper, who usually associates with his descriptions a series of facts, alludes only to a single case of dislocation of the wrist, and does not consecrate many lines even to general remarks on it; but I shall presently mention four other cases, one from Cruveilhier, one from the *Journal de Médecine*, tome 39 (Thomassin,) one from Malle, and one from the *Lancet*, copied from a German journal, as proofs of its occasional occurrence, and there is a specimen in the museum of St. Bartholomew's Hospital.

The extreme rarity of the luxation is explained by the small extent of the lever represented by the hand, and the great strength of the joint, and the support obtained before and behind by tendons. In falls upon the hand, either the weight of the body is directed upon the inferior extremity of the metacarpal bones, or on what is called the heel of the hand; in the first case the efforts are concentrated upon the carpal articulations, causing displacement of those bones; in the second, they are directly transmitted to the radius, which gives way.

Feeling satisfied that the opinion I have expressed of the unfrequency of this luxation is correct, it may be said, how is it to be reconciled with the opinions of persons of much more extended experience than my own? I believe the explanation to be simply this: that these displacements have been described theoretically.

Malle describes a case where a drunken soldier threw himself from a second-floor window into the street. It seemed probable that his right arm was extended, to break the fall, and that its palm first came to the ground. He was conveyed to the hospital insensible; the right wrist was carefully examined, and the conclusion came to was, that the radius was fractured. The hand was extended upon the forearm, and the carpo-metacarpal region seemed much, shortened: at the anterior part of the articulation a remarkable projection was observable; the radius and ulna were prominent posteriorly; the fingers were flexed, and the flexor tendons very tense. Symptoms of concussion existing, it was thought to be a favourable moment for attempting reduction, and it succeeded. The patient died in three days, from cerebral disorder. After death the wrist was examined: the parts were infiltrated with blood, the anterior ligament of the capsule was ruptured, a little sanguinolent serum was contained in the joint, there was no fracture of the radius, the first range of carpal bones was very moveable.

In Cruveilhier (*Anat. Path.* liv. 9) is an example of luxation of the wrist without fracture of the radius; in other words, a luxation backwards of the forearm upon the hand. (Fig. 1.) In that case the forearm appeared shortened, it formed with the hand nearly a right angle; extension was impossible; flexion could be carried farther than is seen in the figure, the inferior extremities of the radius and ulna projected under the integuments. The superior extremity of the carpus is on a plane anterior and superior to the extremities of the bones of the forearm. Now this fact is in formal opposition with the descriptions usually given: it was a dislocation forwards; that is to say, the inferior bones were in front of the superior. The ordinary description of forward dislocation is the following: "the hand is fixed in extension proportioned to the degree of displacement, the fingers are more or less flexed," &c. Should we therefore regard Cruveilhier's as an exceptional case? I think not; because in mechanics, properly speaking, there are no exceptional cases; the same causes ought always to produce the same effects. I cannot conceive that a dislocation caused by a fall on the back of the flexed hand, can have, as a result, a dislocation with extension of the hand.

As to backward dislocation, I mean that condition in which the carpus is completely behind the bones of the forearm, I can scarcely conceive dislocation to be possible without fracture; for in that case the repulsion of the soil is entirely directed upon the inferior extremity of the radius. On the other hand, I can scarcely conceive the possibility of fracture of the radius as

Fig. 1.

an effect of a fall on the dorsal surface of the flexed arm. Complete lateral dislocation I believe to be impossible, or rather, I would say, I know no instance of it.

Whatever the luxation may be, the movements of the hand are arrested, and rotation of the radius is impossible, in consequence of the destruction of ligaments, distension of tendons, and injury to the soft parts. It is always a very serious accident, from the effects of which recovery is always doubtful: motion at the part is incompletely restored; the inflammation which is developed may pass into a chronic state, and end in white swelling; or, if ill treated, may turn into abscess of the joint, or even gangrene of the hand: it is especially when the radius has violently contused or pierced the skin, that these accidents happen.

Treatment.—It is necessary, in these cases, to proceed to reduction as soon as possible, to combat, by energetic local and general means, the inflammatory action which is sure to be manifested, and not allow the patient to move the hand until the pain and tumefaction have disappeared. If, as in the case of Thomassin, the bones protrude through the skin, and prevent reduction, resection is the best means of removing the difficulty; but if the injury of the soft parts be great, immediate amputation must be performed. If the dislocation be forward, an assistant seizes

the hand near the wrist, and extends it until the carpus is brought to the level of the joint; he then flexes it, while the surgeon grasps the wrist, and with his thumbs pushes down the carpus to its proper place: reduction is usually accomplished without difficulty. In dislocation backwards, the assistant having made extension until the carpus is disengaged, brings the hand into forced extension, whilst the surgeon presses on the bones of the forearm until reduction is accomplished. As to luxations outwards or inwards, I know no instance of them, and I shall, therefore, not further allude to them. After reduction, a fracture apparatus should be applied, and the part kept motionless.

REPORTS OF CASES.

By H. M. HUGHES, M.D.

Physician to the Surrey Dispensary.

PHTHISIS.—Of the thirty cases of this disease of which I have retained some notes, among the far larger number that have been under my care during the last year, sixteen have proved fatal, and probably not less than four died a very few weeks after their removal from my superintendence. The whole number of

deaths occurring among my dispensary patients during the year was forty-two. More than one-third, therefore, arose from this terrible malady; a proportion considerably larger than generally exists in England, or the metropolis. Nothing can, of course, be deduced from so insignificant a number of cases; but as Mr. Farr has, I think, (for I have not the work now by me to refer to,) stated, in the first report of the Registrar-General that in those districts in which the deaths from phthisis, as compared with the general mortality, have been numerous, the gross amount of deaths has been small, I would suggest, that an increased proportion of deaths from phthisis, in relation to the general mortality of a given district in one year as compared with that of another, may probably hereafter be found to co-exist with a healthy period.

Of the thirty cases now under consideration, twenty were males, and ten females. Of the males, two were under twenty years of age; ten were between twenty and thirty; and eight were above thirty. Of the females, two were below twenty; five between twenty and thirty; and three above thirty. Of the sixteen deaths ten occurred among the males, and six among the females, while under my care. The ages at which death took place were 7, 16 (2), 18, 20, 21, 22, 26, 27, 29 (2), 34 (2), 44, 48, and 52.* The two cases noticed in the table as "cured," were examples of the disease in the incipient form, as, at least, appeared to be indicated by the history, the general symptoms, and the physical signs. The treatment was followed by complete suspension, though probably not by the absolute removal, of the disease. It is, however, obvious, that when the latter cannot be effected, it is no trifling advantage to be able, in many cases, to induce the former.

Having written a paper on the "Physical Diagnosis of Incipient Phthisis" in a late number of the *Guy's Hospital Reports*, and intending, in a short time, to add some observations on the treatment of the early stages of the disease, I shall not now enter upon either of these most interesting and important subjects. I cannot, however, refrain from expressing my assured conviction of what I have there asserted, that ap-

preciable dulness on percussion is very far from being an early physical sign of phthisis; that when it is clearly distinguishable below one or both of the clavicles, or in the acromial regions, the complaint has generally advanced too far to be effectively treated, and that it not very unfrequently passes through the whole of its stages without any dulness whatever. I lately attended a man in the last six weeks of his illness, whose chest, during the whole of that period, was more than usually resonant on percussion, but whose lungs were found, on examination after death, to be thickly and universally studded with tubercles, in all the stages of crudity, maturity, and softening. The diagnosis was, however, in this case, and in most others may be formed, from other physical signs combined with the general symptoms. The auscultatory signs of the latter stages of the disease are now so well established, and so generally known, as to need no illustration; and, on the treatment, I have nothing to add to what has already been frequently said before, excepting to express my decided conviction, derived from clinical observation and reflection, that a general tonic mode, both medical and dietetic—"the beef-steak and porter system" of treatment, as it has been disparagingly termed by a high authority—offers in many cases the most rational hope, and is, both theoretically and practically, the best means of securing an indefinite prolongation of life.

Two circumstances of some practical importance, which have lately occurred to me, in the last stages of phthisis, may be, perhaps, advantageously noticed. I know of no symptom which, in this disease, has been more distressing to the patient and, to myself at least, has proved more irremediable, than the constant pricking and smarting of the throat, arising probably from ulceration of the larynx and epiglottis, and so much increased by the act of swallowing, as sometimes to prevent food of any kind being taken into the stomach. I had tried, without effect, a great variety of topical applications, both internally and externally, for this troublesome affection, in a woman, aged 22, whom I saw only during the last two or three weeks of her life, when, rather with the view of trying something fresh, than with the hope or expectation of relief, I ordered *very hot* water to be

* Of these, three among the males, and two among the females, were instances of acute phthisis.

externally applied to the throat, in the same way in which it has been found so efficient a remedy in acute inflammation of the larynx and trachea. I was much surprised and gratified by the result: the pricking and severe smarting were speedily removed, and the patient swallowed with ease and comfort; and, though the annoyance frequently returned, a repetition of the application was, till the death of the patient, always effectual in relieving her. The other circumstance to which I have referred occurred in the same patient. She had been greatly teased, and her little remaining strength had been already much reduced, by a more than usually severe and obstinate diarrhoea, for which I had prescribed chalk and opium, sulphate of copper, acetate of lead, kino, catechu, &c., and ordered opiate injections and suppositories, without any good effect. The few days of life that yet remained to her, would have been not merely curtailed, but rendered wretched, by the continued and exhausting drain upon her feeble frame. I therefore resolved to try the means which I had frequently found so advantageous in dysentery; and though I expected little or no benefit from their employment in such a case, I ordered three or four leeches to be applied to the verge of the anus. The effect very much surprised me: the diarrhoea was checked at once, did not recur, and the patient passed the last three or four days of her existence in comparative comfort. I have never, either before or since, applied either of these remedies in similar cases, and am therefore unable to say that the relief which so very decidedly followed their employment was not merely a coincidence. That relief was, notwithstanding, so marked, and appeared to result so immediately from the applications, that I have thought it right simply to mention the facts, and to hint that, in the examples of these affections in which other remedies fail, the means proposed are at least worthy of trial. Only one of my cases occurring at the Dispensary during the past year, possesses sufficient interest to require particular notice in these reports.

Caroline Aborn, a weak delicate woman, and of light complexion, aged 22, came under my care July 20, 1839. She had for some years been troubled with debility, combined with pain and weakness of the loins, but had never

suffered from hæmoptysis or cough of any severity or constancy, till about three weeks before I saw her. The general debility appeared to have been connected with irregularity of the function of the womb. Her parents were alive and healthy, and her brothers and sisters had not presented any indications of phthisis. When first visited she was pale, feeble, and exceedingly nervous. She complained of oppression of the breathing and frequent cough, accompanied with rather copious mucous expectoration; the tongue was pallid, clean, and moist; the pulse frequent, small, and weak; and the catamenia irregular. Accurate examination of the chest by auscultation and percussion was impossible, in consequence of her great excitability and of the tendency to faint, which was always induced by the operation. From the imperfect investigation that was alone practicable, I was never able to detect any dulness on percussion, or any more decided indication of phthisis than a universally diffused bronchial rattle, with deficient expansion of the upper portion of the chest, and some slight flattening below the clavicles. After the use of counter-irritants, emetics, and sedatives, combined with the preparations of iodine, for some weeks, the affection of the chest was much lessened; her cough almost ceased, and she took tonics with great advantage to her general health. About the end of September she was attacked with bronchitis, in a more acute form than she had hitherto suffered. Leeches below the clavicles, blisters upon the sternum, and small doses of antimony, blue pill, and opium, removed the soreness of the chest of which she complained, but had little or no effect in relieving the cough. She soon began to decline rapidly in strength; her pulse increased in frequency, and it was evident that she was fast sinking, and her end approaching, when, in the middle of the night of October the 9th, after feeling as well or rather better than for some days or weeks before, a not very violent fit of coughing was immediately followed by excessive dyspnoea, accompanied with great prostration and flatulence of the stomach and bowels, but without any pain, either temporary or permanent, local or diffused. I was not acquainted with the circumstance till noon, and saw her at 2 P.M., Oct. 9th,

up to which time the symptoms continued with little diminution or variation. I found her lying in the semirecumbent position, turned about half way to the left side; the face and body covered with clammy perspiration; the extremities cold; the respiration hurried and anxious, and with a scarcely perceptible pulse. But little examination of the chest was practicable or justifiable. It was, however, evident that the right side had become exceedingly resonant on percussion, that the resonance extended below the sternum, and that the respiratory murmur was scarcely audible, and appeared distant. The state of the left side could not be ascertained. The escape of air into the pleura, and speedy dissolution, were of course predicted. Sinapisms were applied to the chest and feet, and ammonia was administered internally; but she expired at 10 A.M. the next morning, about 34 hours after the supervention of the alarming collapse.

Inspectio Cadaveris, twenty-four hours after death, (made by Mr. Nettlefold, the apothecary of the Institution, as I was unfortunately engaged).—The chest alone was examined. On cutting through the ribs, a rush of air escaped from the right side. The right lung was compressed to about one-fourth its natural size, by air which occupied the remaining portion of the pleural sac, and which had pushed the heart and mediastinum to the left of the sternum. There was no fluid or any other evidence of inflammation of the serous membrane. The apex of the right lung was adherent to the pleura costalis, and was studded throughout with miliary granulations, with a few opaque tubercles interspersed between them. In the mammary region was found a small cavity about the size of a nutmeg, which, though near the surface, did not communicate with the pleural sac. In consequence of the lungs not being inflated, the opening from the air cells was not discovered. On the left side the lung was congested, and sprinkled throughout with tubercles, generally immature, but in a few instances just beginning to soften. The pericardium was healthy, and the heart small and flabby, but otherwise free from disease.

The gentleman who made the preceding inspection for me, afterwards mentioned a similar, but more remarkable case of the same kind, which, as

it never has been made public, with his permission, I append to this paper.

A remarkably fine young man, aged 19, of light complexion and flaxen hair, whose parents were alive and healthy, but one of whose brothers had died of phthisis, without any previous indisposition, and having never been troubled with cough, was suddenly attacked with hæmoptysis. In about a fortnight he was sufficiently well to remove to the coast for change of air. He had remained there with benefit to his general health for three weeks, when he was suddenly attacked with violent dyspnœa, and died in ten hours; only five weeks after the first decided indication of disease of the lungs.

Inspectio Cadaveris, twenty-four hours after death.—Percussion elicited a remarkably clear sound on the left side, while on the right side the sound was dull, especially at the posterior part. On dividing the cartilage of the fifth rib on the left side, air escaped from the chest with a whizzing sound. Two-thirds of the pleural cavity were filled with air; the superior and posterior third of this side of the chest being occupied by the collapsed lung. The pleura was itself free from disease, excepting some adhesion connecting it with the apex of the lung. The whole of this lung was sprinkled with tubercles, some of which were so near the surface as to produce an elevation upon the pleura pulmonalis. The right pleura was firmly adherent both to the parietes and the pericardium. The apex of the right lung contained some immature tubercles; the inferior lobes were simply, but considerably congested. The smaller bronchial tubes in both lungs were much coloured by injection; those of larger size were pale and natural. No ulceration or laceration of the pleura, giving rise to the escape of air, could be detected after minute examination; but a blowpipe was not employed for the purpose of discovering it. The pericardium was firmly adherent to the sternum, the cartilages of the ribs on the right side, and to right pleura pulmonalis, but the internal surface was free, and the sac contained rather more fluid than is usual. The heart was flabby and thin, and was pushed upwards and to the right, as far as the external adhesion of the pericardium would permit.

PARATIVE ANATOMY.

By T. WILKINSON KING,

Curator of the Museum of Guy's Hospital.

[For the *London Medical Gazette*.]

THE explanation of the shutting up of the foramen ovale appears to be well understood, but the contraction of the ductus arteriosus is, I think, under somewhat different circumstances. The first branches of the pulmonary artery increase in relative size shortly before birth, and the first respirations render their circulation still more free: at this time, perhaps, the communication between the pulmonary artery and aorta becomes less direct (more oblique) than before; but the changes here mentioned have

never seemed to me adequately to explain the rapid disappearance of the arterial passage. There is, I believe, no other account of this event in the records of physiology.

I had long entertained a different opinion; but it was not until lately that other considerations presented themselves, apparently rendering my view more reasonable, and somewhat more than curious; and even now I quite feel that it should rest with the reader to consider whether so theoretical a matter comes within the limits of his useful or proper studies.

It is in connection with more extended views of the circulation, which I hope to take some part in illustrating, that this inquiry may derive importance. It is in the pathology of congenital deformities that the opinion advanced seems to be requisite as well as illustrative.

It is in a few curious facts of comparative anatomy that the opinion obtains its most remarkable corroboration.

DIAGRAM NO. 1.—Shewing the relative position of the ductus arteriosus. This is a sketch from a dissection at the fourth month of foetal life, and may serve to

explain the general relation of the great air tubes (as represented by dotted lines) with the artery.

A very cursory reference to the larger parts immediately about the ductus arteriosus, as seen at the period of birth, will be sufficient to make this view intelligible. The pulmonary artery at its point of bifurcation gives off the temporary tube which the aorta receives near the summit of its descending portion. The division of the trachea occurs close behind the middle of the arch of the aorta, and the left bronchus curves downwards to the left into the lung, before the descending aorta, beneath the ductus arteriosus, and behind the left pulmonary artery. Now the close packing of these parts in the unborn child is, if any thing, even more remarkable than in after periods; and to this state of things I

would refer the consequences of the first respirations. In foetal life the air tubes contain only a little fluid; they are probably but partially expanded, while the circulation is nearly single and equable, the auricles pretty equally full at all times, and the ventricles equally powerful. The chest continues of limited capacity; the diaphragm high, and the lungs confined about the heart.* We

* I am scarcely disposed to think that no motion takes place in the respiratory muscles of the child before birth, but I rather suppose that along with the common movements of the foetus there is also some and perhaps frequent exercise of the well-developed thoracic muscles, especially towards the end of uterine life. On this point I may add, that some cause remains to be found for the manifest proportional increase of the right and left pulmonary artery, as well as decrease of

may now reflect upon the principal effects of the first inspiration: a general expansion is made, which is never again to have its commensurate collapse; and, although that fulness of the lungs (as to air) which may be regarded as necessary and permanent, be not obtained till later, it seems pretty evident that the first inspirations must have a far larger share than any others in effecting this condition. Now the trunk becomes straighter; the neck is no longer bent forwards on the breast, and the trachea is elongated; the diaphragm, and with it the heart, is considerably drawn down, while the lungs are generally expanded, but most particularly outwards;* and one particular result of all these changes, I imagine to be, that the left bronchus is rendered more full and tense, and also raised at the same time that the ductus arteriosus is drawn down with some force, and perhaps with some disposition to elongation. In fine, it is to the sudden and intimate cross contact of these two tubes that I would mainly attribute the closing of the blood-vessel, which is in a manner bent over the bronchus, and has also a more oblique direction given to its communication with the aorta. I think that the appearances on dissection are corroborative, although I confess that the study of the parts,† with which we are concerned at different periods before and after birth, affords no positive proof of the opinion explained; nor have I been able to make the experiments in the way of injection and inflation more conclusive. The following, however, from pathology, are, I think, some farther corroborations of the view I suggest:—

First, if the pulmonary artery be closed at its origin only (congenitally) the arterial ductus remains open after birth, seemingly by the force of the current from the aorta, which is filled by the two *communicating* ventricles; but if the pulmonary orifice be open, even in a very small degree, the duct becomes as thoroughly closed as ever, although the

two ventricles still communicate freely; that is to say, that no force from the aorta, short of the entire current claimed by the pulmonary arteries, is sufficient to keep open the ductus arteriosus; and this there is abundant evidence to prove. I ask, is it not reasonable to infer some extraneous cause of the disclosure of the duct, when it has become fully developed with the mouth of the pulmonary artery closed or open in any degree, and yet contracts at birth in all cases except where the mouth of the pulmonary artery is impervious?

Secondly, if again there be a simple transposition of pulmonary artery and aorta, the duct remains open; but if, in a like case, there be but a very small communication between the ventricles, the ductus closes. In cases of transposition the auricles communicate, and the power of the left ventricle being too great for the pulmonary circulation only, it assists to fill the arterial duct, which is thus prevented from contracting; but if any communication exist between the ventricles, their power is necessarily more nearly equalized, and the duct closes, notwithstanding that a considerable and direct distending force must be in operation within.

I shall not dwell upon the various interesting circumstances relating to this inquiry, which comparative anatomy supplies. Some animals seem to change from an aquatic life to an air-breathing state, as it were; from a fetal to a post-natal existence, every day—as the frog, turtle, and crocodile; and in these we find various substitutes for arterial ducts, with indications of alterations in the course of the blood, according to the state of the lungs. The insertion of a slip of the diaphragm into the apex of the heart of the crocodiles (with a communication between the aorta of the right and left ventricle), seems peculiarly to connect the circulation with the respiration in these animals. The passage of an aorta over both bronchi in all the instances mentioned, and an apparent provision to send the most aerated blood upwards, are also to be remarked. Some of the chelonians have also a diaphragm inserted into the apex of the heart. I conclude, too, that serpents may share in this varying distribution of the arterial fluid, according as it is freely or scantily aerated. One example may serve to illustrate my meaning, if not to establish my opinion. The

the arterial duct, which slowly occur prior to birth: respiratory movements may be equal to this.

* The sternum is at the same time advanced.

† A series of these gradations are to be seen in the museum, as well as illustrations of all the statements which follow. The state of animals which are born blind, and in whom the arterial duct closes but slowly, may be thought to favour the view maintained above, but a conclusive proof is still to be found. It may, perhaps, occur in the rare instances in which the duct continues freely open in after life, when the situation of the bronchus shall be noticed in such cases.

case of the alligator is, I suppose, as follows:—

The origins of the great aortæ (L A and R A) are dilated and elastic reservoirs. Relaxation of the diaphragm and its cardiac insertion (D), with col-

lapse of the lungs, produces an excess of dark blood in the right ventricle (R A), which can only find ready exit by the right aorta (r A); the pulmonary arteries (P) being more or less obstructed at this time. Now I imagine the

great aortic arch crossing the bronchial tube (B B) on either side, to be relaxed, and to transmit the blood more freely; and also I deem it a reasonable inference that a part of the dark blood in the right aorta (r A) will pass by the opening (O) into the left aorta (L A).

With a free inspiration the heart must be supposed to be drawn down, and (from the dissection of those parts *in situ*, in the alligator of Jamaica) I venture to assume that the great arches are rendered more tense and angular, and less free, by contact with the bronchial tubes (B B). I even conclude, that when the dark blood prevails in the right aorta, it may even cause a reflux into the left from the abdomen, by the union of the two (A B) at that part.

The object of all this seems to me to be closely comparable to the arrangements in the human fœtus, by which the better blood goes to the head and arms, while

the worse passes to the abdominal parts and depurating organs; and analogous also to those changes in the child at birth, by which the currents are permanently diverted.

NOTICES OF ŒDEMA PULMONUM OCCURRING IN PARTURIENT WOMEN.

To the Editor of the Medical Gazette.

SIR,

I do not recollect to have met with any work in which œdema pulmonum is set down, and treated of as one of the accidents happening during the parturient state; nevertheless, it does happen occasionally, and that now we have diagnostic means of ascertaining its existence, I think special attention should be drawn

to it. Soon after I began practice I met with a case, which I thus notice in the rough notes of my diary of cases:—

“Nov. 1st, 1827.—Mrs. A.: protracted labour; strong uterine action; but narrow pelvis; first child thirty-four years of age; healthy woman. During labour considerable dyspnœa; accumulation of mucus in throat; much distress; fourteen hours in full labour; lost little blood; constant tickling cough.”

“Nov. 16th. — *Rale* in throat has continued, as also short distressing cough, with much general debility. Child doing well.”

Again, in 1837, I find the following note, after the brief statement of a somewhat similar case:—“In the progress of severe and protracted cases of labour, I have repeatedly met with the development of a loud bronchial and tracheal *rale*; it is very loud and very distressing, and I have heard a patient express great fears, from its similitude to the “dead rattles.” I have tried many things for it: nothing relieves it so completely as a little warm fluid, such as common tea, or beef-tea. I never like to hear it: the cases have more than once required the forceps in consequence of their duration; the breathing is more or less difficult.”

Again, 1838, I find the following notice in my diary of this affection. “At page 8 (of Note Book G) are a few remarks on a loud mucous rattle in parturition, to which I subjoin the following case, and wish it to be regarded as a continuation of these remarks. In more than one case of protracted labour, when this symptom appeared, I have observed unequivocal marks of an œdematous state of the lungs. A young woman (Mrs. M'G—, æt. 22) fell in labour of her first child. She had been for some time in a feeble and cachectic state, with considerable anasarca swelling of her feet, forearms, and occasionally of her eye-lids. During her labour, which, from irregular uterine action, was protracted, she complained of oppression of breathing, occasioning much distress; a *single* frequent hard cough, and the rattle in her throat. These symptoms went on increasing during the labour; she became exhausted, and I applied the forceps. The cough and oppression of breathing assumed a very alarming degree after delivery, and I shared in the fears of her friends that she was dying; more par-

ticularly as she lost a considerable quantity of blood.

“On listening to the sounds of breathing, I heard the subcrepitant *ronchus* very extensively, and but very feeble respiratory murmur any where: at some parts, particularly the left lower part of chest, there was much dulness on percussion. These symptoms continued for eight days. She found relief from a mixture of squill (syrup of) with peppermint-water, and anodynes. In time she quite recovered, and has borne a child since, without any bad symptom. I have also noticed slighter cases of œdema pulmonum in parturition: they have always, with one exception, been in feeble women. In one case the woman was so full that I ventured to bleed her. I do not know that she had any immediate relief from it. In none do febrile symptoms happen. Anodynes afford the speediest and most permanent relief. My anodyne in such cases is the following:—

R. Træ. Camphoræ Comp. ʒviii.; Solutionis Muriat. Morph. ʒj. M. sumat sæpe ægra gut. x. in frustulum sacchari urgente tusse; et Cochlearia minima duo ex Infus. Linî, h. s.

In conclusion, I would remark that none of the women were subject to cough or dyspnœa: these came on during the labour.—I am, sir,

Your obedient servant,

ALEX. J. HANNAY,

Prof. of Physic, Andersonian University.
Glasgow, June 25, 1840.

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

WILL you allow me to express the gratification I experienced on perusing your excellent article on the Vaccination Bill. Without dwelling on any other part, there is one remark made there which I think might be reiterated with advantage to many members of our profession, “The plain truth is, that there is no proof whatever that with cow-pox any other disease can be communicated, while all facts and probabilities militate *in toto* against such an opinion.” Subscribing heartily to this doctrine, I much regret that the contrary opinion is held and promulgated by many practitioners,

not only to the discredit of vaccination generally, but at the risk of damaging their own reputation as well as that of others, and with the certainty of exposing themselves to much needless annoyance. Whilst, on every account, it is a manifest duty to employ lymph from healthy children only, it is neither wise nor fair, when no other cause for a disease can be assigned, to attribute its origin to vaccination from an unhealthy source. A medical friend in this place, (much my senior, and whose authority consequently is much weightier than mine), lately pronounced on an eruptive case, that it arose from the child having been vaccinated from an unhealthy subject. I have been astonished at the number of persons from whom I have heard of this child "turned into a most horrid spectacle;" and I find that the caution of parents (always in the extreme on this point) has of late been aggravated to a very annoying extent. It is not enough to be able to answer for the parents of the child, but I have had inquiries put to me respecting the preceding generation; and if the fancies and fears of the idle and wealthy are to be sanctioned and encouraged, it will be soon expedient that practitioners in this place should furnish themselves with the genealogy of all the clodpoles in Gloucestershire, together with a record of the integrity of their constitutions, and a voucher for the purity of their morals. Not long since I had a lucky escape: I was asked to vaccinate a child, but from some cause neglected to do so for some weeks; in the interim porrigo manifested itself, which proved both severe and obstinate, and I missed the credit of making a "horrid spectacle," as I learnt from the father, who said he did not know how to account for it, *especially as the child had not been vaccinated.*

While on this subject, I wish to inquire if there is not a typographical error in the second line of the Statistical Notices of Small Pox, which appeared in your last number but one, but of which there is no notice of error in your last number? * It is true that the orthographical difference between vaccinated and unvaccinated is very slight, but its importance is every thing with respect to the statistics in question. I have been, at times, tempted to ask you to insert an examination of the various statistical notices of small-pox which have

appeared in your volumes, in order to determine what questions they may be expected to solve, what is their relative importance, and what deductions may be fairly drawn from the statements, but have been afraid of entering on so tender and irritable a topic. I am, however, convinced that a small-pox statistic is apt to overrate the value of his researches; and to him would be peculiarly applicable the observations which Carlyle, in his pamphlet on Chartism, has applied to the political statistic: "To him it seems he has extracted the elixir of the matter, on which now nothing more can be said. It is needful that you look into his said extracted elixir, and ascertain, alas, too probably, not without a sigh, that it is wash and vapidity good only for the gutters."—I am, sir,

Your obedient servant,

HENRY COLES.

Cheltenham, July 6, 1840.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

An Essay on the Treatment of some Affections of the Prostate Gland.

By R. A. STAFFORD, Esq. &c. &c.
London: Churchill. 1840.

OF late years much attention has been given by pathologists and practitioners to the diseases of the genital and urinary glands and cavities, as well as to the fluids that are generated or deposited in them. Amongst the former, the prostate gland has been examined anatomically and pathologically, with much care and considerable success, by those who, in this country, have very recently investigated the history of that organ in its morbid condition. The author of the present opusculum is one to whom, however we may differ from him on some points, we must give the credit of having been at much pains in the collection of facts, and in the contrivance of instruments and other means for the cure or alleviation of prostatic diseases. It is now several years since Mr. Stafford published a volume in which he described and illustrated by cases and drawings a new method of treating urinary obstructions, depending on diseased urethra or enlarged prostate gland, by puncturing, so as to make free passage from the bladder along the

* We are not aware of any error.

penis. Since then his attention seems to have been much directed to the subject, and new difficulties have been met with and new contrivances been adopted. Of those contrivances it is the object of this work to lay before the public a short statement. The point of practice more particularly handled by the author is the removal of that form of prostatic disease in which either the body or the middle lobe is enlarged, and projects inwards or upwards, so as to form a barrier inside the sphincter urinae; over which, in extreme cases, the urine can with difficulty be forced by the strongest efforts (of which Mr. S. gives a remarkable example at p. 13). Of the treatment of those extreme cases the author has spoken in a former work, above alluded to, in which he describes his method of puncturing and perforating the obstructed lobe of the gland; but cases less aggravated he seems to find manageable without any cutting operations. The following short extract will indicate sufficiently the general character of the author's method:—

"If the third lobe (of the prostate) has only partially been enlarged, I have then employed remedies, such as iodine, iodide of potassium, belladonna, &c., locally, always in a diluted form, and combined or uncombined with other substances as the urgency of the case might require. If it (the third lobe) be so large that it will not yield to the application of those substances, I have in some instances punctured it with advantage; and when its volume has been so great as to block up the neck of the bladder and cause retention of urine, I have then been under the necessity of perforating it." He then speaks more particularly.

"The power of iodine and iodide of potassium in reducing glandular swellings is well known." "It was this circumstance that led me to think it might be advantageously employed to reduce an enlargement of the prostate gland." "I at length" (after various unsuccessful trials and other means) "thought of a simple mode of applying it by charging a bougie at its point with the iodine, iodide of potass, or any other substance, and then dipping it in the melted tallow, so that a coating might be formed on it. By such a method, I have been able to introduce any application I might desire up to the prostate gland, without touching the surface of any other part of the urethra. The bougie having reached

the desired spot, its point is allowed to rest on the diseased part, when the tallow gradually melts, and brings the iodine or iodide into contact with it, and by drawing the instrument gently backwards and forwards the necessary friction is produced." He then subjoins useful cautions and explanations. "At first, I have found it necessary to employ even anodynes, such as belladonna, opium, hyoscyamus, &c., to quiet irritation and pain; when these have subsided, I have begun carefully by introducing the iodide of potassium, in the proportion of one grain to the drachm of the unguent. cetacei, and increasing it as the patient could bear it. I have then gone on with 2, 3, 4, 5, and even as far as ten grains or a scruple to the drachm, according as the case required. After this I have applied iodine to it; half a grain, 1, 2, 3, 4, and even more grains, in the same manner. The surgeon who applies it can only judge of its effects." He then subjoins sixteen cases in illustration of his method: of these, five appear to have been cases of general enlargement of the gland, successfully treated with iodic and anodyne remedies, either by the anus, in the shape of suppositories, or by the urethra, in the manner above described. Six were cases of diseased middle lobes, treated nearly in the same manner as the former. The five remaining cases were examples of puncturation of the gland in the author's peculiar manner, or of perforation through it into the bladder. The author concludes his Essay thus—

"The object I have had in view has been to point out a set of cases of prostatic disease, where relief might be obtained, and to put my professional brethren in possession of the means by which this desirable object might be accomplished. I would not presume to say that the treatment I have recommended is adapted to all cases, although I have reason to believe that, in many, the remedies I have employed will be found very effectual. My own experience is much in favour of the treatment I have employed for enlargement of the prostate gland, and its third or middle lobe. It now only remains, therefore, to be confirmed by a more extended experience than one individual has it in his power to acquire."

To conclude, we have read Mr. Stafford's work on the Prostate Gland with considerable interest: the great

frequency of such diseases, their difficulty of management, their extreme inconvenience, when not urgently dangerous, render every attempt to improve their treatment worthy of encouragement, and entitle the practitioner who, with a view to such improvement, ventures out of the beaten road of practice, to our liberal consideration in any event; and, should he obtain any useful new results, to our cordial thanks for his services, and our sincere congratulations on his success. With those feelings we close Mr. Stafford's volume. We have no personal experience of those portions of his plan or means that are new, but his results, as given in his Cases, strongly testify to their efficiency; and we see no reason to doubt that similar results, in the hands of other distinguished surgeons, will shortly be found to substantiate their utility.

The Principles of Botany, structural, functional, and systematic; condensed, and immediately adapted to the use of Students of Medicine. By W. HUGHES WILLSHIRE, M.D. Edin. &c. London, 1840. 12mo. pp. x. and 232.

DR. WILLSHIRE, who is the lecturer on botany at the Charing-Cross Hospital, has drawn up this work, not from any deficiency of elementary works on botany, but because "he thought he could present to the student of medicine a more condensed view of the first principles of the science, combined with circumstances, and illustrated in a manner which would more immediately interest him, than was done by any mere single text-book with which the author was acquainted."

There are five divisions in the work. The first treats of the anatomy of plants; the second, of their morphology; the third, of their physiology; the fourth, of their pathology; and the fifth of systematology.

Under the head of physiology, our author gives an account of germination, nutrition, respiration, generation of heat and light, secretion, colour, taste and odour, irritability, growth, and generation.

After giving an account of the Linnæan classification, Dr. Willshire explains the natural system of Decandolle, and arranges the officinal plants of the London College in accordance with it. For instance, under the head of *Papaveraceæ*, he gives the botanical characters

of the group, and terminates the account thus:—

"*Geographical Relations.*—Europe and North America chiefly, though they are found elsewhere, as in China and Japan for instance.

"*Properties.*—Narcotic. This deleterious property resides in their juices, their seeds being oily, but not possessed of any soporific powers.

"*Officinal Plants.*—*Papaver rhœas*; *Papaver somniferum*." (p. 169.)

The following extracts will afford our readers some notion of the varied information diffused through the work:

"We have stated that a certain degree of heat is necessary for germination to ensue, and it is generally said no seed will germinate at a temperature below the freezing point of water: Edwards and Collin say, not below 44° Fah.; Goeppert allows to 37° Fah. The subject requires further investigation in relation to some cases, as in Nova Zembla, for instance, where plants are to be seen in flower in a soil whose highest temperature at the time is only 34° Fah. According to the last-mentioned observer, no degree of cold can destroy the *vitality* of a seed, if it be perfectly dry, or have absorbed no moisture.

"The degree of ascending temperature that seeds will bear is various; some have borne that of 235° with impunity, whilst 113° has been fatal to some; much depends, however, on the hygrometric relations of the heated air and seed: fluctuations of temperature are generally detrimental." (p. 173.)

"The Beet-root and Plane-tree root contain much saccharine matter, and in that obtained as exuding from the bark of *Fraxinus ornus*, called Manna, a principle named *Mannite* is found. According to Decandolle, Manna, occurring in the form of tears, is caused by the injury of insects on the bark, but that in masses by natural exudation, in consequence of a superabundance in the interior of the plant." (p. 101.)

"The *Fucus vitifolius*," says Bonpland, "removed from a depth of 190 feet in the ocean, offers a curious phenomenon in vegetable physiology. Experiments made by divers render it probable that beyond a depth of ninety feet the penetration of light is very little, notwithstanding which this *Fucus* was of as fresh a green as the young leaves of our Vine or Grasses."

Dr. Willshire's book will be read with

advantage by those who intend to study botany thoroughly; but we hope and believe that the directors of medical education in Blackfriars are not so *exigents* on the subject as might be conjectured from the appearance of so deep an elementary treatise. He who has eight or ten years to dedicate to professional education may study the physiology of plants, but the student who is limited to thirty months ought to make short work of botany.

Primitiæ Floræ Sarnicæ; or an Outline of the Flora of the Channel Islands of Jersey, Guernsey, Alderney, and Serk, &c. By CHARLES C. BABINGTON, M.A. &c. London, 1839. 12mo. pp. xvi. and 132.

The following extract will gratify some of our readers:—

“I will now give a short list of rare English plants which are frequent in these islands.

Matthiola sinuata.
Helianthemum guttatum.
Erodium moschatum.
Lotus angustissimus.
L. hispidus.
Herniaria glabra.
Polycarpon tetraphyllum.
Bupleurum aristatum.
Cicendia filiformis.
Orobanche cærulea.
Scrophularia scorodonia.
Bartsia viscosa.
Trichonema columnæ.
Cyperus longus.
Knappia agrostidea.
Cynosurus echinatus.
Asplenium lanceolatum.

“The following list includes the plants that have been found in Jersey and Guernsey, but have not been included in the British Floras (as English), although several of them are now found to be not uncommon natives of England.

Ranunculus ophioglossifolius.
Erucastrum incanum.
Sinapis cheiranthus (sands near Penard Castle, Swansea, Mr. Jos. Woods).
Polypala vulgaris, *β. oxyptera* (Sussex, Mr. Borrer; near Liverpool, C.C.B.)
Arthrolobium ebracteatum (Scilly Isles, Miss White).
Myriophyllum alterniflorum (Shropshire, Rev. A. Bloxam).

Hypericum linarifolium.
Callitriche platycarpa (common in England).
Centauria isnardi.
Hypochaeris glabra, *β. balbisii* (Kent, Mr. Borrer).
Senecio erraticus (Buttington, Montgomeryshire, C.C.B.)
Echium violaceum.
Orobanche barbata (on ivy in many places).
Linaria pelisseriana.
Salvia clandestina.
Armeria plantaginea.
Atriplex rosea (common on the British coasts).
A. deltoidea (near London, C.C.B.)
Orchis laxiflora.
Neottia festivalis.
Allium sphærocephalum.
Potamogeton plantagineus (common in Britain).
Scirpus pungens,
Festuca rubra, *β. sabulicola* (British coasts).

Bromus maximus.
B. diandrus, *β. rigidus.”*

Besides Serk, there are two other islets belonging to the channel group, called Helm and Jethou; not to mention a rocky mound named Crevichou, which is connected with Jethou at low water. This last contains twenty-two species of plants; the number in the whole book being 848.

Mr. Babington's book will be a useful addition to our British Floras, and a pleasant companion to those who are inclined to spend a few weeks in the Channel Islands.

MEDICAL GAZETTE.

Friday, July 10, 1840.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
 CICERO.

MEDICAL REFORM IN FRANCE.

THE anomalous condition of the medical profession in these islands, on which we touched in our last article, is by no means confined to them.

On the other side of the Straits of Dover, as well as here, the old maxim of *dat Galenus opes* is falsified by con-

stant experience. It seems that in France, as well as in the British Islands, the demands of the nation for medical advice have outstripped the progress of national wealth. Hence the share of hard cash which falls to each practitioner is small indeed; and since in our profession, beyond any other, a smart appearance must be kept up, it is to be feared that there also genteel penury is the lot of too many hard-working practitioners.

It may seem curious that the French still call for medical reform; nay, it is promised; but they, too, have their procrastinating friends, and must wait. On the 18th of April, a writer in the *Gazette Médicale* spoke with joy of the approaching reform; "*les augures sont favorables; un vent de réforme et d'amélioration commence à souffler dans nos parages*"—and so forth. It does not clearly appear, however, in what the proposed reform consisted, except in a change respecting the *agrégés*, who were in future to enter upon the duties of their office immediately on their appointment, and to exercise them nine years instead of six; and in an increase of the number of examinations to be gone through by candidates for the doctorate.

On the 13th of June, the same correspondent writes to his *cher confrère*, the editor, in a tone of jocosé despair. He finds that another session is to pass away without the promised law, and declares that in future no mention shall be made in his letters *de la fable législative dont on berce éternellement notre souffreteuse bénignité*; adding, that if a bill for medical re-organization should be presented to the Chambers, he will repeat the news after all the other journals, and after having assured himself of the truth of the fact by hearing, seeing, and touching; till then he will keep silence, and have neither confi-

dence in promises, nor belief in rumours; let who will, expect or hope.

The French, we may observe, have already got much of what our reformers desire. They have united medicine and surgery, and they have only three towns where doctors are created, namely, Paris, Strasburgh, and Montpellier. What, then, is wanting? Something to make the pot boil. M. Cousin, indeed, threatens to add Rennes to the three Faculties, but we do not know whether this has actually been done.

Another correspondent of the *Gazette Médicale*, who signs himself A. M. P., discusses the question whether it is advisable to add to the number of Faculties, and answers it in the negative.

As his letters, (contained in the Nos. for May 23, May 30, and June 6,) throw much light on the state of the profession in France, and even tend to elucidate the social problems connected with it throughout Europe, we shall probably gratify our readers by considering some of his facts.

He informs us, that many physicians and several medical corporations have expressed the opinion that the three Faculties of Paris, Montpellier, and Strasburgh, are not enough, and that it would be well to add one, two, or three to the list. Lyons, Bourdeaux, and Nantes, are among the additional towns proposed; these, as well as the other places suggested, being all noted for their intellectual culture, wealth, and population.

A. M. P., on the other hand, were it not that he respects vested rights, would rather abolish one or two of those actually existing; but before he gives his reasons for this, he thinks it right to set forth what a Faculty is.

A Faculty, then, is a College of Physicians founded by law for a two-fold purpose; the first is that of teaching

medicine completely; the second is that of conferring the degree of doctor of medicine or surgery, after examinations. Now, to fulfil this double object, it is requisite, first, that the establishment should contain all that is wanted to teach the exercise of the art: thus, it must possess at least thirteen theoretic professorships, namely, those of natural philosophy, chemistry, natural history, anatomy, physiology, external pathology (or surgery), internal pathology (or medicine) operations, therapeutics and materia medica, pharmacy, midwifery, hygiene, and forensic medicine; besides three practical professorships, being those of clinical surgery, clinical medicine, and clinical midwifery. Several of these chairs require more than one professor. Every Faculty, therefore, must have a great number of professors; and these, again, must have plenty of assistants, under the name of *agrégés*, *chefs de clinique*, *prosecteurs et aides d'anatomie*, *aides de chimie*, *de botanique*, &c. All this forms an expensive array.

Secondly, the additional matters required are equally costly—namely, a library; theatres of anatomy and chemistry; a cabinet of natural philosophy; a botanic garden; and a museum of anatomy, surgical instruments, &c.

Thirdly, a Faculty must necessarily be situated in a town capable of supplying all these requisites, and above all, sufficiently populous, and sufficiently supplied with hospitals, to afford the patients and the subjects required for instruction.

Hence, concludes the objector, a Faculty is one of the most expensive, nay, the most expensive, of all the institutions designed to teach physic; and, therefore, if the whole cost is to be defrayed by the pupils, they must resort to it in great numbers. Yet, taking the present number of medical students in France (which every one allows to be more than sufficient for the wants of the

population), there ought to be only one Faculty, if the pupils are to defray the whole expense; and consequently, the greater number of these establishments in France, the more must be given by the State for their maintenance. New Faculties should, therefore, not be formed, unless they are absolutely necessary, or would produce social advantages not to be obtained by a lighter outlay, and so great as to compensate for the charge.

Lastly, there are very few towns in France where a new Faculty could be established.

It may be objected, says the correspondent of our contemporary, that our scheme for a Faculty is too large, and that we make it expensive by a superfluity of chairs. To this he replies, that the number he proposes is made absolutely necessary by the circumstance of the Faculty conferring degrees as well as teaching physic. If it did the latter alone, a smaller number of professorships would suffice, as the deficiency might be supplied elsewhere; but a faculty which examines candidates in every branch of medical knowledge must also teach them.

The legislature and the University have always been of this opinion, and the same idea is to be seen in the bill of the 20th of last April, for the establishment of a Faculty at Rennes. It is true that the bill projects the establishment of only eight theoretical, and two practical chairs; but the difference is apparent, not real. Thus, professorships of natural philosophy, chemistry, and natural history, are not founded; but then the minister hopes, that the Faculty of Sciences, which he is founding simultaneously at Rennes, will supply the want. Again, although there is only a single professor to teach hygiene and forensic medicine, the acknowledgment is made, that both these medical sciences must be taught in a Faculty. Lastly, although the bill

makes no mention of a professorship of operative surgery, can we approve of this? Is it not rather a blameable deficiency? So far A. M. P. We have often expressed ourselves against the wanton multiplication of courses and lectures, which distract the student's attention, and too often imbue him with about as much of each subject as might be learned from Pinnoek's Catechisms; but, of course, a greater number can be attended in France, where the student has four years for his professional education, than here, where he is too commonly limited to two years and a half. We think, with our French contemporary, that hygiene is a subject of great, nay, we would say of primary importance. We should be glad to see it more studied in England. It is too extensive to be made a mere fraction of the course on forensic medicine; and, though this would be better than nothing, we would rather see botany suppressed, and hygiene installed in its place. Or, supposing botany to be retained, a valuable improvement would be effected, by making the examination in botany, chemistry, and the art of reading prescriptions, a preliminary to the two years and a half now devoted to medical education. Time would thus be gained for the more important subjects, and the pupil's mind would not be harassed synchronously by so great a variety of studies.

The physicians who urge the establishment of new faculties, allege in favour of their scheme, that before the Revolution there were eighteen. To this the correspondent replies, that the eighteen were far too numerous, and had of themselves sunk to nine in 1789; and that the three established by the National Convention, in 1794, have been found quite sufficient during the forty-six years which have since elapsed.*

* Two schools of medicine were created by the consular government in 1803; but they were in the conquered provinces, one being at Mayence, and the other at Turin: and, moreover, they were not on the large basis of the present faculties.

Are these Faculties overworked? Not a bit of it. Their members are never obliged to work double tides, to toil at night, or to shorten the examinations in order to get through more of them. The Parisian faculty has always created the greatest number of doctors, but has never spent more than two hours and a quarter a day in this duty; and the services of each professor are required only twice, or at most thrice, a-week. Nevertheless, there are six examinations, each of the first four lasting three quarters of an hour for each candidate, while the fifth and the thesis take an hour. It is quite clear, too, that of the three existing Faculties, the Parisian one creates more than half the doctors, and that the expenses of the others exceed the fees which they receive. At Strasburgh, indeed, the maximum of doctors who graduated in any one year from 1823 to 1838 was 57, and the minimum 14; in 1839, the number was 23. Hence, if the faculty at Strasburgh were not useful in other respects, it might easily be dispensed with as a fountain of doctors. The average number who graduated at Montpellier was from 120 to 130 annually. So far, therefore, A. M. P. has proved his case; new Faculties are not required, from the old ones being overwhelmed with examining candidates for the doctor's degree. The other reasons for and against new institutions of this kind we will discuss in a future article.

MR. TOMES AND MR. OWEN.

To the Editor of the Medical Gazette.

SIR,

IN the commencement of the year 1838, when a student at King's College, I began to investigate the structure of the teeth, especially human teeth, under the impression that nothing definite was known upon the subject: nor was there, in England, at this period. Before I had been long engaged in this pursuit, many novel facts presented themselves, and these, as they

became known to me, I mentioned to Dr. Todd, and to many of my fellow students, and at the same time shewed the preparations that led me to them. In May of the same year, having prepared many specimens (I might say hundreds), I shewed those I deemed most interesting to Mr. Bell, who expressed himself highly pleased; and as he considered the subject to be quite new, he recommended that I should write a paper as soon as possible, and proposed that he should present it to the Royal Society before the termination of the meetings of that season. At the same time, Mr. Bell inquired if I knew Mr. Owen. I did not know Mr. Owen at that time, but felt anxious to do so; and Mr. Bell very kindly gave me a favourable letter of introduction to him. I did not, however, call with my introduction for some days; when I did, after waiting for some time in the room into which the servant had shewn me, Mr. Owen came, and brought with him his microscope. He had seen Mr. Bell, he said, since I had, and had been told of my intended visit and its purpose—that of shewing him some of my preparations. I had with me some specimens prepared for the microscope; these were examined, and much praised; but Mr. Owen told me, that though the subject was new in England, yet it had been considerably studied by continental physiologists. Mr. Owen also shewed me two curious sections of teeth, which, he said, he had prepared. They were curious from being large, and so thick that they could scarcely be seen through the transmitted light, and were on pieces of glass scarcely larger than themselves; they were fitted also into a black paper case, of curious appearance. Mr. Owen, at this time, advised me to draw up an account of my researches, and offered to give me any assistance in his power, in the way of obtaining for me specimens to examine: and upon this occasion I left his house with several rare teeth, but upon the condition that I should give him a section from each. Afterwards, my visits to Mr. Owen were pretty frequent, and, for several successive visits, Mr. Owen acted up to his promise, and furnished me with valuable specimens for examination. He expressed a strong wish that I should examine fossil teeth, and he furnished me with such. The teeth of the *Megatherium* and *Toxodon* I may mention as amongst the number of those furnished to me by Mr. Owen. Shortly after, however, he declared his intention of following this branch of the subject himself, and it was not long before he told me that he had taken up much of my valuable time, as he said, and that he would not trouble me to make any further examinations. At the same time, he advised that

I should not publish on the subject till some translation of the foreign investigations had appeared. Shortly after I became acquainted with Mr. Owen, he mentioned my name in his summer course of lectures at the College of Surgeons, in connection with the above subject, as having confirmed Retzius's views, and said he had good reason to believe that I had gone further into the subject than the Swedish author. A day or two after the lecture alluded to, Mr. Owen, as promised, had some sections of teeth (most of which I had given to him) exhibited in the library of the College to any who might think proper to attend. Mr. Owen was absent at the time the specimens were shewn, but Mr. Clift was there, and gave the necessary explanation to those who attended.

The two curious specimens before spoken of were exhibited, and Mr. Clift gave of them the following history:—He said, that Retzius had visited him some months before, and had given to him these two identical specimens; that he, Mr. Clift, was very busy at the time, and put them by in a drawer; and that it was only by accident that he found them a few days before that time, and had given them to Mr. Owen.

Had Mr. Owen's advice as regards publishing been in accordance with that of any of my friends, I should no doubt have adopted it; but such was not the case. Every other person, who was in any way acquainted with my proceedings, strongly urged me to publish, and especially as it became almost impossible for me to pursue the subject farther during that year, in consequence of other and, to me, more important engagements. A paper was, therefore, written, and presented to the Royal Society by Mr. Bell. An examination of the proceedings of the Royal Society for that year will tell, that the paper was received on the 14th of June, 1838, and read on the 21st of June, 1838. The paper was entitled, "On the structure of Teeth, the vascularity of these organs, and their relation to bone." (The paper has since been published in the *MEDICAL GAZETTE*, No. 585.) The paper was referred by the Royal Society to Mr. Owen, and he advised that it should not be published in the Transactions. This I should not have taken any account of; but, in September of the same year, Mr. Owen read a paper before the British Association upon the same subject, containing many of the same facts, and, as I believe, in some parts descriptive of some of the specimens which I had prepared and given to him, and all this without even mentioning my name. By this same paper Mr. Owen claims considerable credit as confirming

the views of Retzius—a claim to which he has no right whatever. I see, in a letter of Mr. Owen's to Mr. Nasmyth, published in the *GAZETTE* of last week, that Mr. Owen reports himself as the first in this country who investigated the structure of the teeth. If you, Mr. Editor, will take the trouble to refer to dates, the facts will appear, that Mr. Owen has no claim to priority either in the examination of dental structure, or in detailing the results of an examination, but that there is great reason for believing that he got the idea of working at the subject from me and my preparations, none of which were reserved from his inspection.

Your most obedient servant,

T. TOMES.

41, Mortimer-street,
Cavendish Square, July 1, 1840.

UNIVERSITY OF LONDON.

BACHELOR OF MEDICINE—FIRST EXAMINATION.—1840.

Forty-eight Candidates presented themselves for Examination. Monday, July 6th.—Morning, 10 to 1.

ANATOMY AND PHYSIOLOGY.

Examiners, Mr. KIERNAN & Dr. SHARPEY.

1. Describe briefly the form and structure of the sacrum, its articulations with the neighbouring bones, and its mode of ossification; name the muscles to which it gives attachment.

2. What motions take place in the following joints, and to what classes of joints do they respectively belong? 1st. The articulation of the bones of the forearm with those of the carpus. 2d. Of the carpal bones with each other, and with the metacarpal bones. 3d. Of the metacarpal bones with the phalanges. 4th. Of the phalanges with each other. Enumerate the muscles of the forearm and hand, classifying them according to their actions; and mention the order in which the tendons are placed round the wrist joint, commencing with the flexor carpi ulnaris, and proceeding outwards.

3. Describe the parts seen on the surface of a transverse section of the thigh about its middle, and their relative positions. Mention the names of the vessels which usually require ligature, and the situations in which they are to be found.

4. The integuments being removed for a handbreadth above, and to the same extent below the occipital protuberance, and as far forward as the anterior edge of the mastoid process, describe the muscles, blood vessels and nerves, thus brought into view, with their relative position.

5. Describe the dissection required to show the course and distribution of the gluteal and ischiatic arteries, commencing at the integuments of the gluteal region, mentioning the parts cut through or exposed in the order they are met with, and describing the arteries and their branches, with their relations to the adjacent parts.

6. State the leading facts which serve as proofs of the circulation of the blood.

Afternoon, 3 to 6.

1. Describe the parts met with in the successive stages of the dissection of the inguinal region. Describe the inguinal canal, and its contents in the male, and in the female, and the alterations occasioned in the canal by hernia. How is the cremaster formed, how are its fibres arranged, and what varieties does it present? What is contained in the canal prior to the descent of the testis, at what period does the descent take place, and what changes take place in the canal after the descent? How is congenital hernia formed, and in what respects does it differ from the ordinary form of external inguinal hernia.

2. Describe the parts met with in dissecting, from the integuments to the median plane of the tongue, that space which is bounded above by the lower jaw, below by the os hyoides, anteriorly by the median line, and posteriorly by the pharynx.

3. Describe the structure of a lymphatic gland. What has been ascertained as to the mode of origin of the lymphatic vessels?

4. What is seen on the surface of a vertical section carried through the cerebrum, cerebellum, tuber annulare, and medulla oblongata, in the median plane?

5. Name the nerves distributed in whole or in part to the following muscles, viz., sterno-thyroidens, deltoides, pectoralis major, serratus magnus, trapezius, coracobrachialis, gluteus maximus.

6. Describe the course and distribution of the laryngeal nerves, and state what is ascertained respecting their functions.

7. Mention the differences in structure between the circulating organs of the fetus (at birth) and those of the adult.

Tuesday, July 7th.—Morning, 10 to 1.

CHEMISTRY.

Examiner, PROFESSOR DANIELL.

By Experiment.

The solutions of two salts will be placed before you, marked A and B, with appropriate tests labelled: apply the tests, describe the phenomena which take place, and explain the constitution of each salt.

1. In what does the boiling of a liquid essentially consist; and how is the tem-

perature of a liquid connected with its boiling?

2. According to Dulong and Petit the boiling point of mercury is 360° centigrade: to what degree of Fahrenheit's scale does this correspond?

3. Take two similar thermometers, and, on a calm clear night, place one of them on wool fully exposed to the aspect of the sky: place the other similarly on wool under the cover of a tree;—what would you expect them to indicate after the lapse of a short time? and to what cause would you ascribe the effect?

4. I have measured 21.5 cubic inches of a gas standing over mercury; the level of the mercury within the jar is half an inch higher than without; the height of the barometer is 29.74 inches, and the temperature 52° Fahr.,—what is the correct volume at standard pressure and temperature?

5. State and exemplify the laws of definite and multiple proportions.

6. What is meant by the statement that 40 parts by weight of potassium are equivalent to 8 parts of oxygen and 16 of sulphur; and how would you illustrate the meaning by the constitution of sulphate of potassa?

7. Describe the constitution, mode of production, and principal properties of ammonia.

8. Describe the constitution of nitrate of ammonia, and explain by symbols, and by a diagram relating to volumes, the changes which it undergoes upon being exposed to a temperature a little above its melting point.

Tuesday, July 7.—Afternoon, 3 to 6.

MATERIA MEDICA AND PHARMACY.

Examiner, Mr. PEREIRA.

1. Describe the usual mode of procuring sulphuric ether. Explain the chemical changes which take place during the process. State the atomic composition of alcohol and ether.

2. Give a botanical description of *Digitalis purpurea*, especially describing the leaves and flowers. State to what class and order, in the sexual system of Linnæus, this plant belongs, and what is its natural order. Describe its effects and uses, point out the cautions to be exercised in the employment of it, and mention the dose of its powder, its infusion, and its tincture.

3. State for what particular cases the most frequently employed cathartics are respectively adapted or unsuited, and why? Mention what are the appropriate purgatives for febrile complaints; alvine obstruction, with great irritability of stomach; inflammation of the urinary organs, and

sluggishness of the colon: and what purgatives are improper in diseases of the rectum, in uterine irritation, and after operations about the pelvis and abdomen?

4. With what substances is scammony usually adulterated, and how is their presence to be demonstrated? What are the physical and chemical characters by which the goodness of *elaterium* is ascertained? How would you proceed to detect the presence of tartaric acid in suspected powder of citric acid? By what physical characters are the leaves of *cynanchum argel*, found in Alexandrian senna, distinguished from the *cassia* leaflets?

5. Describe the effects both of medicinal and poisonous doses of opium; and point out the peculiarities of its narcotic operation? Mention the appropriate remedies in poisoning by this substance?

6. What are the best disinfecting processes for the sick chamber, and for uninhabited buildings?

Tuesday, July 7.—Afternoon, 3 to 6.

STRUCTURAL BOTANY AND VEGETABLE PHYSIOLOGY.

Examiner, Professor HENSLOW.

1. Explain the terms axil, bract, tendril.

2. Define an arillus, and mention examples where it occurs.

3. Describe the cellular tissue, and its various modifications.

4. Describe the specimens marked

1. [*The common Campanula.*]

2. [*Virginian stock.*]

3. [*Pod of the common pea.*]

5. Give sketches of the principal forms of vernations.

6. Explain the structure and functions of pollen.

7. What is meant by vegetable irritability and sleep; and what are the external stimuli affecting these properties?

WESTMINSTER HOSPITAL.

CASES ILLUSTRATIVE OF THE CEREBRAL SYMPTOMS INDUCED BY DISEASE OF THE KIDNEYS.

To the Editor of the Medical Gazette.

SIR,

If the following cases be deemed worthy of a place in the MEDICAL GAZETTE, their insertion will oblige, sir,

Your obedient servant,

FREDERIC BIRD, A.L.S.

Clinical Assistant to the Westminster Hospital.

Eliza Glynn, æt. 32, was admitted into the Westminster Hospital, under the care

of Dr. Hamilton Roe, labouring under a form of dyspepsia, connected with bowel irritation, for which ordinary remedies and carefully regulated diet had been employed with advantage, and she was returning to a state of health, when she became suddenly attacked in the following manner:—A few minutes after having retired to bed, she was seen by the nurse apparently sleeping, and on attempting to rouse her it was found that all efforts to do so were quite ineffectual, and I was then called to see her, at which time she was lying on the back, breathing calmly, but rather more slowly than usual; countenance, which had previously been flushed, was remarkably pale; the pupils of natural size, acting freely under the stimulus of light; the pulse quiet, regular, but feeble, 96; the limbs motionless, with the exception of the legs being two or three times slightly moved, just sufficiently so indeed to point out the absence of paralysis; the skin cool and moist; chest expanding freely; respiration quite unaccompanied by stertor; heart's action natural. On inquiry it was found that her bowels had been freely evacuated during the day, and that the urine had been passed just before the attack. After the lapse of an hour and a half, during which time she remained in the same state of complete insensibility, the face had resumed a cadaveric pallor, the respiration was still slowly but naturally performed, excepting that occasionally the angle of the mouth on the left side was puffed out during expiration; the pulse rather more full, and 92; skin rather increased in temperature. A catheter was passed, but not more than 3ss. of urine drawn off, which, when tested by heat and nitric acid did not appear to be albuminous; but from the smallness of its quantity its exact characters were not satisfactorily determined. Hitherto the only treatment employed consisted in the application of a large blister to the back of the neck; but the pulse having now become more full, and the respiration more frequently accompanied by the puffing of the lips, the temporal artery was opened, and about ʒx. of blood abstracted. The blood at first flowed slowly, but shortly afterwards passed out with considerable force; the pulse became more frequent, and she was observed to swallow the saliva and mucus, which had accumulated at the back of the throat, but not the slightest consciousness returned. She continued nearly in the same condition during the night, both urine and fæces escaping involuntarily from her: fearing, however, an accumulation, a catheter was again passed, and about three ounces of rather high-coloured urine was removed, which, on the addition of nitric acid, became turbid from the precipitation of a thin cloud of albumen.

On re-examining the extremities the left ankle was discovered to be very slightly oedematous. No appreciable alteration occurred in her symptoms, with the exception of three or four slight convulsions, affecting the upper extremities, and she rather quickly sunk; the whole seizure having occupied rather more than 18 hours.

Section cadaveris, fourteen hours after death.—*Head*: The brain was perfectly healthy, nor had any effusion taken place into the cavities. *Chest*: The lungs healthy, with the exception of a few old adhesions at the apex of the left, together with some puckering of the pulmonary tissue. The heart of natural size; the aortic valves opaque, and the anterior curtain of the mitral considerably thickened and shortened. *Abdomen*: The left kidney much enlarged, flabby and pale; its upper portion containing cartilaginous deposit, and its lower irregularly granulated and mottled. The right kidney was much smaller than that of the opposite side; its proper tunic scarcely separable, and its whole surface granular, and presenting several spots of increased vascularity, almost resembling ecchymosis; the cortical substance much diminished in thickness, and contained two small cysts; the mucous membrane of the small intestines considerably injected, particularly at the lower third of the ileum.

The case I have just related is, perhaps, more interesting, from its being one in which the diagnosis of disease of the kidneys rested almost solely upon the peculiarity of the cerebral symptoms to which it had given rise, than from any supposed rarity of occurrence; instances of renal affection terminating in disorders of the brain being far from unfrequent, but in such it commonly happens that the previous history of the patient, together with the presence of the ordinary symptoms of disease of the kidneys, leave but little difficulty in the way of arriving at a correct diagnosis. In the present example, however, no such general means were afforded, but so strongly were the characteristic cerebral signs of this affection marked, that no difficulty could be entertained in recognizing it as dependent upon renal disease. The principal indication relied on consisted in the combination of great cerebral disturbance, with the perfectly quiet pulse, the unaffected pupil, and the remarkable pallor of the face, constituting, in fact, the peculiar symptoms described by Dr. Addison, in the Guy's Hospital Reports, and which I have often had the advantage of seeing pointed out by him. The only point of difference observed in the present instance was the occurrence of convulsions; but these, when first remarked, were so slight as scarcely to

be regarded otherwise than as proving the absence of paralysis, and subsequently they could be considered only as premonitory of dissolution. The occurrence of convulsions, however, is by no means uncommon in the progress of renal disease, and, in the third and fourth forms of cerebral disorder, described by Dr. Addison, they constitute one of the most prominent characters. A case illustrative of this point, as well as shewing the manner of attack peculiar to another form, occurred in the person of Edward Ferry, who was recently admitted into the Westminster Hospital, under the care of Dr. Bright. His occupation had been that of a cab-driver, and he had been long accustomed to the free use of spirits. Four months prior to his admission, he first observed that his legs became oedematous, and his face frequently puffed; his urine shortly after began to decrease in quantity, the lower extremities becoming distended by anasarca, and respiration difficult and painful. He then applied for relief; at which time, in addition to congestion of the lungs and bronchitic inflammation, he was the subject of confirmed renal disease; the urine being scanty, high coloured, and loaded with albumen. In a few days (during which time he had improved) he began to complain of occasional dull pain in the head, with tendency to sleep; his manner becoming sluggish, and evincing much stupidity: these symptoms, after the lapse of three days, gradually passed into a semi-comatose state, in which he frequently became convulsed. Under the treatment adopted he rallied, but was again similarly attacked; the convulsions occurred with greater frequency, and assumed a more violent character; coma, accompanied by the peculiar hissing stertorous breathing observed in these forms of cerebral affection, ensued; and he died. On dissection, no lesion of the brain could be detected, but both kidneys were found in the state of granular degeneration.

In this case, independently of the cerebral signs, the presence of albuminous urine and anasarca left no doubt of the existence of renal disease; but in that before described, no suspicion of this kind was entertained until the supervention of the cerebral disorder, which became the earliest indication upon which the diagnosis of disease of the kidneys was founded; and instances of this kind are by no means uncommon,—a fact now established by the observations of several physicians of rank and experience. Two cases, closely resembling the first which I have detailed, occurred lately in the private practice of Dr. Roe, who has kindly permitted me to refer to them. In both of these no suspicion of renal mischief had been before admitted,

but the peculiarity of the quiet stupor, the unaffected pupil, together with the absence of stertor and the other ordinary symptoms of cerebral affection, immediately convinced Dr. Roe of the existence of disease of the kidneys; an opinion in the one case verified by dissection, and in the other by the presence of albumen in the urine.

Westminster Hospital,
June 22, 1840.

METHOD OF DETECTING POISONING BY COPPER.

LAST year we gave an account of the method by which M. Orfila is able to detect arsenical poisoning, when all traces of the metal have disappeared from the alimentary canal.* He has also shown that antimony may be discovered in a similar manner; and he found it in the liver and spleen of a woman to whom M. Bouvier had given a grain of tartar emetic, and who died fifteen hours afterwards without vomiting. M. Orfila recently read a paper before the Academy of Medicine, in which he showed that the same method is applicable to the detection of the salts of copper. We will content ourselves with translating his conclusions, as we find them in the *Gazette Médicale* of June 20, 1840.

It follows, he says, from the experiments and considerations detailed in his paper:—

1. That the acetate and sulphate of copper, when introduced into the stomach, or applied to the subcutaneous cellular tissue of living dogs, are absorbed, and carried into every organ in the system.

2. That it is probably the same in man.

3. That it is possible, by chemical means, to obtain metallic copper from the absorbed portion of the cupreous salts.

4. That it is indispensable to have recourse to this process, when these poisons have not been found in the alimentary canal, or in the other parts to which they had been immediately applied, or in the matter vomited; for if we limit ourselves, as has hitherto been done, to searching for the cupreous salts in the matters obtained from the stomach and intestines, we run the risk of not discovering them at all: either because none remains in the alimentary canal, or because the matters vomited have been removed; while the metal can always be obtained from the portion absorbed.

5. That a medico-legal report must in future be declared incomplete and insufficient, if, in the case just mentioned, the

* *MED. GAZ.* Sept. 14, 1839.

examiner has omitted to look for the cupreous salts in the parts where they are to be found after having been absorbed.

6. That besides the portion of the cupreous salt absorbed during life, and which is to be found unequally scattered over all the tissues, several organs (particularly the abdominal viscera, if the salts have been introduced into the alimentary canal) contain some of the salt, which has reached them by imbibition after death. This happens more particularly on the part of their surface which is in contact with the alimentary canal; and the quantity varies according to the period when the body was opened. The copper obtained from these organs proceeds partly from what was absorbed during life, and partly from what had penetrated the tissues after death.

7. That the imbibition here mentioned, and which has been perfectly proved by the experiments of Fodera, Collard de Martigny, Magendie, Müller, &c. as well as by my own, is not peculiar to poisoning by copper, as it is observed whenever any poison, having been incompletely absorbed during life, remains upon the tissues after death; providing that the poison is dissolved, or is capable of being dissolved, in the liquid which touches it. And thus, what has been said of the proportion of the cupreous poison furnished by the viscera, whether in consequence of absorption or imbibition, is applicable to all cases in which the poisons have been absorbed.

8. That it is possible, in the majority of cases, to determine if the cupreous salts, or other poisons obtained from the viscera, in medico-legal investigations, have been introduced during life or after death, by paying attention to the symptoms which preceded death, and the structural lesions observed on opening the body, or by means of chemical experiments on some organ remote from the digestive tube, rather than on another which is near it, or on one part of a viscus rather than another. It is true, that in a few rare cases—as, for instance, if a long time has elapsed since the burial of the body, when nothing is left but the *detritus* of the viscera—the problem might be less easy to solve, unless the examination was assisted by the information collected by the magistrates, positively demonstrating that the poison was not introduced into the alimentary canal after death. The annals of justice, moreover, do not supply a single example of an accusation of poisoning, where wickedness has been carried to such a pitch as to introduce poison into the alimentary canal of a corpse, for the purpose of founding a charge.

9. That the absorbed cupreous salt, which caused the death of the patient,

may be detected by boiling the viscera, or the flesh, for an hour in distilled water, drying the filtered decoction, and carbonising it with nitric acid, or decomposing it by nitrate of potash.

10. That if boiling water does not dissolve the whole of the absorbed cupreous salt even in six hours, still enough is extracted to put its existence beyond the reach of doubt.

11. That boiling for an hour in distilled water does not dissolve any trace of the copper naturally existing in our frame; for this can only be partially separated by the concentrated acids, and totally by incineration alone. Hence the examiner may conclude, that some preparation of copper has really been introduced during life, either as a poison or as a medicine, if he obtains copper from an aqueous decoction prepared as above mentioned, unless it is proved that the copper penetrated the tissues in consequence of imbibition after death.

12. That it is best to boil, in the first place, the viscera which are distant from the alimentary canal; next, those portions of the abdominal viscera which have not been in contact with the canal; and then the parts which have been in contact with the stomach and intestines; for, by thus operating, we are certain to obtain from the latter a greater quantity of poison, and to collect information adapted to solve the questions which might be raised concerning imbibition.

13. That if the medico-legal researches, instead of relating to the viscera, referred to alimentary or excrementitious substances, contained either in the digestive canal or the liquids vomited, these substances must be boiled for an hour in distilled water, and the decoction is to be filtered, dried, and decomposed by pure nitric acid, or by nitrate of potash not containing any copper. The presence of copper, after the decomposition, enables us to affirm, that a cupreous preparation has been taken, unless, indeed, it has been introduced after death. Although boiling water dissolves only a small part of the salts of copper when they are intimately combined with organic matter, yet the solution contains enough of the metal to coat a plate of iron.

14. That if, after having treated these alimentary or excrementitious matters with boiling water, no copper is found, it would be wrong to treat them with the strong acids, or to incinerate them; because even if copper should then be obtained from them, it would not prove that it had been taken as a poison or a medicine, since several alimentary substances contain enough copper to be detected by strong acids, and still more by incinera-

tion. It is better in such a case to give up the search for copper in these alimentary substances, and to treat the alimentary canal, the liver, spleen, kidneys, &c. with boiling water.

15. That while I admit, with M. Devergie, that the quantity of copper naturally contained in the intestines of an adult does not exceed 46 milligrammes, (9 10ths of a grain,) I cannot grant him that it is worth while, in forensic medicine, to take account of this copper, and decide, by incineration, whether the copper obtained is, or is not, that which is naturally present; because, as he says himself, the quantities of normal copper found in the few experiments he made, were too variable to permit him to consider the above-mentioned quantity as exact; and, still more, because it may easily happen, that, after poisoning by a cupreous salt, so little remains in the intestines, that, after adding the copper thus introduced into them to that which they naturally contain, only 40 or 50 milligrammes can be obtained.—(See M. Devergie's *Médecine Légale*, 2nd edit. vol. iii. p. 536 37.) The copper obtained by incineration can be taken into account only when it much exceeds the quantity which farther and multiplied experiments shall have shown to be the maximum of normal copper; but, even in this case, it is infinitely preferable to use the means I propose, because they furnish the clear and precise results which I will conclude by repeating,—*Copper, which has been employed as a poison, may be obtained in part from viscera boiled in water for an hour, but not an atom of the copper naturally existing in them can be obtained in this manner.*

HYPEROSTEOSIS OF THE RIBS IN CHRONIC EMPYEMA.

DR. STOKES exhibited the thorax of a female who died fourteen months from the first attack of pleuritis of the left side. On her admission, an extensive effusion existed, and the heart was found to pulsate at the right side of the sternum, and soon after pericarditis supervened, yet without pain or increased irritability of the heart. The disease was only discovered by the existence of the friction sounds over the whole heart. This was the third case noticed by Dr. Stokes, in which a perfectly latent dry pericarditis occurred while the heart was dislocated by an empyema. Dr. Stokes exhibited drawings illustrative of two cases of this description, in which there had been no pain, palpitation, or irregularity of the heart, preceding or accompanying the attack of pericarditis. The effusion in the case now before the society was partially absorbed, and the heart was restored to its natural position, but the side continued

extremely dull on percussion. After some time the patient began to expectorate large quantities of mucopurulent fluid, and soon after this a large and distinct gurgling could be heard in the supra-spinous and supra-clavicular region. Soon after this the patient complained of the occurrence of an unusual sound in the anterior portion of the left side whenever she coughed. A puffy tumor made its appearance in the second intercostal space, which could be easily obliterated by pressure, and conveyed a distinct sensation to the touch, as of air mixed with liquid. The tumor was reproduced in each fit of coughing, and its appearance was always accompanied with a sound audible to a great distance, and much resembling the barking of young puppies. For a considerable length of time this phenomenon used to recur at irregular intervals. The abdomen ultimately became enlarged, and the patient sank with diarrhoea.

The compressed lung was strongly adherent to the mediastinum and postero-superior portion of the chest. It was not more than three inches and a half in length, and one in depth. It presented scarcely a trace of its normal structure, and the large bronchial tubes and the branches of the pulmonary artery terminated in culs de sac. The left pulmonary artery, previous to its entering the lung, was not diminished in size. The eighth nerve was somewhat smaller than its opposite, and felt unusually hard. There was no evidence of tubercle in the affected lung, nor in the right lung. A sinous passage existed in the second intercostal space which seemed to communicate with the mammary abscess, which had so long existed; but dissection did not discover the source of the emphysematous tumor above mentioned.

The structure of all the true ribs in the affected side was remarkably altered. They were exceedingly dense and hard, and nearly three times as thick as those in the opposite side. They were so closely approximated as that in many places the intercostal spaces were wholly obliterated. Between a few of the ribs, however, the intercostal muscles could be seen forming a red elevated line, as if they had been doubled in themselves, and forced outwards between the ribs. There was no actual bony union of the ribs, but the chest on the affected side felt, when pressed upon, as if it were a continuous bony case, giving a dull sound on percussion, and resisting remarkably. The ribs on the opposite side were thin and very elastic.

Dr. Stokes observed, that though from the analogies of the disease we might be prepared to expect such a change of the ribs in every chronic empyema, he was not aware of its having been hitherto described. Dr. Stokes concluded by alluding to the

observations of Andral on the ossification of the costal cartilages in phthisis, and the hypertrophy of the bones of the cranium in chronic hydrocephalus. (Museum, Park-street.)—*Dublin Journal of Medical Science.*

LUMBRICI IN THE HEPATIC DUCTS.

DR. J. POWER exhibited the recent parts in this case; the ductus communis was distended with a large collection of lumbrici; its diameter exceeded half an inch; the hepatic duct was still larger, being in some parts more than an inch in diameter, and filled with lumbrici. The duct in the substance of the liver contained numbers of this description of worm, as did likewise the stomach and intestines. It was not known whether there were any symptoms of hepatic derangement during life, the specimen having been found in a subject brought into the anatomical room of the Richmond School of Medicine. (Museum, Richmond School.) *Ibid.*

EXTRA-UTERINE GESTATION.

To the Editor of the Medical Gazette.

SIR,

IN the paper recently published in the MEDICAL GAZETTE, by Dr. Lee, on the situation of the deciduous membrane in cases of extra uterine gestation, he states, that "In all the cases of fallopian tube conception which have since been recorded, except those of Mr. Langstaff and M. Velpcau, a deciduous membrane has been described as present, lining the cavity of the uterus; and most authors have believed it to be formed in cases of this description."

Dr. Murphy, of Dublin, has since pointed out a case which came under his observation, in which there was no deciduous membrane within the uterus, and of which he has published an account in the Dublin Journal of July 1839.

It appears from the following note, that there are, besides these five cases, other two of extra-uterine pregnancy, described by Dr. Blundell, in which no decidua was found within the uterus, and with which Dr. Lee must have been unacquainted; otherwise he would not have failed to allude to them to support his opinion—that in all cases, the true decidua is formed around the ovum, within the tube, and not within the cavity of the uterus. "Mr. Langstaff, who has paid so much attention to morbid anatomy, examined a case in which there was no well-formed tunica decidua, and I have myself seen two tubal cases, in which the decidua was wanting*."

* Principles and Practice of Obstetrics, by James Blundell, M.D. London, 1834, p. 712.

Other cases may have been recorded, and probably several might be discovered, of which no account has been given, were the numerous specimens of extra-uterine gestation contained in the different museums of Great Britain carefully examined.

I remain, sir,
Your obedient servant,

GEO. H. PARK.

July 8, 1840.

GLASGOW CHAIR OF MIDWIFERY.

DR. CUMIN has resigned the Regius Professorship of Midwifery in the University of Glasgow; having been obliged to remove to Clifton for the benefit of his health, at the close of last autumn.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISLOCATIONS, *continued.*

METACARPAL BONES—PHALANGES—*Their Nature, Varieties, Symptoms, and Treatment.—The FEMUR—The TIBIA at the KNEE-JOINT—Their Varieties, Symptoms, Diagnosis, and Treatment.*

THE OS MAGNUM.

SIMPLE luxation of almost all the bones of the carpus is impossible, in consequence of their very slight mobility and the strength of their ligaments: the os magnum, however, is an exception. This bone has a head which is received under a species of vault formed by the scaphoid and semilunare. The centre of motion of the two ranges of carpal bones, it may be displaced, but never completely, and only backwards. It occurs very rarely, however, under exaggerated flexion of the hand on the forearm. The head of the bone then projects on the back of the hand: this projection increases under flexion of the hand, and, if it be pressed upon, disappears under extension. It may be masked, or confounded with ganglions, which are often developed about the wrist.

The means of reduction, after what I have said, are obvious, but the reproduction of the displacement is easy. In most cases it does not at all interfere with the motions of the hand, but in some cases it very much weakens the wrist: this is seen in two cases to which Sir A. Cooper refers.

In women, to whom appearance is an object, and in persons who play upon instruments, the complete reduction of this luxation is important. In such a case pressure upon the joint must be conveniently made and long sustained; and it is seldom that patients have patience to submit to the necessary confinement of the part.

FIRST METACARPAL BONE.

The arrangement and the solidity of the articulations at the superior extremities of the last four metacarpal bones, render their displacement, except from gun-shot or some heavy body falling upon and crushing the part, almost impossible. Still, in certain violent movements, the ligaments may be partially destroyed or distended, from whence results a painful tumor, which has been mistaken for articular displacement.

The first metacarpal bone is, however, occasionally luxated upon the trapezium. The motion at this point, backwards, forwards, and laterally, is so free, that we might expect the occurrence of displacement in each of these directions; but if we look more carefully, we see that forced adduction of this bone is limited by its coming in contact with the second—that forced abduction is limited by the muscles of the first interosseous space.

We have, then, to consider luxation backwards and forwards; but the backward movement necessary for displacement is so limited, the muscles which cover the anterior part of the trapezo-metacarpal articulation are so thick and so strong, that luxation forward is regarded by the majority of surgeons as almost impossible. Yet Sir A. Cooper has seen no other than forward luxation. Backward luxation occurs in forced flexion of the thumb and its metacarpal bone; it may, therefore, be occasioned by falls on the radial border of the hand; but, in this case, luxation of the

inferior articulation of the thumb is most likely to happen. In backward luxation there is forced flexion of the thumb and its metacarpal bone into the palm, and impossibility to extend them; projection under the skin of its superior extremity behind the trapezium, and change in the direction of its extensor tendon, with apparent shortening of the thenar eminence. Spite of these signs, this luxation is often mistaken: it is rapidly followed by great tumefaction, which continues long, and renders examination very difficult. It is most important, in these cases, to ascertain at once the nature of the injury, because at first it is easily reduced, but if a few days only pass over, it becomes almost, if not quite, irreducible.

Treatment.—To reduce a dislocation backwards, an assistant firmly grasps the forearm above the wrist; another grasps the thumb, first drawing it forwards in the direction of the displacement; then, when the head of the metacarpal bone is brought to the level of the trapezium, it is continued in the sense of extension. The surgeon now grasping the wrist, brings both thumbs to bear upon the superior extremity of the luxated bone, and pushes it forward and downward. A dull sound, and the disappearance of the deformity, indicate that reduction is completed. To prevent the recurrence, and to dissipate the tumefaction, the joint should be surrounded with compresses, wet with evaporating lotion; and some such apparatus should be applied as that we described when speaking of metacarpal fractures. In the forward luxation, as observed by Sir A. Cooper, the metacarpal bone was directed inwards, between the trapezium and the head of the second metacarpal bone, forming a projection towards the palm; the thumb was thrown backwards, and could not be directed towards the little finger; there were also much pain and swelling. To facilitate reduction, the thumb must be inclined towards the palm of the hand during the time extension is made, for the purpose of lessening the resistance of the flexors. No sudden effort will avail; extension must be firmly but gradually made. If simple extension be insufficient, the general impression seems to be, that it is wiser to leave things to the amelioration which time may bring about in them, than to divide muscles and expose nerves and blood-vessels.

THE FINGERS UPON THE METACARPAL BONES.

The solidity of their ligamentary support, increased by the extensor and flexor tendons, and laterally by those of the lumbricales and inter-ossei, renders luxation very rare. Four species are, it is true,

admitted, but the slight extent of abduction and adduction, limited, as they are, by the other fingers, should render lateral luxation, at least of the middle and ring fingers, very unfrequent. The index and little-fingers may be displaced; the former outwards, the latter inwards. I speak now theoretically, for I know no detailed cases of either. It is not so with the first phalanx of the thumb, which may be luxated outwards or inwards.

Forward luxations can scarcely happen in the four last fingers: the inferior articular extremities of the metacarpal bones are so much extended in this case, and the movement of flexion is consequently so extensive, that the anterior surface of the first phalanx is in contact with the palm before any displacement can happen. It is, however, different with the thumb; its flexion is limited, and, spite of the great resistance of the surrounding parts, it may be luxated forwards. *Backward luxation* has been observed in all the fingers; the posterior part of the joints is less protected than the others, the movement of extension is limited, and if by violence they are carried beyond that point, dislocation backward may follow. Cases are described where muscular action alone has produced it in the thumb: whether this be not mainly owing to particular conformation or relaxed ligaments, it may be difficult to say. This luxation is characterized by a tumor in the palm of the hand corresponding to the joint, or more precisely the inferior extremity of the metacarpal bone, by another tumor at the dorsal surface formed by the superior extremity of the first phalanx: placed in forced extension posteriorly, it describes a right angle with the metacarpal bone. The two last phalanges, on the contrary, are strongly flexed by the dragging of the flexor tendons; the finger is immovable, apparently shortened; there is pain and tumefaction; and this luxation rapidly becomes irreducible. Usually reduction is easily accomplished: an assistant firmly holds the forearm above the hand; another at first draws the finger in the sense of extension, then quickly in that of flexion; the surgeon, with both thumbs, pushes the phalanx below the metacarpal bone.

Sometimes we completely fail in luxation of the thumb, especially if it have existed some days. Most surgeons have met with unfortunate cases, and have attributed it to various causes. Some persons have attributed it to the little opportunity of making counter-extension afforded by the thumb, and the resistance of the very strong muscles which surround the joint; Hey, Dupuytren, and Bell, to the distension of the lateral ligaments, which, not being always ruptured after displacement,

take a perpendicular direction, and are thus opposed to restoration of the surfaces. Bell, for the purpose of vanquishing this obstacle, proposed to divide the lateral ligaments by means of a cataract needle. Vidal and Pailloux think it is owing to the interposition of the anterior ligament between the two surfaces. If the ordinary means of reduction fail, it is advised that recourse be had to the following means of

Fig. 1.

increasing extension; but it must not be carried too far, or the phalanx may be fairly torn off. If that mode of extension fails, many surgeons act upon the opinion of Sir A. Cooper, that it is better to leave things to chance than to interfere with the joint by means of a cutting instrument, as Desault advised.

PHALANXES.

Luxation of the second phalanx is rare, and has very seldom been observed in any other direction than backwards; forwards, the extent of motion is so great that the anterior surface of the second phalanx may be perfectly in contact with the corresponding part of the first, without any displacement of the articular surfaces. As to lateral luxation, the size of the articular surfaces must cause it to be very rare. Luxation of the last phalanx is still more rare than the preceding, in consequence, no doubt, of its affording so small a surface for the action of violence: it may be luxated in any direction, but it has been generally seen directed backwards. In this injury it is the last phalanx which is carried in the sense of extension; in forward luxation it is in the sense of flexion. The prognosis is not always favourable in these cases, even though reduction be speedily accomplished. Sanson has twice seen backward luxation of the second phalanx of the thumb followed by gangrene; which in one case extended to the arm, in the other determined tetanus.

Treatment.—The treatment in these cases varies, according as they are simple or compound: the first should be reduced as quickly as possible. If the means already indicated fail, the Italians are accustomed to take a riband, make a slip knot on it, place the slip knot just beyond the luxation, protect your own hand, then twist the ends of the riband around it, and make extension. This method rests upon

a new idea: you act directly upon the displaced extremity of the phalanx.

If these luxations be accomplished, prompt reduction should be attempted, and active antiphlogistic measures used. Sir A. Cooper advised that, in such cases, resection of the second phalanx should be performed; and passive motion should not be attempted for a fortnight or three weeks.

FEMUR.

The form of the cotyloid cavity is slightly oval; its greater diameter commences superiorly, below the anterior-superior spine, and ends inferiorly above the tuberosity of the ischium. It is at these two points that the cotyloid border is most prominent; setting out from these, are two hollowed or notched borders—the anterior most so—at a point corresponding to the foramen ovale, the posterior at a point corresponding to the external iliac fossa. Now what are the most extended movements of the thigh? Those which direct the head of the femur upon the anterior and posterior borders of the cotyloid cavity, precisely where the depressions exist: dislocation might, therefore, be naturally expected to be most frequent forwards and backwards; and some persons have wished, for the purpose of simplification, to include all dislocations of the femur, primarily, under two branches—forward and backward, as in the accompanying figure; but the head

Fig. 2.

of the femur may escape from the acetabulum in other directions; and therefore it seems proper to describe them as *upwards and outwards*, into the iliac fossa; *downwards and inwards*, upon the foramen ovale; *backwards*, into the ischiatic notch; *forwards*, upon the pubis; *downwards*, upon the ischium. Of these, the

most frequent, in the proportion of twelve to twenty, according to Cooper, is the displacement *upwards* and *outwards*; to produce which, the thigh must be forcibly adducted, whilst external violence carries it from without inwards; as is the case when a person carrying a heavy load falls under it, the thigh being in a state of forced adduction. In this movement the head rolls in the cotyloid cavity, from within outwards, breaking through the capsular ligament, and is carried under the *glutæus minimus*. It usually occurs in a fall from a height, or in sinking under a burden. The limb, according to Cooper, is shortened from one and a half to two and a half inches, the fold of the buttocks is higher and more prominent than that of the healthy side, the knee and the foot are rotated inwards, the knee is on a plane, a little anterior to that of the healthy side; the great toe corresponds to the tarsus of the other side, and the great trochanter is nearer to the crest of the ilium, by so much as the limb is shortened. (See fig. 3.) The thigh is flexed, and a little adducted; this may be increased so far that the affected limb may cross that of the opposite side. Abduction and rotation outward are impossible; extension is very limited and painful, and the corresponding buttock is prominent. Cooper's opinion is different; he thinks that the absence of the projection over the trochanter is characteristic.

If the luxation be not reduced, the limb remains shorter; the patient is ultimately obliged to wear a shoe with a high heel; the thigh is atrophied by inaction; certain muscles are almost useless; others (the hamstring ones, for instance) form a projection. After moving much, the patient experiences pain in the healthy hip and the injured thigh; he cannot stoop without difficulty, and if he try to pick up any thing, he flexes, at a right angle, the knee of the affected side. He requires two sticks to walk, and slight obstacles throw him down.

With moderate care, this luxation need not be confounded with fracture of the neck, either within or without the capsule. In the latter, the limb is shorter, and the trochanter is nearer to the crest of the ilium; but in the vast majority of cases the limb is rotated outwards, and the slightest extension is sufficient to reduce it. Rotation outwards, and abduction, are also usually easy. Still less excuse should we have for confounding it with dislocation and shortening, consecutive to hip disease.

Downwards and inwards or sub-pubian.—This variety of dislocation is said to occur in the proportion of three out of twenty cases. This proportion is small, considering the frequency of abduction, the depth of the

anterior hollow, and the feebleness of the capsule, at this point. But it must be remarked, that it is especially by a fall that this dislocation is produced: in that case usually, by a kind of instinct, the thigh is carried inwards; yet a man may fall, the thigh being abducted, or being on the knees, the thigh separated, a weight may fall on the haunch, and push the head inwards. In this luxation the capsular ligament is destroyed: still there is a point upon which authors are divided—is the *ligamentum teres* ruptured? Sir A. Cooper thinks it must be ruptured before the head of the bone quits the cotyloid cavity. Boyer thought that a very extended displacement of the head was necessary, to cause the total or partial rupture of the ligament. Which of the two opinions may be right it is not in our power to say. I know of no examination after death in support of one or the other. It is true Sir Astley Cooper describes a specimen, dissected long after such a luxation, in which the round ligament was completely ruptured; but as we see also, that the sub-pubian ligament, and the external obturator muscle, had also completely disappeared, we are uncertain whether the *ligamentum teres* was destroyed by the accident, or whether it subsequently disappeared. Besides the destruction of the capsular ligament, the *psoas* and *iliacus*, the *glutæi* and *pyramidalis*, muscles are elongated, the adductors raised and injured, especially the *pectinæus* and short adductor.

It is during forced abduction, as shewn in fig. 1., that this accident happens: either the patients fall to the ground between their legs, as it were, or they fall under a burden, the burden coming on the hip or the loins; in this position the head glides downwards and inwards. The contraction of the adductors contributes much to bring the head into the *foramen ovale*.

We distinguish the luxation by the lengthening of the limb; by so much as the space between the cotyloid cavity and the *foramen ovale*, the limb rests on its outside, and cannot be brought into contact with the other; the leg is flexed. (See fig. 3.) If the hand be placed in the perineum at the internal and superior part of the thigh, we feel a tumor, formed by the head of the femur, and according to Cooper, a hollow below Poupert's ligament. The buttock is tense, flattened, or even hollowed; the fold is depressed, and instead of presenting its usual crescentic character, it exhibits at its middle a slightly obtuse angle. The raised adductors present a cord-like tension: adduction and rotation inwards are impossible. Cooper maintains, as a decided characteristic, the flexion of the trunk, by the action of the *psoas* and *iliacus* muscles.

Fig. 3.

If the reduction be not accomplished, walking is accompanied by the same difficulties as when there is elongation of the limb from any other cause; the patient supporting himself on the whole of the plantar surface, and flexing the leg to render it easier.

Upwards and forwards.—In luxation upwards and forwards, which occurs in the proportion of one in twenty cases, the femur breaks through the anterior part of the capsule, ruptures the round ligament, and passes on, below Poupart's ligament, to the horizontal portion of the pelvis. Cooper has known this luxation to be accompanied by laceration of Poupart's ligament; the head of the femur, lodged between it and the pelvis, raised the psoas and iliac muscles, causing tension of their tendons. After a time the head and neck are flattened, and a cavity hollowed out for the neck upon the pelvis. For this luxation to occur the pelvis must be carried forcibly downwards and backwards; the head of the femur being directed upwards and forwards. When, for instance, the foot is advanced forward, and unexpectedly gets into a hole, the superior part of the body is inclined backward. In this luxation, the patient falls backwards instead of forwards. The symptoms of this luxation are easily distinguished: the limb is shortened by an inch, according to Cooper, is turned outwards, and cannot be directed inwards; the head of the femur, placed upon the pelvis, presents in the groin a rounded tumor, on the inner side of which we may feel the crural vessels. The great trochanter directed forwards, is

situated on a vertical line drawn from the anterior superior spinous process of the ilium; the buttock has lost its rounded form, and is flattened; there is severe pain in the inguinal region, which is extended along the thigh in the direction of the crural nerve. Though believed by Petit and Boyer to exist, tumefaction of the leg from pressure upon the crural vein rarely occurs. It is not easy to confound this luxation with fracture of the neck; the only relation between the two is the rotation outwards. The head of the femur upon the pubis is a sufficient characteristic; still Sir A. Cooper mentions three cases in which the mistake has happened.

Luxation backwards of Cooper; sacro-iliac of Gerdy; backwards and downwards of most authors. The nature of this dislocation is still a subject of controversy. Boyer believed it primarily impossible, and maintained that it was a displacement, consecutive to that in which the head of the bone was upwards and outwards: Delpech entirely rejected it, either primitive or consecutive; still it does occur, according to Cooper, in the proportion of five in twenty cases, and the limb is usually shortened half an inch to an inch; the knee and foot turned inwards; the flexion of the leg upon the thigh is moderate; the whole femur is turned inwards, so that the great trochanter, though behind the cotyloid cavity, is turned a little forwards, the external border becoming nearly anterior, as well as the external condyle; the head is generally jammed against the ischiatic notch; rests on the pyramidalis, between the upper edge of the sciatic notch and the sacro-sciatic ligament, so that in fat persons it cannot be felt. In this luxation, besides destruction of the capsular ligament, the round ligament and a portion of the gluteus maximus and medius, there is a complete rupture of the gemelli (Billard); and in Sir A. Cooper's case of the pyramidalis, gemelli, obturator, and quadratus.

It is in flexing the thigh that this accident is produced; that is to say, there is extreme flexion and adduction; an external violence forcing the knee inwards and forwards, so as to cross the opposite leg; the head of the femur instead of escaping at the superior part of the posterior border of the cotyloid cavity, escapes at the inferior part, and is directed upon the sciatic notch.

Luxation downwards, on the tuberosity of the ischium.—Cooper never saw this accident; B. Bell is the only person who has observed it; in his case it happened during violent abduction of the thigh. The symptoms were slight flexion of the thigh upon the pelvis; it was strongly abducted and rotated inwards; it was not sensibly elongated. It was impossible to extend the

limb. Ollivier (Arch. t 3, p. 545) gives an example of a rather singular and contradictory kind.

Incomplete Dislocation.—In the case of Robert (which he considered incomplete) the signs were as follow:—Thigh flexed, adducted, and rotated inwards; elongation to the extent of seven or eight lines; buttock rounded and very projecting; head of the femur felt above and behind the tuberosity of the ischium. The patient dying, the quadratus was found to be destroyed; the orbicular ligament largely opened at its posterior and inferior portion; the inter-articular, ruptured. Certainly those signs more clearly indicate a complete than an incomplete luxation. In fact, it is not with the hip as with the shoulder joint. The heads of the femur and the humerus are similar, it is true—both rounded, and almost spherical—but the articular cavities are very different. If the head of the femur rested for a moment upon the edge, it would either be slipped back, or drawn away by muscular contraction, and luxation must necessarily be complete. The glenoid cavity, on the contrary, has a form almost plane; its extent relatively to the head of the humerus is also much less than that of the cotyloid cavity with reference to the femur. This character of the humero-scapular articulation brings it much nearer to that of a ginglymoidal articulation, in which incomplete luxation often happens. I, therefore, do not believe in the existence of incomplete luxation of the femur—I regard it as impossible.

The ordinary characters of dislocation of the femur are sometimes not well marked, and may be mistaken; but such cases are unfrequent: generally, the signs are clear and evident, and the disease easily detected; it is, therefore, difficult to account for those instances where they have been confounded with fracture of its neck. In dislocation, it is impossible to restore the limb to its natural direction without reduction; in fractures, it may be moved in any direction. These movements may produce crepitation. We may usually without any difficulty restore the limb to its natural form and length, but it resumes its unnatural form as soon as it is left to itself. In fracture of the neck of the femur, there is eversion of the foot, and shortening of the limb. In dislocation, shortening happens only when it is upwards; when the head of the femur is on the dorsum of the ilium, there is shortening and inversion; eversion is only seen when the dislocation is forward. It therefore results, that dislocation upwards and forwards is the only one which presents those two symptoms common to fracture, shortening and eversion; but the rigidity

of the limb, and the presence of the head of the femur upon the body of the pubis, ought to prevent mistake.

Compared with other articulations the luxations of the thigh are very serious, from the importance of the joint, the difficulties and inconveniences often attendant upon reduction, and, if not accomplished, the lameness which is a consequence; but tumefaction and inflammation often disappear after reduction, and the patient might walk in eight or ten days.

Dislocations of the thigh are usually reduced after much traction, because of the muscular contraction. The most difficult to reduce is the luxation downwards and backwards; then outwards and upwards; then downwards and inwards; then forwards and upwards: at last, that downwards, whose reduction is the easiest. Sir A. Cooper thinks the easiest is that on the foramen ovale, and the most difficult that into the ischiatic notch.

The complication of luxation of the femur with fracture may retard or prevent reduction. There may be fracture on one side, with luxation on the other, and then the diagnosis is very difficult. However, luxations are not always irreducible even after the consolidation of a fracture. A remarkable observation of luxation on the pubis, with fracture, mentioned by the French translators of Sir A. Cooper, was reduced on the eighth day.

Treatment.—At the present day there exists much difference of opinion as to the best general method of reduction. In France, until of late years, the use of machines was proscribed; in England, following the advice of Cooper, the use of pullies is general. Whatever means are employed, it is necessary to determine first the position which ought to be given to the limb before extension is made. Wattmann, Kluge, and Rust, have proposed several modes of lessening muscular contraction; but they do not so far differ from those in general use as to render a detailed description necessary. It must be borne in mind, that the principal difficulty to be overcome is muscular contraction; therefore it is thought wise to adhere to the advice of Pott, and place the limb in a state of semi-flexion—the thigh upon the pelvis, and the leg upon the thigh.

The position to be given to the patient is to place him on a bed, or table, covered with a mattress, the head turned towards the point where a hook or ring is fixed; the groin is to be protected, and a towel or sheet passed around it and fixed to the hook; another sheet is passed around the pelvis, which is then fixed upon the table. These precautions taken, a bandage is now placed around the thigh, just above the knee, and extension with or without pullies is to be

made. The extension must be made from without inwards and a little forwards for a luxation upwards and outwards; a little outwards, for the luxation downwards and inwards; almost parallel to the limb, but a little downwards and backwards, in the luxation upwards and inwards. If the displacement were downwards and backwards, the flexion of the thigh consequent upon dislocation may interfere. Reduction is usually accompanied by a noise, which results from the shock of the head against the floor of the cavity; we may not hear it if the muscles be tired by long traction. In all cases, we immediately detect it, by the direction, the conformation, and the possibility of moving the limb. Usually for some days the limb is longer than the other, which may be owing to a tumefaction of the soft parts within the joint.

To overcome muscular contraction, in this country, we have been accustomed to bleed to the extent of 16, 20, or 40 ounces, then place the patient in a warm bath until faintness comes on. During the time the patient is in the bath, a grain of tartar emetic may be given every ten minutes until nausea is considerable. The patient is then to be taken out of the bath, and wrapped up in a blanket; but these severe depleting means are not always required. When the luxation is into the sciatic notch, it will be necessary to place a towel around the upper part of the thigh, with which an attempt is to be made during extension to raise the head up.

As to the time which may have elapsed without precluding us from attempting reduction, we have no certain data. Fabricius Hildanus would not attempt to reduce a luxation of four months' standing. Petit believed them curable at the end of a month or two; and when there is fracture he recommends that no attempts should be made before consolidation is complete, which may, says he, be six months, a year, or even more. In the memoirs of the Academy of Surgery, t. v. p. 529, is a well authenticated case, where two years had elapsed, and yet reduction was effected. In the memoir of Marx upon old dislocations, are some cases of reduction after a long interval, 26, 31, 78 days, without much difficulty, and without lameness. Cooper believed that three months after a luxation of the shoulder, and eight weeks after that of the hip, may be named as points beyond which it will be imprudent to attempt reduction, unless in persons of very lax fibre, or persons advanced in age. He gives cases of dislocation of the femur reduced at the end of five, seven, and nine weeks.

It is curious to inquire, what becomes of luxations left to themselves. A new articulation is formed. After luxation up-

wards and outwards, we find, according to Moreau, the femur atrophied, its head less convex than natural, and received into a cavity on the ilium, under the gluteus minimus, which is transformed into a capsule for it; the cotyloid cavity somewhat shallower; the new cavity not invested with cartilage, but with a thickened periosteum. After the luxation upon the foramen ovale, Moreau describes the appearances upon a specimen possessed by Morand;—of the foramen ovale, where the head of the femur rested, there remained only a small part on the side of the symphysis pubis. An osseous plate was formed under the internal obturator muscle, and nearly closed the opening; from the ischium and pubis arose numerous osseous productions, surrounding and confining the head of the femur; at the same time the cotyloid cavity was narrower downwards, and deeper, and irregular osseous projections arose from the trochanter major. In Sir A. Cooper's case the external obturator muscle had disappeared, as well as the obturator ligament, the foramen being blocked up by the head of the femur. Around the foramen osseous matter was deposited, deepening the cavity where the head was confined: this cavity surrounded the neck of the femur without touching it, and the head could not be extracted without breaking up the edge of the cavity. Its internal surface was smooth and polished, while the cotyloid cavity was studded with osseous matter. The head of the femur was a little altered; the round ligament was entirely ruptured, and the capsule partly destroyed. And such are the means which nature seems usually to resort to for securing the displaced head of the femur.

CONGENITAL DISLOCATION.—Deformities of the pelvis, and of its articular surfaces, have a certain influence upon the functions of locomotion, and are occasionally accompanied by congenital luxation of various kinds; but the luxation need not be always congenital, it may be produced in after life. Thus, Dupuytren mentions the case of an old woman who had in her family many such cases; in her the accident did not occur until she was thirty, but there can be no doubt that the malformation had existed from birth. There are persons who no doubt present these malformations, who can luxate the limb at will. Portal saw a person who could do so, the Abbé de Saint-Bonnet. There is a medical man, now living at Troyes, who can also do so.

The disease is mentioned in the books of Hippocrates, also by Avicenna and Paré, and especially by Verduc. Paletta first gave a good description and a plausible explanation of this kind of malformation. Dupuytren, Breschet, Cru-

veilhier, and Delpech, have studied the disease with great care.

In this dislocation the limb is shortened, the head of the femur is upon the dorsum of the ilium, the great trochanter is prominent; almost all the muscles of the upper part of the thigh are retracted towards the crest of the ilium, where they form around the head of the bone a kind of cone, of which the base is the iliac bone, and the summit at the great trochanter; the tuberosity of the ischium is abandoned by these muscles and almost denuded; the limb is inverted, the calf of the leg and the heel are everted; the thighs are directed obliquely downwards and inwards; and this obliquity is as much greater as the patient is advanced in age and the pelvis larger; the femurs then tend to cross each other inferiorly. The whole limb, but more especially its upper part, is emaciated; motion is very limited, especially those of rotation and abduction. The lower limbs are altogether arrested in their development, and bear no proportion to the trunk and upper extremities; the contrast is rendered more striking by the size of the pelvis, the development of which has not suffered.

If we examine a patient suffering from this disease, in the erect position, we see the superior part of the trunk directed backwards, while the lumbar portion is projected in the inverse direction, so as to leave a considerable posterior hollow in that region; the abdomen is strikingly prominent, the extremities, only, of the feet resting on the ground. No description of the disease can give a better idea of the appearance presented, than the simile which Delpech attached to it—that of a dog standing on its hind legs. When the patient is about to walk, he raises himself on the point of his toes, inclining the superior part of the trunk towards the leg which is about to support the trunk, and with difficulty raises the other to follow it. The oscillations which characterise this mode of progression are painful to look at; and when the hand is placed upon the head of the femur, on which the body rests, it is found to glide along the iliac fossa, and the pelvis is proportionately depressed. When anatomically examined, the connection between the head of the femur and the acetabulum is very imperfect—(see fig. 4)—the head is altered in form, so as to present sometimes the appearance of a flattened spine; or it assumes a simple styloid prolongation, which is situated in the external iliac fossa, outside of the acetabulum, which presents the most varied character; sometimes it is almost effaced, sometimes the articular cartilages are entirely wanting; usually the two articular surfaces are united by an intermediate

Fig. 4.

ligament, but sometimes they are entirely independent. The muscles seem to have mounted up to the iliac spine; among them some are atrophied, others highly developed. The displacement upwards and backwards explains the obliquity of the thighs, and their disposition to cross each other, at the same time that it accounts for the state of flexion they present, and for the direction of the feet inwards.

To assign a cause for this malformation is not easy; many hypotheses have been proposed; whichever we adopt, so much seems certain, that it is produced during intra-uterine life; for no morbid symptom would justify us in admitting its development after birth; indeed, the total absence of pain would exclude the idea. It therefore differs from ordinary luxation in this respect,—it is usually met with on both sides at the same time, it is not preceded by any symptoms of coxalgia, it is seldom manifested until the patient attempts to walk. It has been a much debated question whether the disease be not only developed, but pass through its stages during intra-uterine life. Dupuytren, it would appear, inclined to the opinion that it was a consequence of violence exercised upon the limbs during uterine life. This hypothesis seems hardly tenable, for there is no sign in most cases which would induce us to admit this mechanical cause of luxation. Paletta's opinion would appear more probable; and is sustained by strong arguments by Delpech, Cruveilhier, and Breschet: they refer it to an aberration of the orthomorphical power; and the following are the inductions upon which the opinion is supported: it is much more frequently seen in females than males; it is also in female children that other deformities which supervene during the evolution of the embryo are most frequent. Cruveilhier has described and figured a case in which

this existed, in conjunction with other malformations. Marjolin has seen congenital luxation of the femur transmitted from mother to child, as is sometimes seen in other deformities.

This deformity does not compromise the health, nor injure the sexual functions; but is a serious obstacle to progression, increasing with the development of the pelvis, and the increase of the bulk of the upper part of the body.

The general impression which exists with regard to this disease, is, that whatever might be our confidence in the resources of mechanics as applied to deformities, it is impossible to believe that articular cavities could be hollowed out. Certain palliative agents have been proposed to remedy to a certain extent the inconvenience: thus, Dupuytren recommends cold bathing as a means of strengthening the muscular system, and also a bandage passed around the pelvis, against which the head of the bone might find support. It is found that when the patient pays much attention, the lameness is less marked; and for the purpose of rendering this attention constant, military drilling has been recommended. Again, an impression has been very generally entertained that the cotyloid cavity is always destroyed or effaced; that, consequently, all efforts to reduce the dislocation must be useless. Humbert has shown that the cases where the cavity has become effaced are a minority; it nearly always exists, but is usually smaller than natural; but even then it is often large enough to admit the head of the femur. In consequence of this, Humbert has ventured to employ in the treatment of this disease nearly the same means as are used in accidental luxation. Several observations contained in his work attest the success of his method: he himself admits that when the cotyloid cavity is wanting, the plan must fail; but he says, as we cannot *à priori* recognise these cases, extension should always be employed before incurability is admitted. M. Humbert continues extension for a considerable time after reduction, for the purpose of accustoming the parts to their new situation: this M. Pravaz thinks necessary; but both concur in the necessity of extended repose and of great caution in the first attempts to rest the body upon the limbs. Humbert recommended, when we are satisfied that no cotyloid cavity exists, to dislocate the head into the foramen ovale, and in this recommendation Pravaz concurs, upon the principle that when luxations into this fossa have not been reduced, after a time the patients have walked pretty well.

The question still remains undecided in

my mind whether actual cure happens. I do not accept the cases of Humbert as cures. I apprehend the ameliorations, which I do not question, do not result from the head of the femur being brought into its own proper cavity, but that it is carried into the sacro-sciatic notch below the pyramidalis, where conditions more favourable for artificial joints are found. I do not by this seek to lessen the credit which fairly belongs to him, but only to place his merit on its proper footing. The time occupied in the treatment is very long; in one case Pravaz had the patient under extension four months; seven months in another was required to bring the head of the femur to the level of the cotyloid cavity, and as much more to secure it there solidly. I have seen no case of so-called cure, where I could not distinguish the head of the femur, when the thigh is flexed upon the pelvis; and I regard no case cured where this sign can be distinguished, together with a slight increase of projection and elevation of the trochanter, an appreciable shortening of the limb, and much difficulty of abduction.

KNEE JOINT.

The articular surfaces are so large, and the means of union so numerous, that luxation at the knee-joint is rarely seen.

Two kinds of complete luxation have been observed at this joint; the one, a consequence of direct violence, and suddenly produced; the other, a gradual result of disease. Duverney believed it impossible that the knee should be luxated forwards; or, indeed, that a true luxation should happen in any direction. Boyer, who, in the main, agrees with Duverney, says that complete luxation of the knee backwards appears to him impossible. Certainly, the case of luxation "inward," extracted from La Motte, by Boyer and Sir A. Cooper, was not well interpreted by them, for it was, unquestionably a luxation backwards. Opposed to Duverney, who does not admit luxation forwards, is Boyer, who cannot conceive a luxation backwards, and as other authors deny a lateral luxation, practitioners naturally feel embarrassed. I have no hesitation in saying, that both backward and forward luxations are possible, without fracture, and without laceration of the integuments.

The oldest case of complete luxation on record is that of Meyer, which was forward; it was reduced, and the patient was cured. Heister, in his *Institutes*, describes a backward luxation, the result of which was no less fortunate than that of Meyer; that of La Motte was similar; so was that of Walshman, with this exception, the tendon of the triceps was ruptured. Sir A. Cooper has seen it twice, forwards, both

cured. Sanson saw, at the Hôtel-Dieu, an old fat woman who had complete backward luxation, cured in three months. Duviivier saw a case of forward luxation also cured. There are several other cases on record, among which the most detailed is that of Blanchard (*Mém. de l'Acad. Royale de Méd.*, t. iv. p. 451), and that of Louyer Villermay, the subject of which was the celebrated Benjamin Constant. Altogether we may find twenty-four cases of a luxation, which many men have regarded as impossible; ten were cases of backward, and fourteen of forward luxation.

As to complete lateral luxation, doubt may still be entertained; in one of Sir A. Cooper's cases, and in that of Gerdy, there was a certain extent of lateral displacement, but then they were cases of luxation forward.

Causes.—Relaxation of the tissues around this joint does not seem to have predisposed the greater number of those patients to luxation: most of them were young and vigorous, and the accident was the consequence of great violence. They seem to have been produced by some object fixing the foot, while the body and the thigh were pushed backwards, forwards, or laterally, with force. The thigh may be the fixed point, and the leg be carried in either direction. In the first case the tibia glides upon the condyles of the femur; in the second, the femur glides upon the surfaces of the tibia. The ordinary motions of the joint, to whatever extent they may be carried, are incapable of causing dislocation.

Symptoms.—This accident is usually easily detected; the limb is shortened, is usually fixed, though it is sometimes very moveable; commonly, the deviation from the natural direction is less than might be expected, and, usually, a considerable numbness is experienced; the deformity at the knee is considerable, varying, however, with the kind of luxation. In the dislocation forward the condyles of the tibia project considerably in front of the inferior extremity of the femur; the patella is higher than natural, and inclines to the right or the left; the condyles of the femur project backwards, and press against the popliteal artery, vein, and nerve. The dislocation backwards is characterised by the projection forwards of the condyles of the femur, and the depression of the patella. Looking backwards, the leg does not seem shortened; looking at it in front, it appears much shortened. The ligamentum patellæ, which in the forward luxation is applied upon the anterior border of the head of the tibia, is here stretched like a cord under the extremity of the femur; the articular notch of which is distinctly felt. Pushed backwards, the vessels and nerve are flattened upon the posterior inter-

condyloid notch of the tibia; the general shortening is less than in the former case. If seen at once, or before there is much infiltration, these characters are so marked that a mistake can scarcely happen; but when the tumefaction is great, and it usually supervenes rapidly, all those points must be borne in mind.

Experiments upon the dead would seem to prove that a luxation forwards cannot occur without rupture of the crucial ligaments; and the lateral ligaments occasionally share the same fate. Similar experiments would lead to the opinion, that the luxation backwards might happen without the lateral or inter-articular ligaments suffering. We see, therefore, that, *ceteris paribus*, the luxation forwards ought to be more easily distinguished than the posterior. Mistakes have sometimes arisen between these luxations and fracture of the inferior extremity of the femur; but then the crepitation, the facility of rendering to the limb its natural conformation, the shortening when traction is suspended, should render this mistake unfrequent. Left to themselves, dislocations of the knee-joint are very dangerous; for the circulation and innervation are commonly interfered with, and gangrene may be the consequence; and for some time considerable disturbance at the articulation is the ordinary consequence.

Prognosis.—To the older surgeons this accident appeared so formidable, that amputation was recommended as the only remedy. Percy believed that if we followed a different plan, and attempted to save the limb, for every one saved a hundred would be lost. Heister's opinion was similar; Larrey defends it. As a general rule, the principle of Percy is improper; amputation is indicated only where there is rupture of the ligaments and vessels, a large wound communicating with the joint, and such an infiltration as would render gangrene almost inevitable. Except in such cases reduction should be attempted, and the limb, if possible, saved. Of the twenty-four cases, seventeen recovered the use of the limb; of the remaining seven, four were in the condition for which amputation should have been performed. Three were cured by it, two died without operation, and two were for a long time infirm. In each case, where reduction has been fairly tried, it has succeeded—without suppuration, without much inflammation, and in the space of a month, two months, three months, or four months. Sometimes much stiffness remains in the joint; it was the case with B. Constant, whose body was examined after death, and the crucial and internal ligaments were found ruptured.

Treatment.—The reduction is not often difficult, and it does not usually require

great force. The patient lies on a bed, or table, or chair; the pelvis should be fixed as in a luxation of the femur. If it be a luxation backwards, extension is made upon the foot. Luxations forward require that the leg may at first be carried slightly backwards, and then the femur must be pushed briskly downwards; and as we have no capsular ligament to be ruptured, considerable extension may be made. The reduction is accompanied by a noise, which is heard by those around, and felt by the patient. In simple cases, after reduction, absolute rest for some weeks is all that is necessary. Cold lotions and careful bandaging will usually subdue tumefaction. In robust subjects, where pain is great, and inflammatory action such as to threaten suppuration, bleeding may be necessary. At first the limb is maintained in a semi-flexed position; but after eight or ten days slight movements of flexion and extension may be carefully attempted, and increased so as to admit of the patient trying crutches at the end of a month. If the injury be considerable, a longer period of rest is indispensable; it must not, however, be forgotten, that a too prolonged inaction may favour anchylosis.

Incomplete luxations of the leg are never found to occur either forwards or backwards. In fact, it is almost impossible that the facettes of the tibia should partially abandon the condyles of the femur in the antero-posterior direction. Morgan's case was clearly a lateral one. When the displacement occurs outwards or inwards, the spine which separates the facettes changes the relation of the articulation. When the external condyle of the femur rests on the internal cavity of the tibia, we have a luxation outwards, and *vice versa*. It would seem that another kind of lateral luxation may occur; two patients at Guy's Hospital were said to present the condyles of the femur between the semi-lunar cartilages and the external border of each articular facette of the tibia; but these small differences would give rise to endless variety of description.

The causes of incomplete luxation are similar to those which are complete. A false step, a violent exertion outwards or inwards, acting on the side of the knee, while the foot supports the weight of the body; or upon the foot, the thigh being solidly fixed; a sudden twist of the leg or thigh.

A single condyle may be luxated: when it is the internal, and it is turned forward, there is seen above a deep depression; the patella is turned outwards, as if luxated upon the external condyle, the internal condyle is carried far back;

if the luxation be backwards, the patella is turned inwards; the projections and excavations being inverse to the former. In the internal lateral luxations, the projection of the tibia, and the depression of the femur on the internal side of the knee, whilst an opposite disposition exists on the outside, the patella remaining fixed upon the internal condyle of the femur, are sufficient for diagnosis: the opposite displacement presents characters, inverse to the other. If, to the lateral displacement be joined rotation, the projections and depressions are modified accordingly.

The luxation which fixes the condyles of the femur between the fibro-cartilages and the edges of the facettes of the tibia, will present similar characters, but less decidedly marked. All these displacements render voluntary motion of the leg almost impossible. If we may judge from the published cases of lateral luxations, whatever may be their variety, they seem more rare than complete luxations, though an opposite opinion has existed. Sir A. Cooper relates three cases, one external, two internal. Costallat has published a fourth. Morgan a fifth. Larrey a sixth. A seventh and an eighth occurred at Guy's Hospital.

The *prognosis* is generally less unfavourable than when the luxation is complete: in Larrey's case, however, amputation was necessary, but there was much injury to the soft parts. A case which is mentioned by Cooper, as having occurred at Barbadoes, was very threatening, and at last the cure was incomplete: in the other cases neither life nor limb seems to have run risk. The reduction is not difficult, and four or six weeks have in some cases been sufficient for restoration; but a knee cap is sometimes necessary. Reduction being accomplished, the after consequences depend upon the extent of injury to muscles, vessels, ligaments, &c.

Luxation of semi-lunar cartilages.—In the work of Hey, we find described, a disease which he termed internal derangement of the knee-joint, but which Cooper describes as luxation of the fibro-cartilages. The accident has occurred suddenly, either in walking or in bed, when the great toe hitched in some hole in the sheet, and forced the leg to turn outwards. A pain is suddenly manifested, and is renewed as often as the patient tries to completely extend the limb, disappearing when the limb is at rest. Forced extension and flexion are the remedy recommended by Hey; but Sir A. Cooper has shown that this means may fail: indeed, it is very easily reproduced. To prevent it, and to support the articulation, an elastic knee-cap is generally necessary. Nothing can be more obscure

than this affection. How can we tell whether it be a case like that described by Reid, a rupture of the cartilage, a displacement, or whether it be a loose cartilage in the ordinary acceptation of the term? To reduce them we must follow the directions of Sir A. Cooper and Hey, flex the leg strongly, rotate the foot outwards, or it may be briskly extended. If both means fail, flexion and traction in all manner of directions may be alternately employed; and, if we succeed, the patient must use the leg cautiously for some time to prevent a recurrence, or he must wear a knee-cap.

Slow or spontaneous luxation of the knee is not rare. Its direction is sometimes outwards, rarely inwards; most frequently backwards, scarcely ever forwards. Ulceration of cartilages, destruction of ligaments, and similar diseases, are the habitual causes of this displacement. If the limb be semi-flexed, and the thigh be better supported than the leg, the tibia is gradually luxated externally; by the same mechanism it glides internally, if the limb be lying on the inside. If it be so frequently displaced backwards, it is that in spite of pillows placed in the ham, the flexor muscles of the leg, kept down by the heel as a fixed point pull at the head of the tibia, as much better as the tendency of the extremity of the femur is to project forwards. Instead of acting as above, by the inclination of the extremity of the tibia, the displacement sometimes happens from the extreme flexion or extension of the whole leg. Sir A. Cooper describes a case of Mr. Cline's, in which the leg was united so as to form nearly a right angle with the anterior surface of the femur, so direct that the sole of the foot was directed forwards. Velpeau describes a case quite as marked, though an inverse condition; incomplete ankylosis is the ordinary result. Hydrarthrosis, an extravasation of blood, certain diseases of the soft parts capable of sensibly elongating the envelopes of the knee, may, it is said, in disappearing, give rise to luxation. Velpeau saw such a case, in 1836, at La Charité. A patient, 45 years old, for six months had the knee as large as the head of an adult. Two large blisters were applied, and in a fortnight complete resolution was the consequence. It was then discovered that the tibia was luxated backwards by its own weight; that by extension, made with the hands, it could easily be brought to its proper place; but, when she stood, it could, like Polichinella's leg, be moved in every possible direction.

OPERATION IN A CASE OF VERY LARGE STRANGULATED HERNIA,

WITH SOME REMARKS ON THE TREATMENT OF SIMILAR CASES.

By JOHN CHARLES HALL, M.D., F.L.S.

Fellow of the Royal-Medico-Botanical-Society,
and Member of the Royal College of Surgeons,
London, &c. &c. &c.

[For the London Medical Gazette.]

On Tuesday, June 30th, I was requested by Robert Cook, Esq., Surgeon, of Gainsborough, to visit Mr. B. C—s, a gentleman of eighty-five, who had been his patient for some years, and who, for a considerable period, had been the subject of a very large irreducible hernia. The day before he had been to a village feast, and partaken, perhaps, a little more freely than was his custom of the good things of the table; and, at dinner, of some cherries and rather old and slightly acid ale. Upon his return, he complained of great pain, referred to the pit of the stomach; headache; and sickness, with frequent vomiting. Upon examination, we found that the hernial sac, which nearly reached down to the knees, was more than usually distended; and that there was a feeling of great tenderness upon even gently handling it. The tongue was much coated; the pulse 120. Before I came, the surgeon had very properly taken away some blood, which was covered with a particularly thick yellow crust, and very much cupped. He had also thrown up several clysters, and given repeated doses of calomel, followed by sulphate and carbonate of magnesia in mint water. This was the state of our patient at the moment when I first was called upon to see him. Here was a case of strangulated hernia in an old man upwards of eighty-five; that hernia was irreducible, and had been so for years; that hernia was so large, that the abdomen was shrunk to one quarter its natural size; the sac, which, as I have before said, reached nearly to his knees, evidently holding the greater portion of the intestines: an operation appeared to offer the only chance of safety, however; and it became a question when and how it was to be performed?

Mr. Cook fully coincided with me that an operation was indispensable;

"and," continued my old and experienced friend, "the sooner in this case the better; we have now a chance of saving the old man's life, and it is useless to operate when death is knocking at the door; when the patient has become worse; when there is vomiting in large quantity, mixed with bile and vitiated mucous secretion; when troublesome hiccough comes on; it is too late then, and, in my opinion, the great majority of cases are lost from operating too late." The above remarks cannot be too carefully read—too deeply impressed upon the mind of every student: they come from a man who for the last thirty years has been engaged in active practice; who has seen many times the folly of delay, and the advantage that arises from operating as soon as possible. I have of late had occasion to operate several times in cases of strangulated hernia, and am fully satisfied that, in the great majority of cases, the patient does not die from the operation, but from the operation being delayed too long. It is no kindness to sit by the bed-side of a man until he dies of strangulated hernia, and then to elaim from his friends credit for more than ordinary kindness and attention. After every reasonable means have been tried to return the strangulated bowel in vain, an operation must at once be performed, for

"Gratia ab officio quod mora tardat abest."

Let me, however, again and again repeat, that in no case are delays more dangerous than in strangulated hernia.

As soon as the patient could be induced to submit, I performed the operation in the following manner:—An incision three inches in length was made in the integuments covering the tumor, commencing a little above the external ring; perhaps the incision might extend for two inches and a half below, and one inch and a half above, the external abdominal ring; for I concluded, from the very large size of the hernia, that we should find the seat of stricture either at, or very near to, the external ring. After cutting through a very thick covering of fat, the tendon of the external oblique muscle, and the fascia of the cord, which the reader will remember is derived from the tendon of the external oblique muscle, a little below the ring, was exposed. This fascia was very carefully divided upon a director, as was

also the cremaster muscle. I then passed my finger upwards, and introduced a common hernia knife upon it, divided the ring to the extent of an inch, which enabled both myself and friend to feel satisfied that the stricture was divided, and the strangulated bowel relieved. Some little difficulty was experienced in dividing the stricture. I had experienced a similar difficulty before. I was operating with a common hernia knife, the probe-point of which was much too long. In this case it was no easy task to get the end of the knife under the stricture, and that difficulty was considerably increased by the length of the probe-point. You have to push this along under the stricture before you can turn the cutting edge upwards, and thus bring it to cut the part. I was not, on this occasion, operating with my own knife; but I have had one made by Mr. Pepys, with which I have twice performed the operation, and, from the blunt point being shorter, this difficulty was avoided. I have mentioned this to one or two surgeons, who complain that they also have experienced much trouble from the cause just alluded to.

Shortly after the operation, the poor old gentleman said "He was much better, and that the pain of cutting was nothing to the agony he had experienced before." The pain was gone, the hiccough no longer present, and he enjoyed several hours of calm and refreshing sleep.

I met my friend Mr. Cook every day in consultation until the time of his death, which took place three days after the operation, from inflammation of the peritoneum and bowels: it was, however, satisfactory to feel that the operation had relieved our patient from the stricture under which the bowel was labouring; and had it not been for his advanced age (upwards of 85), there can be little doubt but that it would have been successful. We were sorry that no post-mortem examination was allowed; and I am sorry to add that this is but too generally the case in the country: there is a feeling against it that cannot be got over—a feeling we would fain hope did not exist in this nineteenth century. The present case was one of great interest; it was one of importance to the public; and I do say that when an examination of the body, (conducted, as it always is, in a way that tends not

in any degree to disfigure the mortal remains of those who have been dear to us), can be made of use to mankind at large by the light it throws on the treatment of disease, the relations and friends of the deceased do a positive injury, a direct act of injustice, to society, by saying "no examination after death shall take place." Moreover, it is an act of cruelty also to the surgeon or physician who has attended the poor man during life. I always like the satisfaction of knowing that all has been done that could be done for my patient, and such I am certain is the feeling of the whole of my professional brethren.

Let me now make a few remarks upon cases of very large hernia, and the plan of treating them.

In the case in which I last week operated, it was unusually large; the testicles were wasted, and the penis buried in the tumor. In truth, the skin of the penis and lower part of the abdomen were stretched over it; the cavity of the abdomen was also considerably diminished; in fact, it adapts itself to its contents—a circumstance which must never be lost sight of. The case of Mr. R. C—s was an old oblique inguinal hernia; the neck of the tumor was shortened, and the openings of the canal approximated, and more in a direct line, the epigastric artery being a little behind and to the inside of the neck. It is always more or less displaced in cases of old standing. The direct hernia passing at once through the parietes of the abdomen opposite to the external ring, does not, until it has reached that point, come in contact with the spermatic cord, having on the outer side of its short neck the epigastric artery. The coverings of the two tumors are not—cannot, in fact, be the same. Those of the oblique are the coverings of the cord; the coverings it has peeled off from it. The coverings of oblique inguinal hernia are a prolongation of the transverse fascia, the cremaster muscle, some fibres from the external ring, and the superficial fascia of the abdomen.

In the case more particularly before us the strangulation had arisen from two causes: first, from the accumulation of its solid, fluid, and gaseous contents, its volume was much increased, and its circulation of necessity retarded; and secondly, from another portion of intestine having been forced down; for

though the opening through which the bowels had originally passed was large enough to admit it, it was not sufficiently so to contain the additional portion that had been forced down. Among the causes of hernia in the first instance, and strangulation afterwards, from the forcing down of an additional portion of intestine, I have found, from frequent inquiry, that the violent exertions of patients, habitually costive, to expel the hardened feces, are the most frequent. I have no doubt that violent straining at stool, in this instance, had forced down additional portions of the viscera, and thus induced the serious distress and the alarming danger, the operation was undertaken to relieve. But the hernia was also irreducible, and had long been so. This arose from the very great contraction of the abdomen owing to the long continued expulsion of its contents; from the very small opening through which the viscera had passed causing the parts protruded to become engorged; and lastly, from the nature of the contents of the tumor; for I have little doubt but that the hernial sac contained either the sigmoid flexure or the caput coli; we might also add, by an accumulation of fat in the appendiculæ of the large intestines, which were protruded, or some induration of the omentum.

Before I conclude, by offering some reasons for operating in the manner above mentioned, let me quote the words of Mr. Liston, which I have read since the former portion of this paper was written, and let me record them here in confirmation of the opinion just expressed of the folly of delaying the operation. He says, "the external applications employed to reduce hernia are various, but no external or internal remedy can attenuate and reduce the hernial sac, remove adhesions, or produce an alteration in the tendinous or rigid apertures." It cannot, therefore, I repeat, be of use to continue the taxis hour after hour; let a fair trial be given to it, and other means, and if they fail we can have no excuse for delaying the only plan of safety, viz., to divide the stricture, and thus release the bowel. In the operation above mentioned the stricture was divided external to the sac. Sir A. Cooper, in his valuable work on hernia, says "I know of no situation in which a man is placed under greater difficulty, than in which

a surgeon has to operate on a hernia of very considerable size, and finds a great quantity of intestine on the lap of the patient, and the parts so diminished, from the length of time the hernia has existed, that there is no room to return the intestine which has descended. He tries to push back the intestine, it eludes his efforts, and after repeated attempts, when he has at length succeeded in returning a considerable portion of it into the abdomen, the whole rushes out again into the scrotum. So much handling of the intestine necessarily leads to such a degree of inflammation as to endanger the life of the patient." (Lectures on Surgery, p. 224.)

But this is not the only danger: however carefully we may handle the intestines, however gentle our manipulations in attempting to return them, they nevertheless burst, scattering the feces over the hands of the operator, and the patient either sinks in a few hours, or dies at the end of some days, from want of nutrition; for the part which gives way will generally be some portion of the small intestines, and the poor patient must sink from constitutional irritation and inanition; for that degree of lacteal absorption necessary to the support of life, cannot take place.

It must appear evident to every practical surgeon that after a bowel has become strangulated for even a very few hours, it is in an incipient state of inflammation: in all cases that inflammatory action is increased by roughly handling the parts, and therefore the employment of the taxis, if continued too long, or used with too much force, no doubt tends to increase the danger of the patient, and adds not a little to the causes tending to make any operation that may be performed unsuccessful. This reasoning applies to all cases; but what must be the consequence in such as we are more particularly discussing in the present paper—what the consequence of endeavouring to return any additional portion of intestine that may have come down into an old hernial sac—the hernia having existed for years, and for years being irreducible? We think that in all cases such practice is likely to be productive of the greatest danger, but more particularly in cases of old and very large hernia: by such long and continued attempts at reduction the bowels become bruised and seriously injured, and,

like any other contused tissues, must inevitably most seriously suffer. Am I exaggerating the dangers attendant upon such a system? By no means; but what must be the danger, what the result, if the operation be performed in the old way? if the hernial sac be divided, and the protruded intestines be received into the hands of the operator? if they remain there for the space of half an hour, continually pushed up, as often to fall down again? Before the operation they have been perhaps much injured by fruitless attempts at reduction, and, like any other part of the body, will stand a much better chance of recovery if their surface be not exposed; will stand a much better chance of recovery if not obliged to undergo, for a long period of time, the attempts made to return them.

Again, even if the bowels had never been injured at all, even if a patient were in a state of perfect health, under the most favourable circumstances, what would be the effect of opening so large a tumor, and exposing the intestines? The most hazardous inflammation, increased by breaking down adhesions which had been present for years. And even if the abdomen was able to contain the contents of the tumor, (which in the old gentleman I operated upon last week was quite out of the question) what surgeon would have the temerity to return them? for there is every probability, every reason for supposing, that the return of parts which had so long been protruded, into the abdomen, would bring on the most alarming symptoms.

But, for the reasons already stated, they cannot be returned, and, what is more serious still, they cannot be retained in the sac which has been improperly opened. In the *Journal of Foreign Medicine* (No. 15, page 460) a curious case is mentioned in which the sac was divided in a very large scrotal hernia, and about one foot of the colon which was contained in it could not be returned. The integuments were not sufficiently large to cover it; still its surface granulated, the skin, as the cicatrix contracted, extending itself over the swelling, which also diminished in size, and in a few weeks the man was discharged cured.

In such cases, then, we must avoid pulling the parts about, and perform the operation as soon as possible; we must not dream of opening the hernial

sac, breaking down the adhesions, and attempt to return into the abdomen that which it is too contracted now to hold; nor must we run the risk of exciting inflammatory action by the exposure of the bowels. The rule of Sir A. Cooper here holds good, viz., "That when the tumor is of long standing, exceedingly large, perhaps extending more than half way down to the patient's knees, and its contents have never admitted of being completely reduced, the indication is to divide the stricture, provided a strangulation take place, but without laying open the hernial sac, or attempting to reduce the part."

In performing the operation great care must be taken that the stricture is not only divided, but divided fully. In the present case, after freely using the knife, I requested my friend to introduce his finger, and Mr. Cook thinking that the parts might even be a little more freely dilated, I gave him the knife, which passing along his finger the parts were relieved sufficiently to remove from my mind all apprehension as to the state of the stricture. Dupuytren informs us that in eight out of every ten cases of strangulated bubonocoele, the stricture is seated at the neck of the sac, and he supposed that this took place from some alteration in the structure or nature of the peritoneum at this part. But Mr. Cooper well remarks, that, in a recent protrusion, strangulation cannot depend upon any thickening of the neck of the tumor (vide Cooper's Surgical Dictionary, 7th edition, page 724), and he admits that large external swellings were not very liable to be strangulated in this way. The justly celebrated Dupuytren, (Clin. Chir., vol. i.) has also made some valuable remarks upon the form of the tumor, and directs us to the seat of the stricture, by remarking that "when it is situated at the external ring the tumor formed by the hernia does not reach above this point; the inguinal canal, therefore, is undistended, soft, and indolent to the touch, while the ring itself is hard and tense; on the other hand, when the stricture is at the neck of the sac, that is to say as far up as the superior orifice of the inguinal canal, this is always full, hard, and tense."

In some the stricture extends the whole distance of the inguinal canal, and here we must lay its upper surface open its whole length.

My space will not, however, allow me to dwell upon all the varieties of stricture that are met with; I may, however, trespass to remark that two strictures may exist, a slight one at the abdominal ring, and a second and more serious one at the neck of the sac. This very important fact must ever be kept in mind, for if the surgeon supposes that the stricture exists at the abdominal ring, and divides it only, the bowel is pushed into the inguinal canal, and not into the abdomen: should another stricture exist higher up, in this case the symptoms continue, and death must inevitably follow, sooner or later.

Dupuytren remarks, that when the strangulation takes place at the upper portion of the inguinal canal, the danger is much greater, and the parts sooner become gangrenous, because, the edges of this opening are very sharp, and make very great pressure on the neck of the sac: the abdominal ring is wider and has blunter sides; strangulation in this situation is therefore slower.

Little need here be said upon the treatment of the bowel, should it in any instance be found mortified. Mr. Lawrence recommends it to be freely opened, to obtain at once that relief (viz. evacuation of its contents,) which nature seeks by the process of gangrene. (On Ruptures, p. 299.) Nor must we forget that by this plan Sir A. Cooper snatched from the brink of the tomb a female who was pregnant at the time of the operation, and was afterwards delivered of a child.

Treatment after the operation.—In the first place, the patient must be kept in bed, a pillow placed under the knees, and every means taken to relax the muscles of the abdomen, by placing him in as easy a position as possible. In large cases the hernia must be supported. A large pad or small pillow will answer very well. If the sickness frequently present continues, perhaps the following draught will relieve it sooner than any other:—

℞ Sesquicarbonatis, gr. xx.; Aquæ Cinnam, ℥ss; Liq. Opii. Sed. ℥iv. M. ft. haust. tertia quaque hora cum coch. med. succi limonis sumend.

Although I have never given or seen it used, I am inclined to think that in such cases perhaps this mixture might be substituted with advantage. I shall certainly give it a trial.

℞ Liq. Opii. Sed. ℥viij.; Acidi Hydrocyanici (Scheels), ℥iv.; Potass. Bi-

carbonatis, ʒj.; Aquæ, ʒvj. Misce.
Capiat quartam partem quâque 3tia.
horâ si opus fuerit.

Evacuations from the bowels must be at once promoted by clysters and small doses of sulphate of magnesia—a dram dissolved in peppermint water every two or three hours; the recumbent position must also be maintained, as any exertion will cause the bowels again to come down. Inflammation of the bowels and peritoneum must be attacked by bleeding, calomel and opium, fomentations to the part, and leeches; doses of castor oil will be the best aperient. Should diarrhœa come on, a mixture long used by my worthy friend, Mr. Carrick, R.N., surgeon, Kensington, is very useful, and often affords relief.

R Confect. Aromat., ʒj.; Sodæ Sesquicarbonatis, ʒj.; Aquæ Menthæ Pip., ʒvss.; Tr. Card. co., ʒss. M. Coch. ij. mag. pro re natâ.

Opium can of course be added if required. After the operation, the diet must at first be kept low; but when all danger of peritoneal inflammation is past, this plan must be changed, and wine, quinine, cordials, and a generous diet allowed. We must remember, however, that though we have succeeded in curing the patient, we have not prevented, by the division of the stricture, other portions of the bowel coming down; and, therefore, we must by proper means guard against such an unfortunate occurrence.

In all cases of large irreducible scrotal hernia, the tumor must be very carefully supported by a proper bandage, and injury to the part avoided, as a severe blow might occasion rupture of the bowel, and death. We shall do well also to caution our patients as to their diet and mode of life: excesses of every kind must be most studiously refrained from. In the case of Mr. R. C—s, now before us, strangulation of the bowel was to be traced to this cause. Warm aperient medicines must therefore frequently be taken; as the compound rhubarb pill at bed-time, with some aperient during the day. Clysters of warm water will be of great use; in fact, the bowels must not be overloaded, either by a too free indulgence at the table, or an accumulation of hardened fæces. When it can be taken, a dose of castor oil now and then, at bed-time, will answer every purpose; when it

cannot, the following mixture may be used—

R Magn. Sulphatis, ʒiv.; Infus. Sennæ, ʒv.; Tr. Card. co. ʒj.; Ess. Ment. Pip. ʒxxx. 4tâ pars horâ decubitus.

This will be a mild and useful aperient, and much better than the quack pills with which every shop is now filled, all containing more or less of blue pill. I was consulted only a short time ago by a victim to this system. How long, I ask, will the public be thus blinded? How long will the government allow a portion of the revenue to be derived from profits arising from both the wholesale and retail distribution of poison in the shape of vegetable pills, and every other form, both solid and liquid?

The importance of the subject has led me far beyond the limits I had at first marked out. Hernia is a disease so frequent, of such every-day occurrence, that we are called upon to understand it in all its forms, in all its bearings; to understand not only how to perform an operation, but also how to adjust a truss. For my own part, until I was the dresser of Mr. Babington, at St. George's Hospital, I knew but little of this important procedure; and, if I am not mistaken, many leave our hospitals without ever having seen one put on, much less taking the pains to learn how to do so themselves.

Mr. Aston Key dwells at great length upon the danger of attempting to expose the bowel by opening the sac in a large hernia; and adds, that when general inflammation precedes the operation, the knife seldom succeeds in checking it.

Cases of so large a nature as the one now recorded are certainly not very common. Sir A. Cooper has operated in three cases (Lectures on Surgery, p. 225). He has, however, left in his valuable work abundant information as to their treatment; and he most eloquently urges the attainment of that knowledge of anatomy which alone enables a man to operate with advantage to his patient. We may look on, and think it very easy to divide part after part; and so it is to the man who has gained that information which this surgeon urges all to acquire. An examination of his writings, and the works of Dupuytren, Cloquet, Lawrence, Guthrie, Key, and others too numerous to mention, will afford every facility to the study of this interesting and im-

portant disease; they will, in fact, induce the student to examine the subject for himself, in the dissecting-room; induce him there to read the book of nature—a volume ever open: and amply will it repay the most attentive and diligent research.

Bath Place, Kensington,
July 1840.

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

YOUR correspondent from Cheltenham is quite correct. There is a typographical error in page 544 of your current volume. The word *vaccinated* is printed instead of *unvaccinated*, in line second of the first Statistical Table; but the error seemed to me too obvious to require formal notice, as the words *total unvaccinated* immediately succeeded, and the preceding numbers were added together. As your correspondent is so sensitive on the subject of typographical errors, allow me to call your attention to his own letter, p. 626, line seven from the top, where the word *manifest* is printed instead of *manifest*. I am the more inclined to notice this erratum, because, though your correspondent assures us that it is a "*manifest* duty to employ lymph taken from healthy subjects only," he does not specify the reasons for such careful selection: those reasons are, I dare say, manifest to him, but I doubt if they will be equally manifest to other people, more particularly as he is so perfectly in accordance with you in the opinion you lately expressed touching the impossibility of communicating any other disease along with cow-pox. It appears from your correspondent's letter that some practitioners in Cheltenham entertain the notion that such an occurrence is possible, while you and he hold "that there is no proof whatever that with cow-pock any other disease can be communicated, whilst all facts and probabilities militate, *in toto*, against such opinion." Superficial observers might naturally say, if no disease can possibly be communicated with cow-pock, it is *manifestly* indifferent whether a healthy or unhealthy subject be selected: to prevent such a misconception, and at the same time to discuss the pathological question which you have raised, I venture now to address you.

As this is not a matter of medical statics, and, therefore, not open to be called in the singularly felicitous language of your correspondent, "wash and vapidity good only for the gutters," I hope for his indulgence as well as yours while I offer a few observations upon it.

It is hardly necessary to say that the extreme anxiety manifested by parents in the selection of a subject from whom their children are to be vaccinated, arises from an apprehension that scrofula may be communicated by and with the vaccine lymph: the fears of parents seldom extend beyond this; and the idea of communicating insanity, epilepsy, or gout, is, I believe, rarely, if ever entertained. No grounds whatever exist for supposing that scrofula may be thus communicated, and when we can calm the apprehension of the parent on this score, we have done all that is ever required from us. But your position takes a wider range, and affirms that the *febrile* contagious diseases cannot be thus communicated, and this is a more difficult question to decide.

It is well known that if the lymph of a vaccine vesicle be employed while variola co-exists, such lymph cannot be relied on for communicating the vaccine. There is at least an equal chance that the resulting disease will be small-pox. I have heard the particulars of a case where erysipelas and cow-pox co-existed, and the lymph being unfortunately taken, both diseases were communicated to the child. I have no experience bearing on the question whether measles can be communicated along with cow-pox, but it would be going too far to say that such a thing is impossible. As little have I to say practically on the question of communicating syphilis by means of the vaccine virus, but I am not prepared to deny the possibility of such an occurrence. Dr. Jenner, as we all know, laid great stress on the danger of vaccinating while the system was pre-occupied by herpes, lepra, or psoriasis. I have frequently seen the vaccine vesicle assume the leprous character, nor can I doubt that this combination of the leprous and true vaccine disease would be propagated, if any one were so unwise as to employ such degenerated lymph. The Germans have lately made many experiments to determine the effect of vaccinating persons labouring under true psora, and they have found reason to believe that the two diseases do not

interfere with each other; but I confess, I should take vaccine lymph from the arm of a child labouring under an inveterate itch with many fears as to the result.

These considerations incline me to think that you have expressed yourself on the impossibility of communicating other diseases with the vaccine lymph somewhat too unreservedly, and that the unbelievers at Cheltenham are not so far wrong as your correspondent would wish us to believe; but I am open to conviction, and shall be much gratified to have some additional light on this curious branch of vaccine pathology.

The reasons, then, why we select lymph from healthy subjects are the following: first, because in healthy subjects the course of the vaccine is *cæteris paribus* the most normal; secondly, because we thus exclude the *chance* of communicating any other disease with the cow-pock.—I am, sir,

Your obedient servant,
GEORGE GREGORY, M.D.

31, Weymouth Street,
July 11, 1840.

CASE OF EXTRAORDINARY DEVELOPMENT OF THE MAMMÆ IN THE HUMAN ADULT.

To the Editor of the Medical Gazette.

SIR,

THE exceedingly rare occurrence of a case similar to the following has induced me to forward a report of it to you. It may prove interesting to the physiologist, although the extraordinary effects are to be traced to a primary pathological condition for their cause.

I am, sir,
Your obedient servant,
JOHN GORHAM.

Tunbridge, Kent, July 1840.

William Rogers, æt. 61, a native of Chatham, and by trade a fisherman, states he has generally enjoyed good health. He married at the age of 33, and has had children, the last being 13 years old.

Four years and a half ago he went into the Queen of Spain's service, having been previously examined in the ordinary way, and pronounced quite fit for service, being a strong hale man in every respect.

On attempting to jump over an entrenchment in a retreat, and not being able to clear it, the anterior part of the body, in the situation of the xiphoid cartilage, or thereabouts, was projected with great force against the upper and sharp edge of a wall; he was thus driven backwards, and fell on his back. While lying as if dead, one of the Carlists stabbed him with a bayonet a little below the ribs on the left side, and immediately afterwards he received a sabre wound over the frontal bone of the same side. On regaining his senses he was able to walk a short distance, and was immediately put to bed. The symptoms induced by the accident are referrible to the following parts: the spine—lower extremities—bladder—rectum—the testicles—the mammæ—and the hair.

Spine.—When in Bilboa hospital, he had great pain in the vertebral column, and for this he has been cupped repeatedly. He has now a complete angular or Potts' curvature; the trunk is bent forwards, and the spinous processes of the vertebræ backwards. Pain is complained of, and this, on percussion, appears to be most evident at about the centre of the dorsal region, and also of the lumbar. There is constriction of the upper part of the abdomen.

Lower Extremities.—The right lower extremity is constantly affected with cramps, and is generally colder than the left. He can walk a distance of five or six miles a day.

Bladder.—His urine was not drawn off for about fourteen days after the accident, a complete paralysis of the bladder apparently then existing, but since that time he has been able to retain it.

Rectum.—The alvine dejections were passed at first with great difficulty, sometimes involuntarily, and at others with pain. Since the collapse of the diseased bones, however, and the recovery of the patient, with the consequent deformity, all these symptoms, more immediately dependent on the spinal lesion, have disappeared.

The most remarkable alterations produced, however, are to be found in the three last-named parts—the testicles, the mammary glands, and the hair.

Testes.—Ever since the accident these glands have wasted. That on the right side is soft, pulpy, and of the size of a small nutmeg. It is drawn upwards,

close to the external abdominal ring. The left testicle is somewhat larger, but still atrophied, and, as in health, is more pendulous than its fellow. As regards their functions, the poor fellow has not had the slightest sexual desire since the receipt of the injury.

Breasts.—About three weeks after the accident the integuments around each nipple became painful and swollen, and a tumor, analogous as I imagine to the *areolar* of Sir A. Cooper, was formed. Leeches and poultices were applied; however, the increase of substance did not stop here; for as the testicles decreased in size, hypertrophy of the whole mammary region became more and more evident. Each breast is at this period of the size of an orange, glandular to the touch, and pendulous.

Hair.—This on the face is of very tardy growth, so that he is obliged to shave much less frequently than formerly.

As far as I can judge, from seeing him only for a short time, he is a quiet and inoffensive person. His countenance struck me as being, if not effeminate, yet, certainly devoid of that appearance which so often predominates in the military who have been chosen from the lower orders of people. His voice was subdued; and he received a small trifle placed in his hand as a compensation for allowing me to make a few remarks upon him with apparent gratitude.

His spinal affection it is true might have caused all this; and, therefore, the few circumstances here noticed I could not wish to be looked upon as a part of the narrative of the case.

It was thought at Westminster Hospital that a lacteal secretion might possibly exist, and a cupping-glass was had recourse to, but on producing a partial vacuum no milk issued.

A cast of the head has been taken, he informs me, by Dr. Elliotson; and one of the head, unshaven, together with the bust and other parts of his body, by Mr. Deville. The occiput is very flat; but as the function over which the cerebellum partly presides was quite normal and active before the injury, little weight must be attached to the circumstance.

The pulse is 56, and the respiration 20.

TREATMENT OF CROUP.

To the Editor of the Medical Gazette.

SIR,

OBSERVING in your number for July 3d ultimo, a paper by Professor Hannay, on the treatment of "Croup," I beg to offer the following remarks on the treatment of that fearful disease, deduced from actual practice. I observed the cases reported in the British and Foreign Medical Review, No. 2, and might, like Dr. Hannay, had not my opinion been previously formed from actual pathological observations, come to the conclusion that sulphate of copper would act as a specific remedy in cases of acute inflammation of the lining membrane of the larynx. However, previous to explaining my opinion as to the nature and treatment of croup, it may not be out of place to take a retrospect of those cases reported by Dr. Zimmerman, illustrative of the effects of sulphate of copper. In the first case reported the patient was 3 years of age; on the first day the symptoms became severe, twelve leeches were applied! and small doses of sulphate of copper given every two hours. On the second day, twelve more leeches were applied in the morning: the danger still continuing to increase, notwithstanding the increased doses of the sulphate, and large abstraction of blood, it became necessary to repeat the application of twelve leeches, and the doses of the sulphate, on the same evening. On the third day after the attack the child died.

The second case reported is that of a child, 6 years of age. It was attacked on one day, took doses of sulphate of copper, which acted as so many emetics; on the following day there remained no appearance of croup. There are three other cases reported, viz. 5, 8, and 12, in which the abstraction of blood was not resorted to, and from their history it may be inferred that in all the attack was very mild, and, I am inclined to surmise, of a spasmodic, and not of an inflammatory, nature.

In all the remaining nine cases, blood was abstracted, and to a considerable amount, if we take into consideration the tender age of the sufferers. It will be observed in the first and ninth cases the disease terminated the lives of

the patients. The success attending the treatment of the remaining cases, related by Dr. Zimmerman, I think may be fairly ascribed to the active depletion and vomiting produced by the sulphate of copper, and the consequent reduced state of the circulation; but from no specific effect of the sulphate.

I have no hesitation in affirming that there are two distinct kinds of croup; *i. e.*, an acute inflammation of the mucous or lining membrane of the larynx; and a spasmodic affection of the muscles of the larynx; in several respects these morbid affections assimilate each other. The former I will term true, and the latter spurious, croup. We shall find, in all cases of true croup, high inflammatory fever, attended with a full strong pulse, a difficult and sonorous inspiration, a short and difficult respiration, which becomes increased in paroxysms, with a crowing cough. These symptoms are always preceded by cold, or some other exciting cause. If at this stage of the disease the fauces and throat be examined, they will be found of a bright red or inflammatory appearance; and if the disease does not very early after the attack come under treatment, and that of a most rigorous character, there will be but little chance of the patient's recovery; for the mucous membrane has a tendency to secrete lymph of a very tenacious quality, which encroaches very rapidly on the air-passage, and will produce speedy suffocation. The inflamed vessels of the mucous membrane lining the larynx, in the early period of life, pour out this adventitious membrane, which generally commences about the larynx, and extends to the bifurcation of the bronchi: this I have had several opportunities of observing in cases which have proved fatal. From this brief account of the progress of the disease, it will appear evident, that the first object of the practitioner should be to arrest the progress of inflammatory action; for this purpose it becomes necessary to take large quantities of blood, and that in the briefest space of time, so as to produce a decided impression on the system; and although, generally speaking, children bear large losses of blood badly, yet, in this disease, there is a general exception to this rule. The best mode of abstracting blood is to apply a dozen or more leeches, as the case may require, to the upper part of the sternum, so as to pro-

duce a state of syncope as soon as possible, and then to check any excess of bleeding by the application of the nitrate of silver. This should be followed by an emetic. I do not think it matters much whether it be composed of ipecacuanha, antimony, sulphate of copper, or zinc, so long as full vomiting is produced. After the cessation of sickness, a full dose of calomel should be administered, so as to produce active purgation, which should be assisted by castor oil, repeated at intervals; for in every case that has fallen under my observation I have found the secretions much vitiated, especially the alvine. The general routine of treatment then is, to repeat at short intervals small doses of calomel combined with antimony, so as to keep the patient in a state of nausea, but not amounting to actual vomiting. At the same time a saline mixture, with the *Tr. digitalis* and *conii*, may be administered with very great advantage. I have treated in this manner a great number of cases, and believe with more than ordinary success, not losing more than one in ten. I account for this by the active depletion employed at the onset of the disease, for I do not believe without it there is any remedy capable of controlling this fearful disease. In cases of acute croup blisters are inadmissible, or if not, they should be applied at some remote part of the disease; and even the warm bath does more harm than good unless properly employed, which it scarcely ever is when left to the nurse. When used the child should be placed in the water at about 108°, which should be gradually increased till the skin becomes relaxed and relieved by a profuse perspiration; any thing short of this is worse than useless.

Spurious croup is a disease more formidable in appearance than dangerous; it will generally be found to arise from a disordered state of the stomach, dentition, costiveness, or accumulation in the bowels. One of my own children has suffered from repeated attacks of this form of croup during dentition. The treatment which I have adopted consists of emetics and purges of calomel and rhubarb, with free and repeated scarifications of the gums. This disease differs from the other by the absence of inflammatory action, and in consisting of a spasmodic affection of the muscles of the larynx.

Should you deem these hasty observations worthy a place in the *GAZETTE*,
 You will oblige
 Your obedient servant,
 WILLIAM ROBES.

ON THE DEFICIENCY
 OF
 CLINICAL INSTRUCTION AT
 VIENNA.

[*For the London Medical Gazette.*]

IN my previous letters I have drawn a short sketch of the existing clinics of Vienna, and will now add a few remarks on the deficiencies of the clinical instruction there in a general way. Closely adjoined to the great civil and military hospitals, there is an extensive foundling house, where we find equally the infant, the child, and boy or girl. Although this presents a most advantageous opportunity for the establishment of an extensive clinic on the diseases of children, yet it remains of no avail to the profession; for no one enjoying the confidence of the government has ever thought of converting its means to so useful a purpose. It is even not a little difficult for the inquiring traveller to enter within its limits, from his being constrained to obtain previously a written permission, for that intention, from the Director of Hospitals. Call this heedless neglect of a good and convenient means for cultivating the study of the affections of infancy and childhood by whatsoever name you will, it still seems to me a proof of a state of great moral degradation of the medical faculty there, as well as a blameable want of enterprise and remarkable languor. No impartial individual can retain a doubt as to the great utility, if not actual need, of some sort of clinical instruction in the treatment of children's diseases, in order to fit the youthful physician to practise his art with success in all its branches. Besides those nicer hygienic cares so contributory to the cure, and the modifications of medical treatment more especially applicable in such cases, it is only necessary to mention the more prominent affections of childhood and infancy to convince the most reluctant. Surely after calling back to memory infantile asthma, croup, the tubercle of infants, lobular inflammation of the lungs, dropsy

of the brain, inflammation within the cranium, diarrhoea, convulsions, aphtha, rickets, distortions, malformations, skin affections, eye disorders, &c. all modified in infantile life, no one will venture to affirm that the young practitioner can gain a satisfactory knowledge of such disorders, without the convenience of an extensive clinic; before fatal experience has often proved him to have fallen into error, and his ingenuity only to have served as a weapon for death.

The need of such a clinic is doubly desirable in Austria, where the system of education that the medical man must pursue is such as to prevent his familiarizing himself with those morbid ills, previous to the commencement of the public and responsible practice of his profession. The absence of such a clinic amongst ourselves in England is a circumstance of less importance; though, doubtless, still a great loss to the profession, and an injury of no ordinary magnitude to the social weal. This difference rests on the manner of our medical breeding; since we have a fair chance to witness a moderate extent of practice in this branch of our art at the period of pupillage, both prior to and during the College attendance.

There is a succession of wards in the great civil hospital appropriated for the reception of syphilitic patients, whose number far exceeds even the demands of an ordinary clinical institution; yet such a thing as a clinic on venereal complaints is never dreamed of by the authorities. But this is not all; the evil does not stop there; for it is required to get the good will of the attending physician, and a permission from the director of the hospital, before any student can enter; whilst this favour extends merely to the space of two days. When the physician overlooks a longer attendance, he exceeds the spirit of the hospital regulations, which amounts to a general prohibition. It would be difficult to ascribe the actual reason for a rule bringing such great loss to the successful study of medical practice in a land where the absolute governor does not submit to expose the wisdom of injunctions to public canvass, nor test them by the common sense of the mass of his kind. I incline to the belief, however, that it owes its origin to some false notion in morals. Some poetical moralist has imagined that the sight of the ills born by the victims of unlawful pleasures is

hurtful to the youthful mind. This may be true, inasmuch as it will be sensible to disgust; but that such objects can seduce the youth from virtuous manners, seems to me at once improbable, whilst it is belied by the evidence of fact.

Also in the civil hospital we find a particular department for patients afflicted with the filthy maladies of the skin: but, in this instance, again I must breathe the regret that no advantage is taken of it for the use of a clinic. Thus the physician of Vienna knows as little of the pathology and cure of these complaints—interesting because ordinary—as the Laplander does of the Italian Pellagra. It is, however, true, that some few cases of acute diseases, localised on the surface, are admitted into the medical clinic; but a few cases of small-pox, measles, and scarlet fever, are too inconsiderable, in comparison with the number and general importance of the affection which rank in this branch of pathology. Perhaps an argument of some weight in favour of the special study of skin diseases is the frequent defect of a practical acquaintance with them on the part of the educated practitioner, whilst the rambling quack often supplies his place as restorer of the suffering sick. Not only is the special study of local affections and peculiar diseases, apart from common lot, an advantage to the scholar, but it also offers additional opportunity for a perfect education to the clinical teacher. A clinical education ought to regard completeness, as far as practicable, in every branch; and in this part of their system the French excel us much.

Within the enclosure, not but a few paces distant from the vast hospital, stands, upon a slight elevation, the Narrenthurm, Irrenhaus, or mad-house. This is a considerable oval edifice, four stories in height, and used for the reception of individuals labouring under mental delusion, and also for cases of confirmed epilepsy.

Notwithstanding it is in every respect inferior to the asylums of England and France, it does still present all the convenience for a clinical school for the disorders of the mind, not on account of the number of admissions alone, these being forty two monthly, or thereabout, but likewise from the favourableness of its site. But alas! here again we find the door closed to the zealous student of

disease; he must ask and obtain previous permission for each particular visit; which is, in fact, nothing short of a prohibition of successive attendance. Besides, there being no shadow of a clinic on those most fearful afflictions that mankind are heirs to—perversion of reason, there is not even a strictly punctual visit on the part of medical attendants. It is difficult to conceive how any set of people can in this way shut their eyes with careless neglect to the immense advantages which the excellent arrangement of their hospital offers for the foundation of a practical school of medicine, that might be unequalled in the world. This Narrenthurm, considered as an asylum for the maniacal, is in every point of view unsuitable: it resembles a fortress prison, of a most gloomy aspect, being more fit to inspire strange thoughts, than quiet and dispel the fancies and hallucinations of the madman.

The department of morbid anatomy in the Civil Hospital of Vienna is by far the most extensive in Europe; and the practical knowledge of the cadaveric appearances of diseases taught by a few exceeds by far the experience of the medical men of any clime. The officers in the dead-house are three: Rockitsky, the Professor of Morbid Anatomy; Kolletschka, his assistant; and another young person of promise, who acts as scribe or secretary. The professor proceeds always with two courses at once, but at different hours; so also does his assistant; and thus there are constantly four courses on morbid anatomy going on during the whole year in Vienna. Morbid anatomy does not form any part in the curriculum of study, and is, therefore, a part of the private instruction. This is probably the reason that no student of the school visits the dead-house; he is not obliged to do so—he is not zealous—he is not encouraged—and he has already been wearied by a long and lingering course of education. The morbid anatomy school, with the rarest exceptions, is alone attended by foreigners, who come sometimes from the most distant parts to avail themselves of its most decided advantages. The great superiority of this School of Morbid Anatomy is, that every appearance, fact, assertion, or opinion, pointed out by the teachers, is supported or proved by numerous fresh specimens of morbid changes, whilst the scholar sees and

assists the act of autopsy. The judic ia and the ordinary post-mortem examinations are made in separate chambers adjoining one another. The grand defect of this arrangement is, that the clinic is kept wholly distinct from the department of morbid anatomy; and the clinical student does not avail himself of its aid. It is a most rare sight to see the professors of the medical or surgical clinics visit the dead-house; and when this does happen it is only in some curious case, when their scholars have seen them puzzled. On such occasions some few of the class attend likewise; but as this is like an angel's visit, they are not prepared to profit thereby. The foolish Hildenbrand laughs at the idea of representing morbid anatomy as valuable to the physician.

Believe me ever to remain,
Most truly your's,
* * *

ANALYSES & NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Practical Observations on Blindness from Cataract; with Cases, illustrating the advantages of an early Operation. By JOHN NORTHON THOMPSON, M.R.C.S.L., Honorary Surgeon to the Nottingham Dispensary.

WE have received a small pamphlet from Mr. J. N. Thompson, of Nottingham, entitled as above, which, as it bears the stamp of being the result of considerable experience in ophthalmic surgery, we deem to be worthy of notice. The observations are short, and confined to the consideration of one question: viz., the propriety of *early* operation in cases of cataract. Mr. T. is of opinion that this operation is in the majority of cases delayed unnecessarily long, and he brings forward numerous examples to prove, not only that the lens might be broken up at a much earlier period than is usually recommended, but that when the operation is performed before the cataract has had time to *ripen*, as it is popularly termed, the result is not only more favourable, but more certain. In short, if we understand Mr. Thompson correctly,

as no remedial measures, short of the couching needle, can avail in the treatment of cataract, he advises that this should be had recourse to as soon as the opacity of the lens has fairly declared itself; and that then the best and only operation necessary is that recommended by the late Mr. Saunders, viz., the destruction of continuity in the lenticular structure, so that it may be removed by solution and absorption. This question has not, that we are aware of, been considered before, and to Mr. Thompson is due the credit of priority. The essay, therefore, has its merit, and is deserving the consideration of those who are especially interested in the improvement of ophthalmic surgery.

Observations on the Management of the Poor in Scotland. By WILLIAM PULTENEY ALISON, M.D. F.R.S.E. Second Edition.

IN our editorial articles of Feb. 7th, 14th, and 28th, we introduced the first edition of this remarkable work to our readers. The second edition contains some valuable additions, and should be in the hands of every lover of justice and humanity. Among the monstrous assumptions of the Malthusians, there is one of pre-eminent absurdity, which supposes that if workhouses are made tolerably comfortable, there will be a run upon them; every body it seems would rather eat meat four times a week in prison, than once a week in his own cottage. It is true that this same flocking to the workhouse never occurred yet in any age or country; but, what of that? The assumption makes a good argument for water and gruel, nevertheless. The more reasonable portion of the Poor-Law people are obliged to give up theory, but the prohibition of Christmas beef and pudding still continues in practice.

The present edition, which is printed in a more compressed form than the former one, is sold for the extraordinarily small price of two shillings. Those who have read our former articles on the subject will be ready to acknowledge that Dr. Alison's book is not a mere commentary on the Scottish treatment of the poor, but that it should be studied by every friend to the human race in whatever corner of the empire he may dwell.

Practical Remarks on the use of Iodine, locally applied, &c. By J. DAVIES, Surgeon to the General Infirmary at Hertford.

AFTER some remarks on local therapeutics, and on the therapeutic properties of iodine, Mr. Davies gives an account of the benefit derived from its external application in erysipelas; phlegmon; extensive sloughing of the cellular membrane; acute inflammation of the joints; inflammation of the breast; gout; chronic enlargement of the joints; inflammation of the absorbents; carbuncle; lupus, or *noli me tangere*; malignant ulcers of the tongue and tonsils; serofulous swelling of the glands; whilow; chilblains; lacerated, contused, and punctured wounds; burns and scalds; and ulcers.

Mr. Davies uses iodine externally in two different forms; namely, a tincture made with forty grains of iodine and an ounce of rectified spirit; and a solution of thirty-two grains of the hydriodate of potass in an ounce of distilled water, with the addition of eight grains of iodine. The tincture is diluted with spirit, when necessary; and with the "ioduretted solution a lotion is made by the addition of distilled or common water, varying in strength according to circumstances, from one-eighth to one-fourth of the former." That is to say, the lotion may be one-eighth or one-fourth of the strength of the solution. These preparations of iodine are not the same as those of the London Pharmacopœia. The following extract shows the method of using the tincture:—

"Suppose we are called to a case of severe inflammation of the leg, in a stout, robust person: the limb is intensely red, hot, swollen, and glossy, all the way from the toes to above the knee: it is double the size of the corresponding one, and so painful as to disturb the general health, as to cause quickness of the pulse, white tongue, thirst, &c. We immediately *paint* the whole limb with the tincture of its full strength, extending its application from the toes to several inches above the upper margin of the inflammation: the remedy is applied with a camel's hair brush. This is all the local application requisite for the present. The limb is directed to be kept in a horizontal posture, and either to be very lightly covered over with a sheet—which must not come in contact with the skin—or else to be

left exposed, according to the temperature of the apartment. In less than twenty-four hours—in less than twelve hours—the swelling will be found to have diminished. At the end of twenty-four hours the skin will be seen much corrugated, shewing its contents to have become less in bulk, and the circumference of the limb will measure some inches less than the day before. The diminution will be found to have taken place more particularly towards the upper part of the swelling. We now repeat the application of the tincture, of the same strength. In another twenty-four hours the reduction of the swelling will have gone on rapidly, and only a remnant of the disease will be found to exist. The strength of the tincture must be now reduced to one-half, and its application continued daily, or less often, according to circumstances, until the limb is well. After the second or third applications of the tincture, we sometimes brush the limb over with spirit of wine alone, so as merely to dissolve the iodine which remains on the surface of the skin."—Pp. 17, 18.

If the tincture is applied too frequently or too strong, "it may cause the skin to inflame or the cuticle to blister, but that is the only inconvenience which has ever occurred from its use."—P. 62.

"If any itching, or a slight blush of the skin, should follow the repeated applications of the remedy, especially on the lower extremities, it should be discontinued, otherwise the cuticle will rise into small watery pimples, and will tease the patient for a few days; but this effect is produced by it on the *healthy* skin only—when applied, for instance, to the skin covering a diseased joint, or when any induration or swelling is situated under the skin—for we have never found it to blister the cuticle and to cause exudation of lymph from the surface of an *inflamed* skin."—Pp. 18, 19.

Mr. Davies supposes the iodine to act by contracting the enlarged capillaries of the inflamed part.

In the last page of his essay he gives another list of diseases in which the tincture has proved beneficial; and we must add that he has had eleven years experience of the remedy; so that if our author has not been led astray by the zeal incident to a discoverer, he has made a most estimable addition to the surgical pharmacopœia.—*Nous verrons.*

MEDICAL GAZETTE.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso.”

CICERO.

QUESTION OF INSANITY.

THE TRIAL OF EDWARD OXFORD.

THIS trial has not passed without exhibiting many features of interest in a medico-legal point of view, and in reference to that most difficult of all the questions which our profession are, or at least used to be, called on to decide in public—the suspected insanity of one accused of crime. Although we fully concur in the justice of the verdict, we are at the same time bound to add our belief that no prisoner was ever before found insane on so little evidence, and that in almost any other case than that of an attempt to murder the sovereign, the plea of insanity would have totally failed. Let us suppose, for example, what might very well have happened, that Oxford had attempted the assassination of an equal, after only the slightest possible degree of provocation, or for some imagined injury that he conceived he had sustained, or for some good to which he had a vague notion that the object of his attack was an obstacle in his way. Of what avail would the evidence of the strange and foolish proceedings of his father and grandfather have been? or of what use would it have been to prove that he had himself laughed and cried out of season, and written bad poetry, and done many other silly things, in common with others of weak intellectual powers? Such evidence would have been deemed valueless, and he would probably have paid the penalty of his life. None can doubt this; therefore this case has shewn that, though the evidence of previous insanity be extremely slight, and afford

only the smallest degree of probability of its existence, yet the circumstances of the single crime committed may be such as will establish to the satisfaction of a jury and of the public, that the individual convicted of it was not, at the time of its commission, responsible for his acts. This has been long acknowledged in France and Germany in cases of moral insanity, but had not hitherto, we believe, been fully admitted in our own courts. Of the justice of admitting such a conclusion there cannot be a doubt; the prudence of acknowledging it is much less certain, since the history of all similar cases has shewn, that the expectation of punishment is the surest means of preventing the morbid anxiety for destruction from being carried into effect.

The case of Edward Oxford, however, does not appear to be one of those that can be regarded as examples of moral insanity, or of the “*lesion de la volonté*”; or, at least, if he did labour under a morbid propensity for the destruction of life, it must have been coincidently with a general deficiency of intellect; and as far as his history is given by the witnesses, it had never before made its appearance under that form. The evidence of Drs. Conolly and Chowne, who visited him in prison, and of Mr. Clarke, who had seen him often in his boyhood, was unanimously in favour of his being imbecile; and all the circumstances of his case tend strongly to corroborate the same conclusion. This case, therefore, has sanctioned the establishment of another important consideration, namely, that the absence of a distinct motive in the commission of a crime may be deemed to afford as strong evidence of insanity and irresponsibility as the existence of some delusion under which the perpetrator acted. Here, again, justice and prudence are in some measure opposed: one cannot doubt the truth of the conclusion that none but the

insane commit atrocious crimes without purpose, yet, at the same time, one cannot but feel sure that unless the whole of the *onus probandi* is thrown strictly and heavily upon those who set up the absence of purpose in their defence, such an admission must afford a very dangerous hope of committing crime with impunity.

Such are the two most important points admitted by the verdict in this case; that in cases in which insanity is set up as a defence by criminals, the circumstances of the act itself for which they are accused, and the absence or great insufficiency of motive, may constitute sufficient evidence of the unsoundness of mind, although the previous history of the accused may have afforded only the weakest presumption of it. Such an admission in a verdict, which, if the Chief Justice predicted rightly, "will be an example, which, like former verdicts in the present day, will be quoted in courts of justice as defining the rule,"—"by which the lives of all our countrymen in future times are to be protected," is indeed a circumstance of the very highest interest. But we can scarcely expect that "so dangerous a maxim as that the mere enormity of a crime should secure the prisoner's acquittal by being taken to establish his insanity," will ever again be acted on in a case devoid of the many peculiarities by which this has been marked. No one can doubt that the very enormity of a crime committed without adequate motive must often be one of the strongest, or perhaps the only indication of the insanity of him who has perpetrated it; in the present case, it is quite certain that the plea of insanity would have been valueless as an excuse for a crime of less atrocity, and that the less the crime the less would such a defence have been listened to; but here, as in many other cases, the public safety demands and authorizes the infliction of

some violence upon the strict sense of justice, and the law must have its course against the suggestions of abstract equity. On this ground only should we hold the punishment as a criminal of Oxford, or any other person similarly situated, to be justifiable; if the *salus populi* demanded it, his apparent or partial irresponsibility must be overlooked, and he must fall under the strong arm of that *suprema lex*; but on no other consideration must it be forgotten that the very enormity of an act is often strong evidence of its insanity, and may be sufficient to prove its existence with no stronger evidence of hereditary disposition or of previous extravagance of conduct than was adduced in this case.

Other features in this case, less generally important, yet hardly less interesting to our profession, were the opinions expressed by the eminent lawyers engaged in it respecting the nature of insanity, and the capability of medical men to offer acceptable information upon it. We have often before remarked that the cunning question respecting the definition of insanity, which counsel usually ask for the purpose of confusing or throwing discredit on a medical witness, is a mere foil to direct attention from the consideration of what constitutes insanity in law. In strict pathology there would be no more difficulty in defining insanity, than in defining any other disease, as a disturbance of the functions of any organ from the natural mode of their performance; and it is only because lawyers have required a definition which should not appear incompatible with their own notions of insanity, which are founded on no fixed principles of either law or medicine, and which vary with every case that occurs, that any difficulty has presented itself. If, for example, every man who suffered under an uncertain kind and degree of disorder of the bowels, was liable to be made the subject of legal investigation,

who can doubt but that it would be as difficult to give a definition of disordered bowels, which should please either or both parties of the counsel engaged, as it now is to satisfy them with a definition of insanity.

The fact is, that the legal idea of insanity extends no further than the question whether a man is fit for the performance of some one act, which differs according to the nature of the case in which its consideration comes into a court, or whether he is to be deemed responsible for any crime that he may have committed. Oxford, for example, might, had he been old and rich enough, have made a will that would be perfectly valid in the eye of the law; and none of his relations could, on the score of insanity, have deprived him of the management of his own affairs—yet he is irresponsible for an attempt to murder his Sovereign. Nay, in law, the case is carried further. A man is so mad that he is constantly possessed with the idea of being in love with a princess, to whom he writes with cherry-juice; but, says the Solicitor-General, “if that man had committed a murder would his delusion have borne on the case, so as to alter the moral nature of the deed? Why should it have done so? Could the jury suppose if he had shot any person, an act which would have had no earthly connexion with his delusion about the princess and cherry-juice, that the existence of insanity on a subject so wholly unconnected would have rendered him irresponsible? By no means.” Let us suppose, then, that the subject of this delusion *had* committed murder, or, like Oxford, had attempted the assassination of the Queen. No medical witness could have had the least hesitation in declaring him insane, nor could any medical definition of insanity be made so narrow that it would not include him. Yet in the eyes of the law he is not mad, in respect of the particular

circumstances under which he comes into court. The medical evidence is, therefore, deemed valueless, and the decision of the case must rest on the common laws of general evidence, from which it must be deduced whether he laboured under any special delusion, whether he had any motives for his act, what those motives were, and a number of other circumstances which medical men are scarcely more calculated to judge of than any others of equal intelligence.

This, indeed, is the important consideration which it has been the tendency of all recent trials, in which the question of insanity has been mooted, to establish, viz. that the evidence of medical witnesses is neither essential nor even of peculiar value. The Chief Justice said—“Every sort of insanity, and every mode of proving it, must have reference to the particular object with which it was laid before the court,”—that is to say, there can be in law no definition of insanity—what is madness in one case may in law be sanity in another or in all others—and in each instance the proof must be established according to the common laws of evidence, by reference to the peculiar circumstances of the case; and though “the evidence of the medical gentlemen was to be listened to with all the attention their knowledge demanded, yet the common sense of the jury must be the arbiter of what they saw.” What follows, therefore, will not be unexpected nor seem strange. “There might be cases of insanity in which medical evidence as to physical symptoms was of the utmost consequence; but as to moral insanity, he (the Chief Justice) for his own part, could not admit that medical men had at all more means of forming an opinion on a case than were possessed by gentlemen accustomed to the affairs of life, and bringing to the subject a wide experience.” It was to be gathered from their observation in the course of the trial, that the other judges enter-

tained the same opinion as is here expressed; and although there may be some doubt as to the number and nature of the *physical symptoms* of insanity, of which alone medical witnesses are in future to be deemed the best judges, yet it is certain that the time is now not far distant when they will almost cease to be asked their opinions in courts of law upon questions of insanity, and especially upon those in which the persons supposed insane are charged with crimes.

This, indeed, must of necessity be the result of the admission, that "every mode of proving insanity must have reference to the particular object with which it is laid before the court; for in that case, the general proof of insanity, to which the medical witness must speak, will be of little value, unless there be also a proof of insanity in reference to some single object; and of a proof of the latter kind, it is quite clear that any two persons of equal intelligence and general experience in society are equally competent to judge, whatever be their professions. The opinion of a physician who has especially devoted himself to the management of the insane, would, of course, be still deemed peculiarly valuable; but, with such an admission as that above mentioned, the opinions of the rest of the whole body of the profession on questions of insanity must henceforth cease to be regarded as of any particular importance in a court of law. In short, in criminal, and to a less extent in civil cases, insanity must henceforward be regarded as a legal—not as a medical question.

We are not sure that this need be a matter of regret to the profession, while the law of insanity was so unstable, and admitted of the application of no general principles; it was and ever has been impossible for a medical witness to obtain any solid credit by his evidence in court; and now that he is to be reduced to the rank of other ordinary

witnesses, and to have his evidence set aside by the decision of the very variable and usually very inferior common sense of the jury, it will, probably, be more to his honour to be forgotten, than to be called to offer his opinion on cases of this class.

TESTIMONIAL TO SIR BENJAMIN BRODIE.

HAVING heard a report that the Committee for the Brodie Testimonial had proposed to found with the money subscribed a prize for the school at St. George's Hospital, we have made particular inquiries on the subject, and are enabled to state that such is not the case; the committee being only anxious that the testimonial to be offered to Sir Benjamin Brodie should be such as would shew to posterity the high sense entertained by his professional friends and pupils of the many improvements introduced by him into the science of surgery; and we earnestly trust that a sufficient sum will be raised to enable the Committee to propose to the general meeting such a testimonial as shall be worthy of him, and the profession to which he belongs.

DEATH OF GRAEFE.

WE regret to announce the decease of this distinguished surgeon, which took place on the fourth of the present month, at Hanover, whither he had repaired for the purpose of operating on Prince George of Cumberland, for cataract. His remains have been conveyed back to Berlin.

VACCINATION EXTENSION BILL.

THIS bill, as amended by the Commons, passed the Lords on last Monday, the 13th, Mr. Wakley's Small-pox Prevention Bill, of course, falling to the ground. This result confirms the apprehensions we expressed in formerly alluding to the subject; as the latter, in our opinion, would have been the better act of the two.

The document itself will be found at p. 771 of our present Number.

UNIVERSITY OF LONDON.

EXAMINATION FOR HONOURS.

Tuesday, July 14.—Morning, 10 to 1.

ANATOMY AND PHYSIOLOGY.

Examiners, Mr. KIERNAN & Dr. SHARPEY.

Candidates may illustrate their answers by sketching the parts they describe.

1. Describe the parts successively brought into view in dissecting, from the skin of the perineum to the inferior fundus of the bladder, that space which is bounded anteriorly by the arch of the pubes, posteriorly by the rectum, and on each side by the ramus of the ischium and obturator internus muscle.

2. Describe the internal structure of the kidney; and state what you conceive to be the relation of the blood-vessels to the ducts, adducing the evidence.

3. Describe the intimate structure and chemical composition of interarticular cartilage, and in what respects it differs from articular cartilage.

Afternoon, 3 to 6.

1. Give the dissection required to expose the course of the vertebral artery, from the third cervical vertebra to the foramen magnum; commencing at the integuments on the back of the neck, and describing the several parts successively met with in the dissection.

2. Describe the mucous membrane of the stomach and small intestine; the description to include that of the ultimate arrangement of the blood vessels, the epithelium, the follicles of Lieberkühn, and the glands of Brunner and Peyer. What recent investigations have been made into the structure of the last-named bodies? Describe also the development of the alimentary canal, with the exception of the mouth and fauces.

3. Describe the erectile tissue, and state what recent researches have been made into its structure. In what other parts of the body, besides the corpora cavernosa and corpus spongiosum, has it been said to exist, and what is your own opinion upon this point?

Wednesday, July 15.—Morning 10 to 1.

CHEMISTRY.

Examiner, Mr. DANIELL.

1. How may carbonic acid be generated and condensed into the liquid state? Explain the phenomena which occur when liquid carbonic acid is allowed to evaporate rapidly.

2. Explain and illustrate the meaning of the term DIATHERMANCY; in what do

diathermanous bodies differ from diaphanous and transparent bodies?

3. What are the principal phenomena of polarized light; and how may light be polarized?

4. How may the diffusion of Gases be measured? and what is the law of their diffusion.

5. Describe the construction and explain the action of the electrical condenser.

6. Describe the mode by which a volta-type copy of a medal may be obtained, and explain the process.

7. What is Methylene? How is hydriodate of Methylene obtained, and what is its relation to Alcohol?

8. What is the constitution of Phosphoric acid? What are its relations to water and salifiable bases.

9. What are the principal constituents and characters of the fusible calculus, the mulberry calculus, and of red gravel?

10. Describe the properties of Sulphur and Selenium; state their equivalent numbers, and the points of resemblance between these two elements and their compounds.

Afternoon, 3 to 6.

MATERIA MEDICA AND PHARMACEUTICAL CHEMISTRY.

Examiner, Mr. PEREIRA.

1. What are the crystals contained in the bottles marked respectively A, B, C, D, E, and F? Are they hygroscopic or anhydrous? what are their primary forms? what is their atomic constitution?

2. The fruits contained in the bottles marked respectively G, H, I, and K, were found in Alexandrian senna. State the botanical name, natural order, and Linnaean class and order of the plants from which they were respectively derived.

3. How is the presence of nitrate of potash in fused nitrate of silver to be determined? Bisulphuret of mercury is sometimes adulterated with red lead,—by what means would you detect the fraud? How would you ascertain the presence of carbonate of soda in the bicarbonate of soda of commerce.

4. Describe the method of making *Ammonia sesquicarbonas* Ph. L. Explain, according to the ammonium hypothesis of Berzelius, the chemical changes which occur in the process.

5. State the most important chemical distinctions between *Morphia*, *Narcotina*, and *Codeia*; also between *Strychnia* and *Brucia*; and between *Cinchonia* and *Quina*.

6. How is oil of vitriol made? Explain the theory of the process.

7. Why is the *Liquor Ammoniae Acetatis*, as usually found in the shops, incompatible with acetate of lead?

8. In what part of bark does their me-

dicinal activity exclusively or principally reside; and how do you explain the fact of its residing in one part chiefly?

9. What are the most important constituents of the mineral Waters of Cheltenham and Harrowgate; and for what diseases are these waters respectively adapted?

10. State the peculiar or characteristic symptoms produced by Opium, *Hyoscyamus*, *Belladonna*, Tobacco, *Digitalis*, Aconite, *Conia*, and *Strychnia*.

11. Under what circumstances are Chalybeates to be preferred, as tonics, to the vegetable bitters?

12. Describe the effects, uses, and modes of administration of Iodine.

VACCINATION EXTENSION BILL.

Act to extend the Practice of Vaccination.

“WHEREAS it is expedient to extend the Practice of Vaccination; be it therefore enacted, by the Queen’s most Excellent Majesty, by and with the Advice and Consent of the Lords Spiritual and Temporal, and Commons in this present Parliament assembled, and by the Authority of the same, That from and after the passing of this Act, it shall be lawful for the Guardians of every Parish or Union, and for the Overseers of every Parish in which relief to the Poor shall not be administered by Guardians, in England and Wales, and they are hereby directed, to contract with the Medical Officers of their several Unions or Parishes respectively, or with any legally qualified Medical Practitioner or Practitioners, for the Vaccination of all persons resident in such Unions or Parishes respectively: Provided always, That it shall be a condition of every such contract, that the amount of the remuneration to be received under the same shall depend on the number of persons, who not having been previously successfully vaccinated, shall be successfully vaccinated by such Medical Officers or Practitioners respectively so contracting.

“And be it further enacted, That in making such arrangements as may be required for the execution of this Act, such Guardians and Overseers, and all other Officers engaged in the administration of the Laws for the relief of the Poor, shall conform to the regulations which may from time to time be issued by the Poor-Law Commissioners in that behalf, which regulations the said Commissioners are hereby authorized and required to make and issue.

“And be it further enacted, That such Medical Officers or Practitioners shall make a Report to such Guardians, or

Overseers from time, to time of the number of persons successfully vaccinated by them respectively, and shall make such further Report with respect to the persons so vaccinated, as such Guardians and Overseers under the direction of the Poor-Law Commissioners shall require.

“And be it enacted, That such Guardians or Overseers, shall forthwith, after the conclusion of any such Contract as before mentioned, transmit a Copy thereof to the Poor Law Commissioners.

“And be it enacted, That if such Commissioners shall not annul such Contract within Fourteen Days from the receipt thereof, such Contract shall thenceforth not be liable to be annulled by such Commissioners.

“And be it further enacted, That as soon as may be after the passing of this Act, the Guardians of every Poor-Law Union in Ireland shall (subject to the approbation of the Poor-Law Commissioners), divide such Union into Districts of convenient extent, and may alter the same from time to time, (subject to the like approbation as aforesaid) contract with competent Medical Practitioners for the period of One Year, and so from year to year as such Contract may expire, for the Vaccination of all persons who may come to such Medical Persons for that purpose.

“And be it further enacted, That all the provisions hereinbefore made with respect to England and Wales for the appointment and giving due notice of the appointment of the places and times at which such Medical Officers or Medical Practitioners shall attend to vaccinate such persons, and for the making of reports by such Medical Officers or Medical Practitioners, shall apply to all such Contracts as may be made under this Act by the Guardians of any Poor-Law Union in Ireland; and such Guardians, and all other Officers engaged in the administration of Relief to the destitute Poor, shall conform to the regulations and instructions of the Poor-Law Commissioners, in like manner as hereinbefore directed with respect to Guardians, Overseers, and other Officers in England and Wales.

“And be it further enacted, That any person who shall from and after the passing of this Act produce or attempt to produce in any person, by inoculation with variolous matter, or by wilful exposure to variolous matter, or to any matter, article, or thing impregnated with variolous matter, or wilfully, by any means whatsoever, produce the disease of Small-Pox in any person in England, Wales, or Ireland, shall be guilty of a misdemeanor, and shall be liable to be proceeded against and convicted summarily before any Two or more Justices of the Peace in Petty Ses-

sions assembled; and for every such offence shall upon conviction be imprisoned in the common gaol or house of correction for any term not exceeding three months.

"And be it further enacted, That every word in such part of this Act as refers to England and Wales shall be interpreted in like manner as such word is directed to be interpreted in an Act passed in the fourth and fifth year of his late Majesty King William the Fourth, intituled "An Act for the Amendment and better Administration of the Laws relating to the Poor in England and Wales;" and that every word used in such part of this Act as relates to Ireland shall be interpreted in like manner as such word is directed to be interpreted in an Act passed in the first and second year of the reign of Her present Majesty, intituled "An Act for the more effectual Relief of the destitute Poor in Ireland."

TUBERCULAR PHTHISIS.

DR. GRAVES exhibited the lungs of a woman who had died a few days previously at Sir Patrick Dun's Hospital. She was admitted with symptoms of phthisis, accompanied by chronic laryngitis. Dr. Graves remarked, that it was well known, that where laryngeal disease with stridulous breathing exists, many of the phenomena of phthisis are recognized with difficulty. The character of the inspiration, of the voice, and of the cough, are not the same as when laryngitis is absent, and the sounds of the larynx mark those of the lung. The chief point to which he wished to refer in the case alluded to was this: both lungs were filled with tubercles, and in both there were tubercular cavities, a large one in the left, a much smaller one in the right lung. The right lung was every where closely adherent, in the left there were no adhesions; any one who examined the lungs would have expected, that during life they would have given evident indications of the nature of the disease, and that there would have been distinct dulness on percussion. Dr. Graves had percussed the chest, and it every where returned a clear sound, no dulness could be discovered in any part. He remarked, that in the investigation of diseases of the chest he had been frequently struck with the fact, that although percussion gives in some cases signs of great value, and which, when positive, appear to be infallible, in other cases the information derived from it is questionable. The truth of this he had frequently verified in cases of phthisis, in which tubercle might exist to a considerable amount, and without dulness.—*Dublin Journal of Medical Science.*

MR. OWEN'S REJOINDER.

WE have received a very lengthy paper from Mr. Owen, on the subject of the controversy regarding the originality of the views promulgated in his recent work. We have directed that it and any other paper referring to the same subject, from any of the gentlemen who have taken part in the discussion, be inserted in the *extra-limite* department, in order that the space devoted to the regular business of the journal may not be encroached upon.

RECEIVED FOR REVIEW.

A Treatise on the Structure, Functions, and Diseases of the Foot and Leg of the Horse. By W. C. Spooner, M.R.C.V. &c. Transactions of the Provincial Medical and Surgical Association, Vol. VIII.

Dr. Tweedie's Library of Practical Medicine.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, July 2.

John Medmer Goodwin, London.—Abraham Wolfe, London.—William Holme, Kendal, Westmorland.—Oswald Allen Moore, York.—Henry Boxall, London.—James Nance, Ashford, Kent.—William Rhys Williams, Rochester, Kent.—Arthur James Skrimshire, Northampton.

Thursday, July 9.

On the 8th morning clear, otherwise cloudy, with rain; the 9th generally clear, rain at times; the 10th generally clear, rain in the morning and evening; the 11th morning clear, afternoon and evening overcast; the 12th evening overcast, otherwise clear; the 13th afternoon cloudy, rain at times, otherwise clear; the 14th generally clear, except the evening.

Rain fallen, $\frac{1}{125}$ of an inch.

CHARLES HENRY ADAMS.

WILSON & OGILVY, 57, Skinner Street, London.

MR. OWEN'S REJOINDER TO
MR. NASMYTH.

To the Editor of the Medical Gazette.

SIR,

IN the case of a scientific discovery or theory, enunciated in simple and intelligible terms, nothing seems easier to prove than a priority. To ascertain the dates of publication of the respective works—to determine the degree of correspondence in the definitions or descriptions in question—are the simple processes by which the case is settled.

Whether, besides the undoubted merit to be awarded to the earlier author, the stain of plagiarism is to be affixed to the later writer, must be a more complex and difficult question for the upright and just mind to determine upon. It must depend on the degree of correspondence in the terms in which the discovery is narrated; on the intellectual character and pursuits of the later author, with reference to the probability or otherwise of his originating independently the same idea or theory. Lastly, on his known moral character and habits.

With respect to the theory of the "formation of dentine or ivory by calcification of pre-existing and pre-arranged cells in the substance of the pulp," the right of the author of the memoir communicated to the French Academy, 16th December, 1839, was called in question in two distinct communications, which appeared in the *Gazette* and *Lancet* for June 5th and 6th, 1840; and the priority being assumed to be proved against that author, his relation as a plagiarist from the earlier one seemed in one of the journals to be taken for granted, and coarse abuse was lavished upon him.

It was urged in defence, that, of the works quoted as plagiarised from, the one offering the nearest approach to a correspondence with the new theory could not possibly have been in possession of the author accused, being posterior in date to his work; and it was proved that the passages quoted for the same purpose from the accessible or anterior works were incorrectly quoted, as well as the professed parallel passages in the work of the accused author.

But it was assumed by the accusers that the earlier and later works of the author whose interests they defended

were essentially the same, being exponents of the same views, and, in short, different forms of the same memoir. This assumption led to a demonstration of an important discrepancy in regard to the theory in question, and to the conjecture of the existence of many others, between the earlier and the later forms of the memoir alleged to be plagiarised from.

Moreover, the later memoir, quoted as containing the statement "*that the ivory was an organic deposition of ossific matter in the pre-existing cells of the pulp**," being in the condition of a privately circulated pamphlet, and no copy of it having been transmitted to the accused author, he was compelled to take the best means he could to obtain a sight of it, that he might compare its tenour and amount of resemblance with the earlier and only published forms of the (alleged) same memoir.

And now, having stated the case in question as it stood after my answer to the first charges against me, I may observe that my letter to the officer superintending the publication of the Transactions of the British Association, of which the privately circulated memoir professed to be a part, was a necessary step and consequence of the unfair manner in which I had been attacked—as it were, in the dark. I thought it fair to Mr. Nasmyth to print that letter, and at the same time, however strongly suspicion might point to his having had a hand in the simultaneous and anonymous attacks, yet the private and altered memoir might have come into the possession of a third person, without Mr. Nasmyth having any cognizance of or consent in the abuse, to which he must otherwise have known that the new paragraphs in that altered memoir were to be applied.

The least offensive suggestion as to the motive of such alterations was therefore, obviously, that the memoir about to appear should be *au courant*. And I was glad to read the explicit negation of any concernment in the attacks in question, with which Mr. Nasmyth commenced his letter in your number for June 26th, p. 545: although many of your readers, like myself, must have been at a loss to understand how Mr. Nasmyth's forbearance should have been particularly trespassed upon during the operation of

attacks in which all the praise was for him, and all the blame another's. Admitting, however, that the eighth volume of the Transactions of the British Association could form no element in determining the priority of the theory in question, the desired result might have been attained if either the reviewer for the *GAZETTE* or *Lancet*, or Mr. Nasmyth himself, could have adduced any single passage in the reports of his memoir in the *Athenæum* or *Literary Gazette* of Sept. 14 and 21, 1839, stating the ivory to be formed "by an organic deposition of ossific matter in the pre-existing cells of the pulp," or "by ossific transition or transformation of the pulp's substance." I say, that although such statements would only resemble, to a certain extent, my theory, and fall short of what it enunciates, yet I would yield the palm of priority to the author who, before me, had satisfactorily established and fairly expressed those statements.

This would be the plain and short way that a true anticipator would take: instead of which, your readers have been presented (June 26th) with a letter from Mr. Nasmyth, in which, leaving the refuted charges of his friends the reviewers to their fate, he ransacks the stores of private correspondence for the grounds of new accusations; and this letter is followed (July 3d) by a second review of my Odontography. Letters from a M.R.C.S., residing at a distance in the country, and from a Mr. Tomes, serve to divert your readers' attention from the question at issue, and are meant to damage me in their estimation; and lastly, a second very long letter, from Mr. Nasmyth himself, partly argumentative and exculpatory, partly accusative also, with private correspondence quoted, appears in the *Lancet* of July 11th.

These have determined me again to address you, to set myself right with your readers, whose good opinion I find requisite to cheer me on in my labours, and many of whom may have neither the leisure nor will to sift closely the charges laid against me, which then I feel would require no answer of mine.

And first they may wish to know something of my now avowed adversary and accuser's character for veracity.

Mr. Nasmyth affirms, in your journal of June 26, p. 545, as follows: "I had determined to continue to practise forbearance, and to take no part whatever in the discussion respecting Mr. Owen's plagiarisms from my writings." But

in the *Lancet* of last week it would seem that he had been compelled to admit, that it was himself who transmitted to that journal the private copy of the modified memoir still in the press, and which he knew I could have never seen, together with my memoir of Dec. 16, and these for the express purpose of a comparison between them, which was to establish the charge of plagiarism against me, and which accordingly did draw down upon me the abuse to which I have alluded.

"Had I been aware," says Mr. Nasmyth, addressing Mr. Wakley, "that such a cunning outcry would have been raised on what I shall proceed to show is altogether a groundless assumption, I certainly, for my own sake, should not have sent you that abstract for review. My motive for sending you a copy of it was very natural: I wished you to compare my own account of my researches with Mr. Owen's history of his '*Nouvelle Theorie*.'" — *Lancet*, July 11th, p. 567.

How does this admission square with the previous assertion? How would it tally therewith, supposing that Mr. Nasmyth had marked the particular passages to be compared, or had himself written any part of the attack in a reviewer's disguise?

But taking his own admission alone, what becomes of his veracity? You, Mr. Editor, who have not, as yet, revealed the share that Mr. Nasmyth took in the attack upon me, or 'discussion,' in your number for June 5, can best judge of this point.

But before Mr. Nasmyth's confession that he was the plotter of, and furnisher of the materials for, the *Lancet*'s attack, I had obtained, through Prof. Phillips, the following information, which threw some light on both 'discussions':—

A few weeks before their simultaneous appearance, Mr. Nasmyth obtained a certain number of private copies of his memoir, then, as now, standing in type, as prepared for the Transactions of the British Association, vol. viii., and he transmits a copy of this modified memoir to the editors of two public journals.

Now, inasmuch as the Council of the British Association, by whose authority alone any part of their forthcoming volume can be anticipated, are not as yet cognizant of the act, those private copies were equivocally obtained.

From the use made of these surreptitious copies, it is evident that Mr.

Nasmyth did obtain and transmit them to the editors of widely circulating medical journals, for the purpose of trumping up a charge of plagiarism against me, by the comparison of certain interpolated passages in his unpublished memoir, with similar passages in a memoir of mine published six months before.

And what say the editors, when the fraudulent representative of the unpublished volume is unmasked? You, sir, transfer the onus of the fraud upon your nameless reviewer. Mr Wakley admits that "had he entertained the most remote idea 'that the eighth volume of the Transactions of the Association' had not yet been published, it should never have been alluded to in the review of my memoir" (Lancet, June 27). But without the aid of the quotations from the suppositions volume, the purpose of the reviewer could not have been carried into effect. If the abstracts of Mr. Nasmyth's memoir, in the Literary Gazette and Athenæum of September last, afforded sufficient grounds for proving plagiarism in my memoir of the December following, why does Mr. Nasmyth wait six months, and then, as soon as he can, by hook or crook, get a private copy of his corrected memoir out of the printing press, commence his double attack in the Lancet and Gazette? Is this delay to be carried to the account of the virtuous forbearance he is in the habit of practising? Perhaps your reviewer, who can perceive really no essential difference between the uncorrected edition of Mr. N.'s memoir in the journals above cited, and the edition which Mr. N. has taken care should be more correct, definite, and precise, in the Transactions of the British Association, will be able to explain the delay.

It is enough for me that I am now in a condition to demonstrate the difference in question, and that to an extent which I could only suspect, while kept in the dark with regard to the volume I was accused of plagiarising from. My letter to Professor Phillips was the first necessary step towards obtaining the required evidence; and I thought the fairest way was to print it. Those who have perused that letter (MED. GAZ. June 19, 1840) will know what confidence to place in a reviewer who finds that in it I "resort at once to angry words and reckless abuse" (L. c. July 3, p. 596). Not to occupy more of your valuable space than is needful for my reply, I think it will be

admitted that Mr. Nasmyth's comments on the equivocal transaction, since its exposure, resolve themselves into these: "I had no occasion to make use of the modified memoir,—it was done for convenience merely: it is essentially the same as the published reports in the Athenæum and Gazette." And when it is shown that these do not answer the purpose, it is replied, "They are *bonâ fide* reports, for which I am not answerable, and contain inaccuracies, especially where they run counter to the theory of ossification of the pulp." I therefore proceed to show, first, the high probability that the Literary Gazette report is *verbatim* Mr. Nasmyth's own account of his views of dental development in August last; secondly, I shall demonstrate in what sense it can be called his own; thirdly, the nature and amount of discrepancies between the old and the new versions of the memoir will be illustrated. And since Mr. Nasmyth, in his letter of June 26th, has written me down "plagiarist," without adducing his proof, I may be allowed, in whatever transaction of his I may establish by adequate evidence, to call it by its right name, and illustrate it by fit examples.

First, let me state that I have received, by direction of the Secretary of the British Association, a proof of Mr. Nasmyth's memoir, now standing in type, as prepared for the eighth volume of the Transactions. In your number for June 19th, I could only state that the passages quoted from the Transactions of the British Association, vol. viii., to prove my plagiarism, not only did not exist in the authorized report in the Literary Gazette and Athenæum, but that it was diametrically opposed in meaning to the only paragraph in which the relation of ivory to the ossified pulp is alluded to in those reports. I inferred, therefore, that, in the new version of Mr. Nasmyth's memoir, containing the statement "that the ivory was neither more nor less than the ossified pulp," all the passages in the old version which either directly deny that fact or imply its negation, or which describe the deposition of ivory upon or its evolution from the formative surface of the pulp, or its formation by a transition of cells lying detached on the pulp's surface, must be suppressed or modified, in order to make the new memoir consistent with my theory and with itself. That this is the case the following examples sufficiently demonstrate. As you possess a private copy of

the corrected memoir, you will be able to vouch for the accuracy of my quotations;

and you will observe that the italics are Mr. Nasmyth's.

Version of August, 1839.

"He hoped, by a few facts, which he thought his investigations had placed beyond doubt, to pave the way for a satisfactory explanation of the formation of dental bone. On the surface of the pulp, he observed, are found innumerable detached cells, with central points."—*Literary Gazette*, Sept. 21, p. 598.

The description of cells with central points, or nuclei, lying on the surface of the pulp, is taken from Schwann. Their detached condition is an idea of Mr. Nasmyth's. How came a closely-packed layer of detached cells to be situated between the thin ossific layer of tooth and the formative surface of the pulp? Were they excreted, or exuded, or evolved from the surface below, or deposited on that surface by the ossific layer above? Perhaps Mr. Nasmyth will explain. I have shewn that these detached nucleated cells are *not* a natural state of things, but the result of a violent abrogation of the relation which subsists between the calcified and uncalcified portions of the pulp of the tooth. My observations and arguments to this effect have not been wholly lost on Mr. Nasmyth; yet he is unwilling quite to abandon Schwann's cells, which he describes as detached. Nevertheless, I affirm, in accordance with my theory of December last, that no part of the ivory of a tooth is at any period due to the calcification or transition of detached cells on the surface of the pulp, and that the restriction of such a condition of the pulp cells to the young tooth at the

Diffuse Memoir of August 1839.

"A comparison between the superincumbent perfect ivory and the formative surface of the pulp beneath is always easy."—*Literary Gazette*, l. c.

The succeeding paragraphs in the old version, descriptive of the deposition of the ivory in thin ossific layers on the surface of the pulp, and the consequent facility of their removal, are omitted.

Uncorrected Memoir, August 1839.

"It appeared to him that the framework of the reticulations or cellules of the pulp is constituted by the fibres of the tooth."—*Literary Gazette*, l. c.

Version of June, 1840.

"He should confine himself to a few facts which he had established, and which he hoped would throw some light on the subject. In the young tooth, he said, at the period of the formation of the first layer of ivory, there are found on the surface of the pulp innumerable detached cells, with central points."—*Unpublished proof.*

period of the formation of the first layer of ivory, although it may bring Mr. Nasmyth's Memoir of June 1840 something nearer to mine of last December, is yet, so far as it goes, as remote from the truth as the statement of August 1839, in which this detached condition of the nucleated cells on the surface of the pulp is applied, without reservation, to teeth of every age, and through the whole period of the formation of the ivory.

When Mr. Nasmyth, following Purkinje and Schwann, instead of nature, described the formative surface of the pulp as presenting a general cellular arrangement, which he illustrates by the simile of skeletons of desiccated leaves, he did not know that he was stating what was the result of artificial and violent laceration, instead of describing a natural formative surface. But, as if some suspicion of this fact had occurred to him in the course of his investigations of my Memoir, he, contrary to the assertion of your reviewer (*l. c.* p. 593), does drop the word "formative" in the following passage in the new or corrected memoir, as I suspected he would.

Concise Memoir of June 1840.

"A comparison of the superincumbent perfect ivory with the surface of the pulp beneath is always easy."—*Unpublished proof.*

(Compare *Lit. Gaz.* p. 598, with the private copy, or proof now standing in type.

The next statement is retained, but altered.

Corrected Memoir, June 1840.

"The fibres of the tooth, as it appeared to Mr. N., are derived from the framework of the reticulations."—*Unpublished proof.*

The unsuspicious reader might not esteem this transposition of cause and effect of much moment; not so, however, Mr. Nasmyth; he has craft enough to perceive that the alteration of this passage is so important for his design upon my theory of dental development, that he prints it, as garbled for that purpose, in italics, at least in the proof of his memoir as it now stands in type, and, I suppose, in the private copies which he has already distributed.

If, in fact, the cellular reticulation which the torn surface of the pulp presents when the superincumbent cap of ivory is displaced were a natural formative surface, and if the ivory were deposited upon it, as all writers preceding me, and among them Mr. Nasmyth, declared, either in the form of thin ossific layers, or spiral fibres, or by the transition of nucleated cells lying detached on the pulp's surface, then the ivory so deposited would impress the plastic surface of the pulp with its characteristic sculpturings or inequalities; and, so deeming, the writer would be correct in saying, as Mr. Nasmyth stated in August last, that the reticulations or the frame-

work of the cellules of the pulp were constituted by the fibres of the tooth. But on the theory of conversion or ossification of pre-existing cells in the pulp's substance the proposition must be reversed, as in the new version.

No one will believe it to be an accidental coincidence that the anonymous reviewer in the *Lancet* (June 6, p. 378), though quoting the paragraph in question from the *Literary Gazette*, and with conviction of his transposition inevitable, whenever the quotation should be compared with the original—I say, no one can believe that this hypothetical personage should, in order to establish a plagiarism for the benefit of Mr. Nasmyth, garble the passage precisely as Mr. Nasmyth, for the same purpose, has himself garbled it in his corrected proof of the forthcoming memoir, and, I suppose, in the private copies.

To prove that the reticular impressions of the (so called) formative surface of the pulp were due to the fibres of the superincumbent ivory, Mr. Nasmyth originally adduced their correspondence in diameter; and the paragraph assumes the following form in the new version:—

Old Version, August 1839.

“It appeared to him that the framework of the reticulations or cellules of the pulp is constituted by the fibres of the tooth, which, while in this state, are spirally coiled, and fit into one another. At all events, the diameter of these fibres of the reticulations is precisely that of the fibres of the ivory.”—*Literary Gazette*, p. 598.

New Version, June 1840.

“The fibres of the tooth, as it appeared to Mr. Nasmyth, are derived from the framework of the reticulations; at any rate, the fibres bounding the reticulations are precisely analogous in diameter and direction to the subsequent fibres of the tooth.”—*Unpublished proof*.

Now, one of the arguments by which I supported my theory of dental development in December last, was the correspondence of the linear series of pre-existing cells in the pulp's substance, *in direction*, with the subsequent tubes of ivory, into which they were converted. The anonymous reviewer in the *Lancet*, of June 6th, whom I take to be Mr. Nasmyth, seemed to think that ‘a correspondence of direction between given parts and those into which they were to be converted,’ and ‘a correspondence of size between certain impressions and the parts producing them,’ were identical propositions. But, in order to insure an agreement between his memoir and mine, Mr. N., now, not only reverses the relation of cause and effect, but also the order of appearance of the parts com-

pared: the fibres of the ivory, now, not only do not constitute the framework of the reticulations, but they are subsequent to them in existence; how they should also be parallel to them in direction, Mr. N. does not explain. According to my observation, the calcigerous tubes of the ivory stand at right angles to the direction of the lines which form the reticulations or cellules which the lacinated surface of the pulp presents. In Mr. Nasmyth's proof, however, as it now stands, and doubtless in the private copies, the writer states that he exhibited in August last at Birmingham, “diagrams in confirmation of this view”!

As to the paragraphs which next follow in the *Literary Gazette* report, and which include the illustrations of Mr. Nasmyth's notions of dental develop-

ment by deposition of thin ossific layers of ivory, or the transition of peripheral layers of detached cells with central points on the pulp's surface, and which illustrations he adduces from the known facts of the laminar decomposition of the mammoth's tusks, and the alternate strata of red and white produced by Hunter's experiments with madder, and which Mr. N. asserts to be a result incompatible with any other theory—as these paragraphs, I say, are too stubborn to be made to tell the new story by any process of transposition and mutilation, they are wholly omitted in the proof now in type: in the published abstract, prepared, despite his quibble, by Mr. N. himself, they occupy one column and a half of the closely printed page of the *Literary Gazette*, l. c. p. 598: thus we have the curious phenomenon of the abstract being longer than the memoir; the part greater than the whole.

I thought my conjecture, in my letter to Professor Phillips, as to the requisite extent of mutilation to produce con-

formity, somewhat hazardous; but the quantity of unsound parts in the original memoir which the author has found it essential to excise, surpasses all anticipation.

From the passage enuntiating the correspondence in size between the detached peripheral cells (cells of the pulp, in Mr. N.'s present proof) and those of the ivory, he proceeds at once to discuss the relation between the formation of ivory and ossification of pulp. All that Mr. N. advances respecting detached cells on the surface of the pulp, and the part these cells play in the formation of ivory, is taken from Schwann; but there were ideas broached in that excellent observer's treatise, which ran counter to Mr. N.'s notions of dental development in August last, and not anticipating the new light that was so suddenly to break in upon him, I find the following amount of correspondence between his paragraph touching the ossified pulp in the memoir of August, 1839, and June, 1840:—

Inconvenient Memoir, August 1839.

Schwann regards the dental substance as the ossified pulp, whilst Mr. N.'s observations lead him to conclude that the cells of the ivory are altogether a distinct formation.—*Literary Gazette*, p. 598.

To render this sudden conversion as decent as possible, Mr. Nasmyth looks about in the original memoir, as printed in the *Literary Gazette*, for the best point from which to jump to the new conclusion, and finds it in the proposition enuntiating the correspondence of size and appearance between the cells of the pulp, previously defined as lying detached on the surface, and the cellular fragments of ivory. And here again the new light is blazoned forth by Mr. N. in italics: he is unwilling to leave the discovery of his last adopted opinion to the chances, perhaps remote, of a regular perusal of his corrected memoir, but with all the tact of a quack advertiser, he takes care it shall catch the eye. But he is hasty: in August last, the cellular ivory was anything but the ossified pulp; now it is neither more nor less. My memoir of December last teaches, however, that the ivory is in some respects more than the ossified pulp, and in others less; and that its formation obeys peculiar laws, which differ from those of ordinary ossification. So that before the

Convenient Memoir, June 1840.*

"He concluded, therefore, *that the ivory is neither more nor less than the ossified pulp, and that it can in nowise be considered as an unorganized body.*—*Unpublished proof.*

new version goes to press, Mr. Nasmyth must again refer to my memoir, and again correct his proof, in order, in the disguise of an anonymous reviewer, to substantiate his charge of plagiarism. In that character, in the face of the review of my *Odontography*, again performed in your 41st number, (July 3d,) Mr. Nasmyth still harps upon the analogy which exists between his memoir, as printed in the *Literary Gazette*, for Sept. 21, and mine of the December following. Formerly he illustrated this analogy in the propositions respecting the organized structure of the teeth, and he has since offered no explanation or excuse for the unprincipled manner in which he misquoted my memoir to establish this analogy. He now cites another example in regard to the internal structure of the pulp. Need your readers be informed that I referred in my memoir to the anatomist Purkinje, to whom we are indebted for our knowledge of the granules

* "It was the most convenient and concise, as well as the only correct document for me to refer to on the subject."—Nasmyth, *Lancet*, July 11th, p. 567.

or cellules of the pulp, and that my business was to show, not the structure of the pulp, but how the pulp was concerned in the formation of the ivory. If Mr. Nasmyth can delude any one into the belief that he discovered either the cells of the ivory or the pulp, then let him represent me to that person as doing Mr. Nasmyth great injustice by not acknowledging him as the discoverer.

Nr. Nasmyth now asserts, "that in his papers, as reported in the Literary Gazette and Athenæum, he described the teeth to be formed by a process of ossific 'transition,' and consequently as not being inorganic in any sense of the word."—(Lancet, July 11th, p. 569.) I never said that he, or any writer like him, had denied the teeth to be organic. My memoir is asserted to be borrowed from those reports of September last, because it treats of the formation of ivory by transition. But the question is, transition of what? Of cells in the pulp's substance, or of cells transuded in layers from the pulp's surface, and lying detached on that surface? Oh! but says Mr. Nasmyth, I never used the word "transuded." Well, then, "evolved" from the surface of the pulp. These detached cells must have been secreted or excreted either from the surface below or the surface above, between which they are said to be detachedly situated. If Mr. N. said "that the cellular fragments found upon the surface of the pulp are in size and appearance perfectly accordant with the cellules of the pulp," he could be supposed to mean no other cellules than those which he had defined in the preceding paragraph. But the transition of detached cells, belonging to the pulp, in no other sense than as being transuded from it, is not ossification of the pulp itself. No; Mr. Nasmyth takes care that the readers of his Memoir of August last should not fall into that mistake; and he, therefore, expressly states, "that the cells of the ivory, instead of being the ossified pulp, are altogether a distinct formation." They were so far distinct in Mr. Nasmyth's mind in August last, that they formed a loose and detached layer on the pulp's surface, and were there converted into ivory; which is nothing more than a combination of Schwann's doctrine of the development of tissues by the metamorphosis of cells, with the old ideas of the transudation of the ivory in thin ossific layers from the surface of the pulp. If Mr. Nasmyth re-

ported in August last, that the ivory was formed by "ossific transition or transformation of the pulp's substance," why does he not settle the matter, and refer to any one passage containing that statement, which your readers might verify in either the Literary Gazette or Athenæum, or in any other work, whence it would have been possible to have borrowed it from him before the December following?

But the reviewer, well knowing the amount of Schwann's treatise which is smuggled into the memoir, which Mr. Nasmyth calls his own, is sure that there must be some correspondence between it and mine, and that injustice must be done to his friend by my passing him over in silence. Besides, Mr. Owen himself calls it an *able* memoir. Granted; but what is the nature of the ability which it displays? Ability to an unexampled extent in the amount of plunder engrafted upon it. Let me, according to my custom, give proof of this assertion.

Mr. Nasmyth, as is generally known, abstracted largely, in 1839, from a work by Schwann published in that year, and which I did not see till the following one. But then he abstracted, I find, only those passages which appeared to favour the ideas of dental development which he entertained in August last. These passages enunciate Schwann's notions of the formation of the cellular ivory by the transition or calcification of cells on the surface of the pulp, and which Mr. Nasmyth defines as detached cells: these by-Nasmyth-plagiarised observations, occupy the whole of page 125, and part of the preceding and succeeding pages of Schwann's "Mikroskopische Untersuchungen Ueber die Uebereinstimmung der Thiere und Pflanzen, 8vo. 1839." In Mr. Nasmyth's memoir of August last the wholesale plunder loads more than a column of the 598th page of the Literary Gazette (Sept. 21.) From the passage beginning with "According to Purkinje," and ending with "and of the dental bone," the report of Mr. Nasmyth's memoir, excepting that where Schwann asserts "Mr. Nasmyth observes," and that where Schwann believes "Mr. Nasmyth presumed," is a coarsely literal translation of the German author; including the only fallacious observations perhaps which could have been picked out of his book. The following are specimens of Mr. Nasmyth's originality:—

Schwann, l. c. p. 125.

"Diese in die Länge gezogenen kugeln sind nun offenbar cylindrische Zellen."

"Da sie auf der anderen Seite doch mit der Zahnschubstanz fester zusammenhängen als mit der Pulpa, und an der ersten hängen bleiben so vermuthet ich, das hier ein Uebergang statt findet."

But if he had observed for himself, instead of plagiarizing from Schwann, Mr. Nasmyth might have escaped this error, the nature and source of which my observation on the development of the shark's teeth enabled me to demonstrate.

Then again, when Schwann admits

Schwann, l. c. p. 126.

"Gegen die ansicht, dass die zahnsubstanz der verknöcherte Theil der Pulpa ist, hat man die leichte Trennbarkeit beider von einander eingeworfen, und ich erkenne das Gewicht dieses Einwurfs wohl an."

It might be here pleaded that the reporter mistook Mr. Nasmyth, and thought he was speaking of his own sense of the force of this objection, when he merely meant to quote Schwann's; but what does Mr. Nasmyth ascribe to himself, after having read my memoir proving the dentine to be in a certain sense the ossified pulp? Why the plagiarism in the MEDICAL GAZETTE (Jan. 3d, 1840, p. 541.) then assumes the following form:—"Gegen die ansicht," is now rendered "Against my theory;" and Mr. Nasmyth makes himself address the Medical Section at Birmingham as follows:—"Against my theory," said Mr. Nasmyth, "that the dental substance is the ossified portion of the pulp, the facility with which the one is separated from the other has been adduced, and he allowed the force of this objection." And then Mr. Nasmyth proceeds, nevertheless, literally to plagiarise the remark which Schwann offers as invalidating the force of this objection, suggested by the well-known fact of the facility with which the ossified separates from the unossified portion of bone-cartilage. Now I had myself invalidated Müller's argument drawn from the slight cohesion of the ivory to the pulp by the same obvious analogy of growing bone, but in other terms, long before I had

Literary Gazette, l. c. p. 598.

"These longitudinally drawn out globules, Mr. Nasmyth observed, are plainly cylindrical cells."—*Also Medical Gaz.*, Jan. 3d, p. 540.

"As they cohere more firmly with the dental substance than with the pulp, and remain attached to the former, Mr. Nasmyth presumed that here a transition takes place."—*Literary Gazette*, p. 598, and *Medical Gazette*, p. 541.

the validity of an objection to the theory of the ossification of the pulp, which I prove to have no weight at all, Mr. Nasmyth likewise, in August last, admits its force in the words of his author, and again with a modified version in January 1840.

Literary Gazette, l. c. p. 598.

"Against the theory that the dental substance is the ossified portion of the pulp, the facility with which the one is separated from the other has been adduced; and he (Mr. N.) allowed the force of that objection."

seen Schwann's excellent work. It is quite natural, therefore, that a dull-witted plagiarist, who never originated an illustration or idea in his life, should set down at once such a coincidence as necessarily standing in the relation of cause and effect; but I am much mistaken, if Mr. Nasmyth, by the time he has reached the end of this letter, does not discover that I am not the man who needs to be indebted to any one for an apt illustration.

And now such of you readers as have not been favoured with a private copy of Mr. Nasmyth's correct memoir, and know it only through Mr. Nasmyth's version, printed entire in the *Literary Gazette* for September 21, 1839, may be curious to learn how he disposes of the closely printed column of consecutive plunder from Schwann, since the new theory in the "*Comptes Rendus*" rendered this acquisition useless and unvendable. Here was a new difficulty; the plagiarized column would not tally with the new views. And what was to be done with this large and important share of the memoir of August 1839, when it came to be converted into the memoir of June 1840, became, doubtless, the subject of anxious cogitation. Mr. Nasmyth might have put a bold face upon the matter, and averred, as he before did in the case of similar difficul-

ties, that it was all a mistake of the careless reporter for the Literary Gazette; and that, instead of Mr. Nasmyth's 'observing' and 'presuming' in the borrowed wisdom of Schwann, at the Medical Section at Birmingham, to the extent of sixty consecutive lines of close print, he was actually quoting and refuting Schwann's paragraphs touching the transition of the superficial cells; but then he must have charged the reporter for the MEDICAL GAZETTE with precisely the same blunder. And, more provoking still, there was the unalterable text of the Literary Gazette ready at all times to prove that Mr. Nasmyth had exaggerated Schwann's doubtful leanings to the true doctrine—ossification of the pulp—in order to refute them.

What, then, was to be done? Why, he quietly drops the column of plunder from Schwann, when he finds it no longer worth keeping; and the new memoir, as it appears in the proof sent to me, is thus shorn of another third of its unfair proportions, as printed, in abstract, in the Lit. Gaz. So now the discovery of the formation of ivory is enunciated in the clearest and briefest terms; and instead of the reader being troubled with any of the inductive processes by which it was established, he is at once put into possession of it by the attractive artifices of type: "*The ivory*," says Mr. N., "*is neither more nor less than the ossified pulp.*"

Acquainted now with the mode in which Mr. Nasmyth's original memoir was fabricated, let us examine the validity of one of the statements which he makes in his recriminatory epistle in your forty-second number. He there disowns the report in the Literary Gazette; if we are to believe him, it is a *bonâ fide* report, subject to the ordinary inaccuracies of such productions. Yet, in sixty consecutive lines of the abstract of Mr. Nasmyth's communication to the Medical Section of the British Association, the supposititious reporter attributes to Mr. Nasmyth, observations, beliefs, and presumptions, without deviating a tittle from the text of Schwann, otherwise than in decorating the daw with his pilfered plumes. And again, either you, Mr. Editor, must have had the services of the same hypothetical reporter, or else we have the marvellous fact of two *bonâ fide* reporters reporting discoveries as narrated by an English soi-

disant discoverer in the accidental form of a literal German translation: for the same page of Dr. Schwann gives occasion to the same observations and presumptions of Mr. Nasmyth in your pp. 540 and 541, of the Gazette for Jan. 3d, 1840, as in p. 598 of the Lit. Gazette.

But if Mr. Nasmyth has thus unscrupulously plundered Schwann, he ought, in consistency, to abuse and damage him as far as he is able. And this he accordingly does, for before the plagiarism begins he informs the Medical Section at Birmingham that "Schwann acknowledges that he is ignorant of the process of transition, and he regards the dental pulp as a simple cartilage. In fact, "he starts with a ready-made hypothesis, and founds his opinion rather on the observations of others, and on the inferences he draws from them, than on his own actual researches: with respect to what he himself gives as his own, it accords for the most part with the details Mr. Nasmyth had first communicated." So poor Schwann is obliged to get even his hypothesis ready made to his hand. Modest plagiarist! your fate has been a just one, to steal whatever was apocryphal, and to reject those ideas of your author, which, if understood, might have conducted you into the right track to the theory of dental development.

But being opposed altogether to the doctrine of ossification of the pulp in August last, Mr. Nasmyth exaggerates every statement of Schwann's which leans towards that doctrine, *in order that he may refute him*. Thus he makes Schwann "regard the dental pulp as a simple cartilage." But, if Mr. Nasmyth had procured the whole of Schwann's treatise to be translated, he must have known this to be a false statement; and your reviewer, so far as he is not Mr. Nasmyth, and who, to that extent, must be presumed to possess the requisite learning for his craft, must know it to be untrue, although he quotes it, at p. 594 of your number for July 3d, as if it were not doing a great injustice to Schwann so to represent his statement. Schwann's word, are "The pulp agrees with all the other organs of the fœtus, and with cartilage, inasmuch as it is cellular. It differs in consistence from mammalian cartilage, inasmuch as the quantity of cyto-blasts (nucleated cells) which gives to cartilage its hardness, is very small, whilst there are numerous cylindrical cells lying

close together upon the surface of the pulp.

Again, Mr. Nasmyth drags Schwann's dubious expression of his inclination towards the ancient doctrine of the tooth being the ossified pulp, from a remote part of Schwann's treatise, converts it into a positive affirmation, and places it in juxta-position with the similarly falsified statement of Schwann's ideas of the relation between the dental pulp and cartilage; whereby the readers of the *Literary Gazette* are led to infer, that Schwann regarded the formation of tooth and bone to be identical processes, which Mr. Nasmyth accordingly refutes and denies, in August last, and now admits and affirms. And your reviewer, to reconcile these discrepancies, assures us (July 3d, p. 596,) that, when Mr. Nasmyth says the cells of the ivory are altogether a distinct formation from the ossified pulp, he means no part of the dental substance at all; and yet the title of his memoir, in the new proof, is, on the cellular structure of the ivory, &c.; and the conclusion to which Mr. Nasmyth arrives at the end of his (?) observations on dental development, is thus recorded by himself in the *Athenæum*, (Sept. 14th, p. 707.) "But in whatever respect," said he, "we view the formative organs of the tooth, and the dental tissues themselves, and whether we examine the latter during the process of their development, or after their formation has been completed, we are every where met by appearances which denote a cellular or reticular arrangement."

The case is this: Mr. Nasmyth, in August last, steals Schwann's account of the nucleated cells on the surface of the pulp, and so much of the theory of their transition into ivory as he can comprehend: he sees these observations only through the distorted medium of his old notions of the deposition of the ivory by successive thin layers upon the formative surface of the pulp; he accordingly makes the superficial cells "detached," and strangely jumbles together the doctrines of transudation and transition. Wherever he finds Schwann verging towards the true theory, that of conversion of the pulp's substance, he gives him a lift. He makes Schwann, *e. g.*, whilst indicating the difference between cartilage and dental pulp, assert their identity: and where Schwann modestly expresses his tendency towards

the ancient doctrine, "Ich möchte mich zu der älteren Ansicht hinneigen, dass die Zahnschubstanz die verknöcherte Pulpa ist," *l. c.*, p. 124, — this Mr. Nasmyth metamorphoses into an asseveration "that the dental substance is the ossified pulp," in order that he may display his superior knowledge, in August last, by its refutation.

The only passages on the development of the teeth attributed to Schwann by Mr. Nasmyth in the *Literary Gazette*, are quoted either to receive Mr. N.'s refutation, or to expose Schwann's ignorance: with regard to the details in which they agree, Mr. Nasmyth asserts that *he first communicated them!* and then Mr. N. proceeds to observe and to presume, for a whole column of closely printed type, in the very words of Schwann. And if he still affirms all this to be the mistake of the reporter, why did he not rectify it, divest himself of the borrowed plumes, and give Schwann his due in the next number of the *Literary Gazette*, instead of perpetrating the same dishonesty towards Schwann, aggravated by the additional spoliation of my memoir, in the *MEDICAL GAZETTE* of the January following?

Had Mr. Nasmyth consulted Nature instead of Schwann, he would have escaped the influence of Schwann's errors, and might have advanced further into the track of truth, instead of retreating from it; and he might have saved himself from the necessity of now tumbling awkwardly into this track, affirming vehemently what he denied a few months before I had demonstrated its truth.

That the dentine or ivory is the ossified pulp, is, as Schwann observes, an old opinion; but an opinion is not a theory. Almost every true theory has been indicated, with various degrees of approximation, before it was finally established: but the best philosophers agree "that he discovers who establishes the true theory." Whether the laws of dental development by centripetal calcification of pre-existing and pre-arranged cells in the substance of the pulp were discovered by Mr. Nasmyth or myself, physiologists will not be slow to discover. I should never have taken up the pen in defence of my right to that discovery, had it not been made the occasion of plotting and aiming at me certain slanderous bolts, which it will

now be seen have fallen wide of their mark, or to have glanced back on the shooter.

So much I have thought it requisite to premise in illustration of the character of the author who has foolishly sought to fasten that suspicion upon me, and of the mode in which his memoir of August last was manufactured. I have, likewise, given sufficient evidence in proof of the same author's tamperings with this same memoir, as he proposes it to appear in the Transactions of the British Association, vol. viii.

How Mr. Nasmyth has managed to anticipate the publication of the Transactions of the Association, at whose expense the memoirs of the contributors are printed, he will have to explain to the Council of the British Association. Such an act, in reference to the publication of either the Geological or Linnean Societies, would be attended with the expulsion of the anticipator, if even the surreptitious forestalling of the information, on the freshness of which the sale of the volume depends, had been motivated only by impatient vanity, and not perpetrated with a view to literary theft and anonymous slander.

It is in vain that Mr. Nasmyth, who referred, without reservation, to the accurate Reports of the Athenæum and Literary Gazette, when they were to establish a charge of plagiarism against another, now repudiates them, when he finds they bring that disgraceful act home to himself. He must be content that his views of dental development, in August last, be gathered from those journals with no other allowance than for such inaccuracies as he may be able to prove to the satisfaction of an impartial person. His assertion, though shouted in italics, will fail in stunning any one into the belief that his memoir "*given in the Transactions of the Association contains no interpolations whatever, nothing which was not contained in the papers themselves.*" Even CAPITALS would not convert the explicit negation of a theory into its emphatic adoption, unless, indeed, Mr. Nasmyth means now to deny that the ivory is cellular, and that cells form any part of its substance.

But it is plain that Mr. N. feels that the verdict of guilty is about to be returned against him, and, like too many unhappy men in the same predicament, he adopts the recriminatory line

of defence. He takes my memoir, as published in the *seventh* (he still harps upon the *eighth*) volume of the Trans. Brit. Association, compares it with the abstract printed in the Athenæum, &c. and discovers that the two differ. He finds that my abstract contains less than the whole of which it was a part; and amongst the additional matter, he seizes upon a specification of certain discoveries of two industrious German investigators, which I had acknowledged only in general terms in the previously published abstracts: he further finds that the special testimony which I bore to the accuracy of the discovery, and the extension of its application, of which no notice appears in the abstract, are mentioned in the memoir. Here's a flagrant case of interpolation, cries Mr. N. See how flagitiously this practice was carried on in 1839, says your reviewer! Strange, that in illustration of the odious system, they should be able to select, out of the additional matter that my memoir in the Transactions may contain, that passage only which illustrates a disposition and purpose the very reverse of those of which Mr. Nasmyth has been convicted: that these two persons, if they be two, should take the trouble to prove that my additional paragraph goes to ascribe to a contemporary the merit of his rightful discovery, instead of to deprive him of it.

I suppose the passage was selected because Mr. Nasmyth thought he had proof that it must have been a subsequent interpolation; and, reckless of the forfeiture of caste and character which follows gross violation of the confidences of social life and gentlemanly intercourse, he prints, without my knowledge or consent, my note dated April 1st, 1839. And what does he gain by it? He is thus able to prove that, as soon as I had it in my power to lend a copy of Purkinjé and Fraenkel's Treatise, I lent it to Mr. Nasmyth. This was, perhaps, an act of folly; but more foolish things have been done, even on the first of April, than rendering a civility to an ill-conditioned and thankless person.

I had studied, Mr. Editor, and was well acquainted with the discoveries of Purkinjé and Fraenkel, more than a year before I had a copy of my own to lend to any body. Your readers will find admirable notices of all their discoveries in dental anatomy in the

Jahresbericht, for 1836, of "Müller's Archiv. für Physiologie, 1837," and in "Froriep's Notizen," both which reached the Library of the College in December, 1837, and which I immediately, as is my custom, perused, extracted therefrom the new points, and went to work to confirm or otherwise by direct observation. With regard to the Thesis itself, I immediately took means to obtain it, and Mr. Nasmyth correctly establishes the date of its arrival. It is a work the interest of which is not exhausted by a first perusal, and I shall frequently, and always with pleasure, look into it again.

But what feeling does Mr. Nasmyth expect to excite in the minds of the unprejudiced readers of your journal by his attempt to recriminate the charge of interpolation upon me, and the kind of evidence which he brings forward in support of it? I give credit to Purkinjé and Fraenkel for a discovery; I lend Mr. Nasmyth their book; he takes advantage of the act to damage my character. He thinks it enables him to prove that I could have known nothing of their discoveries at the time I professed to acknowledge them. But Mr. Nasmyth only proves that when I had a copy of the work to lend, I lent it him.

Where shall we look for a parallel to this attempt to turn a civility into a weapon of attack? It is as if you were to overtake a cripple on the road, and, willing to help him on his journey, lend him your stick, the which he no sooner obtains, than with it he aims at you an impotent blow. But to imagine such a case is almost a libel on human nature. The actual parallel of Mr. Nasmyth's attack can only be found in the inferior species. You may see, *e. g.*, any day at the Zoological Gardens, an ill-favoured red-visaged baboon (*Simia rhesus*, L.); you may distinguish it from its quadrumanous congeners by the pertinacity with which it follows and stretches out its hand to the visitor who may possess an attractive dainty. Wearing by the beast's importunities, and amused, perhaps, by its supplicatory grimaces, he gives it what it wants; but, no sooner is the coveted apple acquired, than the ingrate ape flies at its benefactor, shakes the bars of his prison, and grins and chatters impotent malice with such vehement anger, that bystanders, ignorant of the brute's nature, might suppose that it had received an affront instead of a favour.

"*Simia quam similis turpissima bestia* n...". To finish the simile would be unjust both to the species and the poet, who meant to indicate the ape's resemblance to man in physical conformation only, not in psychical deformity.

But even Mr. Nasmyth seems to think that the additional matter which he quotes from my memoir might be deemed by some to reflect credit rather than disgrace on its author; and he dives again into his escrutoir, to fish out another weapon by which my motive may be assailed: and he prints, through your aid and co-operation, my note of December 11th, 1838.

He is conscious that the additional passage, quoted from the Seventh Vol. of the Transactions of the British Associations, as an instance of flagrant interpolation, simply renders to Purkinjé and Fraenkel the merit due to them for their discovery of the coronal cementum of the human teeth, and establishes their accuracy. Mr. Nasmyth, therefore, proceeds to show that the motive of this act of justice was highly reprehensible. "It can have been no other," writes Mr. N., "than that of appropriating to himself the discovery of the enamel capsule." (*Gazette*, June 26th, page 516).

Does Mr. N., then, mean to tell us that the new organ, his persistent capsule, or enamel-capsule, of which the discovery has been trumpeted forth in such various forms and places, is nothing more than the gelatinous constituent of the cementum of the crown of the human tooth, described by Purkinjé in 1835, and acknowledged long before by comparative anatomists as investing the crown of the teeth of the calf, and of all herbivora? If this be the case, I was deceived by Mr. N.'s description of his discovery in the MS. referred to in my note of Dec. 11th, 1839.

I revised that MS. with much pleasure, looking upon it as the first-fruits of the advice which I had tendered to Mr. Nasmyth five months before, viz. to apply the discoveries of Purkinjé and Retzius to the elucidation of the pathology of the teeth, and I again repeat, as in my note of July 25th, 1838, that it would be "a source of great credit, and a matter of importance, to whoever, practising in the line of dental surgery, should combine these discoveries with the practical or remedial part of the

subject." Now, in the manuscript which I recommended Mr. Nasmyth to present to the Medico-Chirurgical Society, I understood that the author's object was to elucidate the "eruptive stage" of the development of the teeth; I found him stating that he had investigated that stage very attentively, and was convinced that the capsule of all teeth was persistent, and that, instead of being deciduous, it was a membrane whose functions continued throughout life. The influence of this persistent membrane in preserving the enamel, and its relation to decay of the teeth, were then treated of."

This is the note that I took of the new point, as it appeared to me, in Mr. N.'s manuscript; and when the paper was afterwards referred to me to report upon, by the Council of the Medico-Chirurgical Society, I recommended it for publication, on the ground of its relation to dental pathology, and believing that Mr. Nasmyth meant what he wrote. I suggested to Mr. N. the possibility of his being deceived by the process he had adopted to demonstrate the so-called "persistent capsule," and that it might only be Purkinjé's coronal cementum, under another form and title; but my suggestion was not well received. In December 1838, the persistent capsule was, to Mr. Nasmyth, anything but the membranous part of Purkinjé's coronal cementum: his MS. then contained not the slightest allusion to that estimable author, or to his discoveries. As to what Mr. Nasmyth's new organ, or persistent capsule, really was, I thought it his business to satisfy the physiological world. So far as it might be shown to explain pathological phenomena, Mr. Nasmyth's remarks were worthy the attention of the profession; but it was my duty, as a teacher of physiology, to take care that no industrious investigators of dental anatomy should suffer either through Mr. Nasmyth's ignorance of their writings, or his unscrupulous appropriation of their discoveries. *Hinc illæ lachrymæ!* Assuredly the rancour of mortified vanity knows no bounds, as Mr. Nasmyth's attacks, and Mr. Tomes's misrepresentations, testify.

Prompted by recent experience, I perused, the other day, Mr. Nasmyth's memoir, as it appears in the volume of the Medico-Chirurgical Transactions, published in September 1839, and I

compared it with the reports of the same memoir, as read in January 1839, which appeared in the Gazette and Lancet for February 2nd, 1839. Such of your readers as may be disposed to make the same comparison, will find that Mr. Nasmyth has not only profited by the suggestion which I made to him, relative to the probable relationship which his new discovery bore to Purkinjé's coronal cementum of the human tooth, but likewise, and largely also, by my discovery of its presence in the simple teeth of many of the lower mammalia. (See *Trans. Brit. Association*, Vol. vii. p. 136.)

In January 1839, "the author begins by observing that of the three stages into which the period of the growth of the teeth has been divided, namely, the follicular, the saccular, and the eruptive, it is his intention, in the present communication, to allude more particularly to the eruptive stage only. Having been induced to investigate this stage very attentively, he is convinced that the capsule of all teeth is persistent." *Medical Gazette* and (*ipsissimis verbis*) *Lancet*, Feb. 2nd, 1839. And here, by the way, may be observed another instance of curious coincidence in the admiring reporters of Mr. Nasmyth's discoveries. But in the memoir, as printed in the volume of the Medico-Chirurgical Transactions, the author professes a loftier aim: finding that anatomists acknowledged that the crown of the teeth is coated with cementum only in the complex teeth of certain animals, he is led, by the philosophical desire to trace and illustrate the laws of conformity in Nature's works, to demonstrate the existence of the coronal cementum in all.

Now, between the period of the publication of the report of Mr. Nasmyth's paper "On the persistent Nature of the Dental Capsule," in February, and the publication of the memoir in September 1840, there appeared my memoir on the Structure of the Teeth, in the seventh volume of the Transactions of the Brit. Association, in which, at p. 136, after quoting Purkinjé's discovery of the coronal cementum in the human tooth, I confirm it, and show that it likewise exists in the simple teeth of many of the lower mammalia. Mr. Nasmyth's future contribution to any Publishing Society may henceforward be regarded as a "trap" for any discovery that may

fall in between the time of reading his memoir, and the publication of the Transactions, only he must be more chary of his abstracts; for they lead to conviction of the tamperings with the text, which the capture of the discovery necessitates.

In January, Mr. Nasmyth was convinced that the membrane he had discovered was the persistent membranous capsule. In September he says, "It is either a production of the capsule, or the entire capsule itself, or a part of it in a state of atrophy, ossified, and adhering to the enamel by means of the ossific matter deposited in it."—*Med. Chir. Trans.*, p. 313. He thus, in September, begins to make a gradual approach to the truth, and when he has quite arrived at it, he will find that the persistent capsule is neither more nor less than the gelatinous constituent of the coronal cementum, previously discovered in the simple teeth of the mammalia by Purkinjé and myself. Yet this person, since his cognizance of Purkinjé's work, and my Memoir on the Structure of the Teeth, sends to the Hunterian Museum preparations of human and calves' teeth, demonstrating nothing more than the gelatinous constituent of the coronal crusta petrosa, and has the effrontery to inscribe them as the "Enamel Capsule discovered by Alex. Nasmyth."

And now I come to the third of the complaints preferred against me by Mr. Nasmyth, by way of reply to my refutation of his first charges. This complaint is founded upon the facts of my having had temporary possession of a Translation of Retzius' Memoir, which Mr. N. asserts he had previously prepared for the press; of my having disowned any desire or intention of publishing any general observations on the structure of the teeth, *in which I had been anticipated* by the Swedish anatomist; and thirdly, by the fact that I had "published certain new general observations on the structure of the teeth, with practical deductions," though not, I hope, all that I am capable of making, as Mr. N. gratuitously asserts. These three allegations I admit, and have, first, to reply,—that with respect to whatever novelties in dental anatomy I have published, it will be found that the discoveries of Retzius and other anatomists are alluded to with no more detail than was essential to the reader's compre-

hension of the new matter I had to treat of. Secondly, I affirm that I have been in no wise indebted to, or dependent upon, the translation of Retzius, which Mr. Nasmyth lent to me in the course of the summer of 1838; but that I acquired my knowledge of the Swedish anatomist's discoveries, from a study, six months before, of Dr. Creplin's German Translation of Retzius' Treatise, published in Muller's Archiv. for 1837, which reached me early the following year. The translation which Mr. Nasmyth had procured was sent to me, not as prepared for the press, but rough from the hands of a translator evidently ignorant of the subject and of its technical terms: I returned it to its owner, corrected by means of a comparison with the text of Dr. Creplin, and with the proper technical words added.

There are still, however, some odd blunders in it, which would almost justify a suspicion that it had not received the benefit of a zoologist's revision; but these are due to subsequent interpolations of Mr. Nasmyth. Take an example: Mr. N. found in his corrected translation, as returned by me, the Swedish word for alligator rendered *Croc. Lucius*. This seems to have puzzled him, being as much an adept in zoology as Swedish. However, he goes to the Latin Dictionary, and finds *Lucius*, a pike: and with this additional information he proceeds to stultify the amended text in preparing it for press. If your readers will turn to p. 99 of the published translation, vended under the title of Mr. Nasmyth's Researches, &c. they will find Retzius made to say—"The teeth of the *crocodile* and of the *pike* have a covering of enamel on the crown, and a tolerably thick coat of cortical substance on that part which is situated within the alveolus," &c.; and a little further on, at page 104, where Retzius is actually speaking of the *Esoc. Lucius*, Mr. N. says, "In the common *pike*, as in most fishes, are found a number of unequally developed teeth, from the smallest loose points to the teeth immovably fixed to the jaw by a solid osseous base. On none of these could Retzius, by means of the microscope, perceive any covering of enamel."

Now these two contradictory propositions respecting the teeth of the pike are contained in the same sheet (H 2),

which may have passed two or three times through Mr. Nasmyth's hands before it went to press. Yet this obtuse individual seems to have been as little struck with the pleasant inconsistency of a pike's tooth having and not having a covering of enamel on the crown, as your reviewer with that between the statements that the ivory is neither more nor less than the ossified pulp, and that the cells of the ivory are altogether a distinct formation.

By a similar but more reprehensible, because wilful, obtuseness, Mr. N. having recourse again to a confidential note, adduces therefrom *the negation of an intention to publish Retzius's discoveries*, and the facts of my subsequent *publication of discoveries, not Retzius's*, as evidence of a versatile disposition. He converts the expression of an absence of desire to publish observations on the structure of the teeth, previously made by another person, into the denial of an intention of bringing before the public any general observations at all on that subject.

Now, as I have thought it worth my while to notice any of the calumnies of my protean tradueer—for I am not ignorant that I might now, as on other slanders, with the least temporary loss of reputation, have used no other defence than silence and sufferance, and honest deeds set against dishonest words—yet as I have striven to say clearly what might wipe off any blemish which my adversary has sought to leave on my good name, I may again state that, in my published accounts of novelties on the structure or development of the teeth, it will be found that the discoveries of Retzius, and other anatomists, are alluded to with as much brevity and succinctness as was consistent with the intelligibility of the new matter I had to treat of: the translation of Retzius and Purkinjé's General Observations on the Teeth I left to Mr. Nasmyth, than whom no one has profited more by the additional advance in dental physiology, which is due to my own proper investigations and discourses.

But he informs us that he was "naturally vexed, and that not a little," at these contributions of mine; and then, as deluded with respect to his own importance and attractive qualities as ever was the honester Malvolio under the influence of his crossed garters and yellow stockings, he vapours forth "his

indignation that a person, calling himself his friend," should presume to give to the world any novelty in dental anatomy at all. He says he was *naturally vexed*, as though it were in human nature to be otherwise. But when Mr. Nasmyth reveals so much of his nature, he, perhaps, did not think that he might be reminded that, in the human species, the naturalness of the act is according to the nature of the individual, and, in the lower animals, according to the nature of the beast. As, *e. g.* Craft is natural to the fox. To steal precious things is the nature of the daw and magpie. It is natural to the hog to wallow in the mire. To receive a favour, and jabber impotent malice at the donor, is the nature of a baboon.

And so, when a man of science devotes the little leisure and cash he may have to spare to the advancement of dental anatomy, and instead of reserving his discoveries for the benefit of one, publishes them, without eye to profit, for the benefit of all, while other dentists are grateful and applaud the act, to be enviously vexed and indignant is the nature of a Nasmyth.

But Mr. Nasmyth's revelations of his own nature do not stop here: it appears to be likewise natural to him to dissimulate this his envious vexation for a considerable period, and he tells us 'that, nevertheless, he remained silent on the subject, hoping that my interference' with his plagiarisms of better men's discoveries, as they successively came into his 'trap,' would cease.

Here, however, his assertion is as little consistent with the fact, as that of his having taken no part whatever in the simultaneous calumnies aimed at me in the *Lancet* and *Gazette*, for June 5th.

Instead of nursing his no-small wrath* in silence, he hypocritically volunteers upon my 'reports' his fulsome praise, with the reservation that I, like Schwann, had only arrived at the same conclusions, which he had first announced. — (*See 'Researches on the Teeth,' of A. Nasmyth, p. 123.*) Then, again, when, writhing under the exposure of the unprincipled means to which he had resorted, in order to sustain his charge of plagiarism, and regretting that he had exposed himself to that exposure,

* "The appearance of his 'voluminous' reports naturally vexed me not a little."—*Nasmyth, in Gazette, June 26th, p. 549.*

he is not ashamed to own that 'his motive for so doing was very natural.' No doubt; but very disgusting nature, at the same time.

There is one statement of mine that Mr. Nasmyth has thought fit to publish, which I regret to see in print, as I never meant it for the public eye. It is, that I once thought myself a discoverer of the tubular structure of the teeth. As, however, I have represented myself in that light to others, besides Mr. Nasmyth, to whom I exhibited my preparations of the teeth, between the months of May and December, 1837, I will state briefly how I fell into that belief. I received from Mr. Darwin many fragments of the teeth of the *Megatherium*, *Megalonyx*, *Myiodon*, and *Toxodon*, soon after his return from his travels in South America. Some of these fragments were in a state of incipient decomposition. Instead of being resolved, like the fossil mammoth's tusks, into parallel superimposed lamellæ, they separated into fine fibres, running at right angles to the plane of the layers, of which, at that time, it was believed a tooth was composed. I exhibited the most characteristic of these specimens at my lectures on the teeth, at the College of Surgeons, in May, 1837, and stated that the appearances they presented were inexplicable on the (then as I supposed) only known doctrines of dental structure; I said that I should investigate the subject further, and endeavour to reconcile the apparent anomaly before the following session.*

At the conclusion of that course, I had sections of these fragments prepared for the microscope; and stimulated by the amount of clearly defined and beautiful structure which they exhibited, I proceeded to examine similar sections of the human teeth, and of those of many of the lower animals. The excitement of the research became heightened as I advanced, and I had collected extensive materials for a treatise on the general structure of the teeth, when the number of Müller's Archives, containing that part of his 'Jahresbericht' analysing Purkinjé's treatise, came into my hands,

in December, 1837, and awoke me from the fair dream of discovery in which I had been indulging: I soon after received Dr. Creplin's translation of Retzius, upon which I abandoned 'my intention of bringing before the public any of the general observations on the structure of the teeth which I once thought were new, but since found to have been mainly anticipated by Purkinjé and Retzius.' I thenceforward devoted the leisure, which I had to spare for that purpose, to new applications of the principle of the tubular structure of the dentine, to its investigation in animals not before examined, and more especially to researches into the laws of development of the dental tissues, which, as then taught, were greatly at variance with the new views of the structure of the teeth. These researches have been published in the 7th volume of the Transactions of the British Association; in the Proceedings of the Geological and Microscopical Societies; in the Comptes Rendus de l'Académie des Sciences; and in so much as has yet appeared of my Odontography. Mr. Nasmyth asserts that he has anticipated me in the application of the microscopic structure of the teeth to the elucidation of fossil remains; and Mr. Tomes says there is great reason for believing that I got the idea of working at the subject from him and his preparations: I affirm that I was incited to, and did labour in this department of anatomy, long before I had the misfortune to see either of these persons.

With respect to the application of the micrography of the teeth to fossil remains, let me state that, hitherto, the instances on record are as follows:—

The *Basilosaurus* of Harlan has been thus proved to be a cetaceous mammal, not a saurian.

The *Sauropscephalus* has been shown to be, not a saurian, but a sauroïd fish.

The *Megatherium* has been demonstrated to be, as Cuvier contended, more nearly allied to the sloths than, as De Blainville supposed, to the armadillos.

The *Glyptodon* has been proved to be a giant armadillo, and to have the rightful claim to that colossal bony armour which before was placed upon the shoulders of the *Megatherium*.

A character has been elicited, which Agassiz despaired of, whereby the

* In Hunterian lectures, for 1837, I treated of the teeth in their relation to the skeleton; in 1838, as parts of the digestive system, when I detailed fully the discoveries of Purkinjé and Retzius, and my own additional observations; in 1839, I considered the teeth in their analogies with the epidermoid system, and pointed out the characteristic differences in their mode of development, illustrated by diagrams of my observations on the teeth of the fetal shark.

genera *Lepidotus* and *Spharodus*, rarely represented save by detached teeth, precisely similar in outward form, can now be distinguished from each other.

Which of these discoveries will Mr. Nasmyth contend I plagiarised from him? Why, if any thing else had been wanting to fix upon him the authorship of the slanderous review in the *MEDICAL GAZETTE* for June 5th, it was his assertion that he had anticipated me in this application; for the instances of such application still remain hidden in his own breast. No one, save himself, as yet knows of his discoveries in this field.

And now I come to notice two other attacks in your journal, by which it is attempted to divert my attention, and that of your readers, from the vulnerable points of Mr. Nasmyth's.

The first professes to come from a "M.R.C.S. residing at a distance from London," complaining of the miserable state of the arrangement, display, and catalogue, of the Hunterian Museum, which I shall leave to speak for itself: the onus of the charge being, that the distant member was refused access to the microscopic preparations of osseous tissues, &c. with which I had illustrated my lectures. Now as it happens that Mr. Nasmyth is the only person who, upon application to the Museum Committee, to use these specimens, has been refused—such specimens not forming part of the collection, but being my private property—I conclude that the 'distant resident from London,' like the editorial 'we,' and the editorially-discarded reviewer, is but another of the disguises in which Mr. Nasmyth has indulged his natural indignation in raking up malicious slander against me.

But crimes, like diseases, are contagious, and no sooner does Mr. Nasmyth—one set of charges preferred against me being refuted—rake up another from the contents of private letters, than his friend Mr. Tomes, recollecting conversations and events that took place in May 1838, next volunteers his version of them to prove that I have no claim to priority in making known to an English audience, or to English readers, the tubular structure of the teeth.

When Mr. Tomes was introduced to me as a discoverer of this structure, I had been working at the subject eleven months, and the number of preparations which I then possessed exceeded a hundred. Backed by the authorities, who had assured him of the novelty of his observations, I found them very difficult to be convinced of their anticipation by Purkinje and Retzius. He received from me the best information I could give him. I showed him as many of my preparations as my time would allow, especially those of the *Megatherium* and *Acrodus*, which best illustrated the analogy of ivory and bone. It was the interest he expressed at seeing these specimens that induced me to furnish him with fragments of the portions of teeth from which they were prepared. He told me he did not understand the German language; but I shewed him the illustrations appended to Creplin's German Translation of Retzius, in Müller's Archives, and the diagrams I had copied from them to illustrate Retzius's discoveries. This fact it does not suit Mr. Tomes to remember; it would not square with Mr. Nasmyth's assertion that I first became acquainted with Retzius's discoveries through the medium of the translation which he, Mr. N., had prepared for the press. And such are the men whose envious carplings and calumnies my time is to be wasted in refuting.

That mortified vanity should impel a man to revenge himself by deliberate misrepresentation, after the instance of Mr. Nasmyth, needed no further illustration by Mr. Tomes.

It is a very unpleasant task to undeceive a man who comes to you under the delusion that he is a discoverer; it is still more disagreeable when such a person, persisting in his delusion, obtrudes his anticipated observations on the Royal Society, and compels you to reject them; and I can assure Mr. Tomes, whose anger on both accounts appears to have been waiting for a vent since 1838, that to no one can these duties be more painful than to, sir,

Your very obedient servant,

RICHARD OWEN.

ment. WHITE-SWELLING—*Nature, Symp-*
toms, Diagnosis, Treatment, Varieties affect-
ing the several tissues of joints.

PATELLA.

DURING flexion of the leg, the patella tends to lodge itself between the condyles of the femur, and at that time it is not very prominent; extension brings it up higher on the femur, and it is then very prominent. In the first case it is fixed, in the second we can impress upon it lateral movements; in both cases the internal edge is most prominent, because it is thicker: blows directed from within outwards might, therefore, naturally be expected to have more effect in displacing this bone than those in an opposite direction. From these data we may naturally conclude, that dislocations would be as much easier as the leg is more extended, and that dislocations outwards would be most frequent. It has ordinarily occurred by the knee coming violently in contact with some angular body, during running or riding. If the internal border has received the shock, the patella is carried outwards; if the external, it is inclined in the opposite direction. These disloca-

tions are called incomplete; yet, they cannot occur without a violent dragging or destruction of the capsule, which is inserted upon the edges of this bone. Displacement may be carried so far as to place one border anterior, the other posterior; the anterior and posterior surfaces becoming lateral. These dislocations have been flatly denied, and no doubt many so called are not so; thus, in an observation contained in the *Gazette Méd.* 1831, p. 266, it is said that complete dislocation resulted from turning in bed: such a dislocation from such a cause necessarily implies anomaly in the condition of the joint; probably a relaxation of the ligaments, and a want of prominence in the condyles. Luxation of the patella upwards or downwards would imply rupture of the ligamentum patellæ, or that of the rectus of the tendon; and of those rare cases we have already spoken. The characters of incomplete dislocation outwards, which is the ordinary dislocation of the patella, are as follows: what first arrests the attention is the prominence of the external margin of that bone, and that of the internal condyle; between those two points there is a depression, which corresponds to that part of the internal condyle which forms the internal side of the femoral pulley: we feel the tension of the tendon of the rectus and the ligamentum patellæ; the leg is extended, and cannot be flexed. The dislocations inward present the same characters, but in the opposite sense, the principal prominence is formed by the internal border of the patella, the other by the external condyle of the femur; there is the same extension and immobility of the leg as in the former case. Incomplete is less dangerous than complete dislocation of the patella; the laceration of parts is less. Dislocations from external violence are more serious than those produced by muscular action, because they suppose a condition of the joint favourable to displace-

ment; they are consequently less dangerous, but more liable to recurrence.

At the first blush we might be induced to think reduction would be easy, because the bone is subcutaneous, very accessible, and placed upon a glistening surface. It would seem that it was only necessary to press slightly upon its border to effect its reduction; experience has shewn the contrary, and cases are not wanting where surgeons have abandoned the task in despair, or called in more skilful operators. Boyer states that in a case of outward incomplete dislocation, such an accomplished surgeon as Sabatier failed; he called in Boyer, who succeeded, it is true, but after many fruitless attempts. The principles on which reduction should be based are, I apprehend, these: first, it is necessary to relax as far as possible the tendons of the extensors of the thigh, and the ligament of the patella; for this purpose an assistant raises the extended leg, so as to flex the thigh upon the pelvis, and the surgeon presses upon the prominent border of the patella, depressing it, and at the same moment pushing it in a direction opposite to the displacement. Mr. George Young, in such a case, got the foot upon his shoulder; with one hand he pressed down the thigh to make extension as complete as possible; with the ball of the thumb of the other he pressed upon the patella and reduced it.

FIBULA.

Dislocation of the superior extremity of the fibula is regarded rather as a possible accident than as a displacement whose occasional existence has been demonstrated. It is so little moveable, so little exposed to external violence, that dislocation at this point can scarcely happen. It is generally supposed that it can only result from a direct cause, acting forwards or backwards; that it may be easily detected, by a prominence caused anteriorly or posteriorly by the displaced head of the fibula; that the reduction would be easy, since all that would be necessary would be to push the displaced bone in an opposite direction to that which it has taken; that a bandage should be rolled round the part; upon which, if necessary, lotion may be applied. Besides the case mentioned by Gooch, I only recollect a single case in which displacement to any considerable extent had occurred; it was that of a woman received into the Hôtel-Dieu; a wheel had passed obliquely over the upper and outer part of her leg; the ligaments of the articulation of the fibula with the tibia appeared to have been ruptured, and the head of the fibula could be easily moved backwards and forwards; but as soon as it was left to itself it returned to its proper place. It is not un-

likely that in this case the head of the bone had been fairly dislocated, and that reduction had been accomplished, by the resistance of the muscles and aponeuroses, which are attached along the whole length of this bone. So far as it goes this fact would seem to prove that permanent displacement of the superior extremity of this bone is very difficult, if not impossible.

It is generally believed that isolated dislocation of the *inferior extremity* of the fibula cannot happen, because the power of the ligaments which attach it to the tibia is so great that the bone would give way first. Boyer, however, mentions a case in which the foot was dislocated outwards; the fibula pushed by the astragalus gave way upwards and outwards; it was reduced at the same time with the foot. In most cases unquestionably the fibula is fractured; and it is probable that in Boyer's case there was relaxation of the ligaments, to which allusion has been made.

FOOT.

By dislocations of the foot, I mean, in this place, in fact, dislocations in which the relation of the astragalus with the tibia is changed; and they are distinguished, according to the position taken by the superior articular surface of that bone, into *outward, inward, forward, and backward*: thus, it is inward when that surface is directed towards the inner ankle; outwards when it is directed towards the outer ankle; forwards when it is directed towards the toes; and backwards when it inclines towards the tendo-Achillis. There may be at the same time a displacement of its surfaces of articulation with the calcis and the scaphoid bone.

Great as is the strength of this articulation, lateral luxations are not rare; most frequently, however, the direction is inwards; this happens as a consequence of the greater frequency of falls on the internal margin of the foot, and of the action of the peroneal muscles, which during excited action tend to raise the outer, and consequently depress the inner border of the foot. In this case the superior surface of the astragalus being inclined inwards, it projects below the inner ankle; the dorsum of the foot is also inclined in the same direction; its plantar surface is inclined in the opposite direction. The internal lateral ligament, and sometimes those which attach it to the fibula, are replaced; sometimes the fibula is fractured. It may also happen that the internal malleolus pierces the integument and projects externally. The next in frequency is the dislocation outwards; it is produced by causes similar to those we have just considered, but acting in an opposite direction. In this case the astragalus, after having destroyed the three

external lateral ligaments, is placed below the malleolus of the same side; its superior surface inclined outwards; its external downwards; the dorsum of the foot is turned outwards; its plantar surface inwards. Sometimes, as in a case I lately had under my care, there is a separation of the bones of the leg, and the space between the two ankles is much increased. After lateral luxations the next in frequency is the backward variety; it is, however, very rarely seen: it can scarcely be produced by a simple flexion of the foot, however far it may be carried, because the neck of the astragalus tends to arrest this movement by its contact with the anterior margin of the articular extremity of the tibia: it more frequently is produced by a fall from a height on a bank or inclined plane: then the sole of the foot rests on the ground; if one foot supports the shock, the thigh and leg are extended; the line represented by the tibia falls obliquely upon the astragalus, glides in front of its pulley, and the force which represents the weight of the body passes through this line, so that the extremity of the tibia is carried forwards, towards the toes; the astragalus remaining behind or being pushed backwards: it was in this way that Boyer's case was produced. Many cases of incomplete luxation are on record. We had a very well marked case the other day in the Infirmary; and in the opposite bed was a case of dislocation inwards. The dislocation backwards is characterised by elongation of the heel; the extremity of the tendo-Achillis is carried backwards; the anterior part of the foot is sensibly shortened by the projection forward of the inferior extremity of the tibia; in front of the projection is a transverse fold of integuments; there is generally, but not always, immobility of the foot, especially if there be fracture of either malleolus. Dislocation *forward* is extremely rare, if it has been observed at all; in the movements which tend to produce it, there is more commonly dislocation of the astragalus upon the bones of the tarsus; more frequently still, fracture of the malleoli. The accident by which the displacement might be produced is uncommon: a violent extension of the foot, the body falling backwards, whilst the foot is retained by some insurmountable obstacle. Authors state that in this case the anterior part of the foot is elongated; that the extensor tendons of the toes are raised in front of the joint by a hard, rounded, large tumor, formed by the pulley of the astragalus; the foot is immovable, and firmly extended; the heel shortened.

When we consider the great power of the ligaments which attach the astragalus to the tibia, and the support which the

ankles give to the joint, we may readily conclude that dislocations cannot happen without much violence; that they can rarely be simple; that there will be much injury to the soft parts; often much effusion of blood; ruptured ligaments or fractured bones; or wounds communicating externally, with protrusion of the tibia or the astragalus, or both: they must, therefore, be very grave injuries. In the most fortunate cases they leave after them for some time considerable stiffness at the affected joint. In other cases ankylosis is the result; in others the ligaments remain for a long time very feeble, and increase the chances of subsequent displacement. Very frequently the consequences are still more serious; always accompanied by severe pain; quickly followed by considerable tumefaction, and violent inflammatory action, which may quickly determine gangrene of the leg, or occasion deep and extensive abscesses, necrosis, or caries, or exfoliation of fibrous structures about the joint: they may necessitate amputation. Still, as the gravity of the symptoms bears a certain relation to the extent of the displacement and the contusion of the soft parts, and these are almost infinitely varied, it must be evident that complete dislocations may terminate in one or other of the modes I have mentioned. Incomplete dislocations, in which the displacement of bones and the contusion of soft parts are less, differ little in gravity from violent sprains, and they may consequently often be cured with ease and promptitude, and without leaving traces in the joint. Dislocations backwards and forwards, which are usually accompanied by a smaller amount of destruction of parts and displacement, are also more easily cured than those cases where the displacement is lateral. Fracture of the malleoli accompanying dislocation, when not comminuted, is not always a circumstance of much aggravation; indeed it is a matter of observation, that many persons, in whom this is the only complication, often do well. Destruction of the integuments and protrusion of the tibia constitute the worst kind of complication. It is particularly in those cases that gangrene is rapidly developed, and the patients die before it is limited by a line of inflammation, and amputation itself often fails; yet wounds with protrusion of bone are not always so grave or so fatal: many examples of cure in such cases are on record.

Treatment.—Reduction of these dislocations, when lateral, is usually easily accomplished: the patient is placed on a bed; the leg, flexed on the thigh, is grasped by a strong assistant; another seizes the foot, as if about to make extension in the fractured leg; he draws the foot in the

direction of the displacement: as soon as he feels the resistance vanquished, and the bones disengaged, he brings the foot into a proper position by adducting it if the dislocation be inwards; abducting, if it be outwards; by bringing it forwards, and flexing it, when it is backwards; by extending and carrying it backwards, when it is forwards. The surgeon, during this time, is on the outside of the leg: with one hand he grasps the small of the leg; with the other the foot, and assists in giving the right direction to the efforts of reduction.

When displacement is forwards or backwards, the difficulties of reduction are sometimes insurmountable. These difficulties are probably owing to the resistance of the lateral ligaments, when they are not ruptured. It is easy to understand that, after having yielded, by elongation, to the force which has displaced the astragalus, they may relapse into something like their former state when the astragalus has passed forward or backward; so that to reduce it it is necessary to elongate them anew: this can only be effected by using a force equal to that which has originally determined the displacement, and can scarcely ever be accomplished.

If we are so fortunate as to reduce the dislocation, we place the limb in the most perfect repose—generally in a fracture apparatus; we carefully prevent any motion at the part, and we use the necessary means to prevent or repress inflammatory action. Those means, if the patient be in good health, are, large local and general bleeding, nauseating doses of antimony, and cold: purgatives have the inconvenience of rendering movement necessary. The other means must be proportioned to the necessities of the case. I have known a case so urgent as to require sixty leeches at once, besides a general bleeding to the extent of thirty ounces; but, in the worst case I ever saw, a case of dislocation, with fracture and protrusion, the patient refused to submit to amputation: thirty leeches only were applied; they were immediately followed by cold water compresses, which, through the affection of a sister, were renewed every ten minutes for twenty-four hours, and the inflammation never exceeded what was necessary for the purpose of reparation. When the dislocation is complicated with fracture of the malleoli, after reduction, it is always prudent to place the limb in a fracture apparatus: if, when there is protrusion, the contraction of the lips of the wound be great enough to prevent the reduction of the protruded bone, the wound should be dilated; and if this do not suffice, the end of the bone should be sawed off, if there be fair ground for believing that the injury can be repaired;

if not, immediate amputation should be practised.

ASTRAGALUS.

The connections of the astragalus with all the bones with which it articulates may be ruptured; but it is a rare occurrence. It occurs under circumstances similar to those we have just considered as destroying its relations with the bones of the leg. It is easily discovered by the projection of the astragalus under the integument. It is most frequently caused by violent extension of the foot, with an inclination inwards or outwards. In Sir A. Cooper's case, and in others, the integument has given way, and the bone protruded; but, as I mentioned some years ago, it may occur under exaggerated flexion; the two cases I then published are evidence of this fact. In one of those cases the patient jumped from his carriage upon the side of a bank, and fell forward; in the other, the patient was fielding in cricket; he was running after the ball, when the heel was jammed into a gutter, and he fell forward. In both cases the astragalus was pushed back from between the tibia and calcis, so as to cause the tendo-Achillis to describe an angle of between forty and fifty degrees.

Those dislocations of the astragalus are a consequence of so much violence, that much inflammatory action might be expected. Reduction should usually be attempted; but it will rarely succeed. If any fibrous or ligamentary tissues seem to prevent the return of the bone, it has been recommended that they should be incised. In some cases a portion, in others the whole of the bone, has been extracted successfully. In my cases reduction was impossible; but, as there was no protrusion, I did not think it prudent to cut down upon and extract the bone: the inflammatory action developed at the part was not great, and the lameness was not, after some months, very obvious: the tibia rested upon the calcis, and a joint was formed between them.

TARSUS.

Heavy weights falling on the tarsus have, in a few cases, occasioned displacement of certain of these bones; they have changed the relation of the calcis with the astragalus, and with the cuboides and naviculars in front.

Sir A. Cooper has seen dislocations of the internal cuneiform bone, the head of the bone naturally articulating with the naviculars, projecting inwards and upwards, drawn in that direction he conceived by the tibialis anticus muscle. Reduction was not accomplished, and there was very trifling lameness. He advises that the bone should be confined

by a strap passed around the tarsus. In such cases the injury of the soft parts is usually the most serious part of the accident.

METATARSUS.

The metatarsal may be dislocated upon the tarsal bones. I am aware this has been denied by all authors who have written specially upon the subject of luxation. It has been regarded as impossible, in consequence of the extent of the articular surfaces, the strength of their ligaments, and the little motion of which they are susceptible; yet there are several cases on record.

To conceive how it happens, we must examine what passes when we walk upon the toes, or the front of the foot. The centre of gravity is then in the tarso-metatarsal articulation; this is found between two diametrically opposite powers; the one, the weight of the body, tending to depress the tarsus; the other, the resistance of the soil, tending to raise the metatarsal bones. The foot being in this condition, any thing tending to increase the force bearing upon the already tense ligaments, such a displacement may occur; the tarsus is pressed down, the metatarsus up, and the latter is dislocated upwards. Dupuytren alone saw two cases; a third is contained in the Bulletin of the Société Anatomique. Dupuytren's first case was that of a woman carrying a heavy burden: she stumbled forward, so that the foot supported the whole weight of the body. At that moment, to prevent a fall, the body was brought forward on that foot in which the displacement occurred. The leg was flexed, the heel strongly raised, and maintained in that position by the contraction of the muscles of the calf, so that the weight of the body was supported by the anterior half of the foot. In his second case, the accident happened to a young man, in a state of intoxication, who jumped into a ditch twelve feet deep: he fell on the point of the feet, and dislocated both metatarsi at the same time. Mazet's case was also a young man: he died, and, upon dissection, it appeared that there was dislocation of all the metatarsal bones.

It does not seem to have been difficult to distinguish this accident. The foot is shortened by the riding of the bones, the metatarsal bones are very prominent under the integument of the dorsum of the foot, and the arch of the foot is almost destroyed by the depression of the tarsus.

If recent, this accident is not attended with very serious consequences; the reduction is not difficult; but, if left to itself for a few days, reduction may become impossible.

Treatment.—In proceeding to reduction, the leg should be flexed and firmly fixed: extension is then to be made by fixing our apparatus on the metatarsus: the surgeon then grasps the foot, brings his thumbs to bear upon the extremities of the bones, and pushes upon them, so as to assist in their disengagement. As soon as the reduction is accomplished, the part should be rolled, and cold lotions applied, and perfect rest at the part maintained for five or six weeks.

The toes are too well protected to be luxated, except under very extraordinary circumstances; and if it happen, it presents the same characters, and requires similar treatment to that of the fingers.

We must now proceed to consider in succession, wounds of joints, inflammation generally, and particularly as affecting the hip and the knee-joints, and ankylosis and loose cartilages.

WOUNDS OF JOINTS.

Wounds of joints may be contused, incised, or lacerated; may be penetrating or non-penetrating.

So long as the wound does not directly implicate the tissues of the joint, it should be treated much like a wound elsewhere; still, as tissues around a joint do not quickly take on inflammatory action, it often ends in suppuration when they do. The form and mobility of joints oppose difficulties to the proper application of bandages, and there is, therefore, greater probability of the lips of the wound not being kept in apposition.

Penetrating wounds are very serious injuries; ginglymoidal articulations being more superficial than orbicular, are more frequently the seat of these injuries. In many species of occupation, the ankle and knee joint are particularly exposed; among ship-carpenters, who place under their foot the piece of wood they are shaping with the adze, the ankle joint frequently suffers; among vine dressers the knee joint is often wounded. Whatever the joint which has suffered, the danger depends upon the intensity or kind of the inflammation which is developed. This inflammation is sometimes very violent, and reasons for this have not been wanting. The ancients, who were impressed with the great danger of wounding tendons and aponeuroses, were impressed with the idea that the injury to those tissues around a joint completely accounted for the occasional violence of the symptoms. The resistance offered by those tissues, and the violence necessary to overcome it, is another and probably a better reason. The action of atmospheric air upon the tissues of the joint was regarded by Monro, Thomson, Bell, and others, as the sole reasons for the

symptoms. Others have attributed them to the action of air and the contact of the dressing, which, probably, is nearer the truth than any of the others; but it is a matter of question whether air alone can exercise a very deleterious influence upon articular or synovial surfaces in a healthy state. When we amputate at the tarsus, at the knee, the shoulder, or the hip-joint, we do not find such serious symptoms developed; but if we open a joint in which there is an accumulation of synovial or purulent fluid, and maintain the communication, a certain quantity of inflammatory action is certainly developed. The fluid is altered, it is in direct contact with the almost inert surfaces of the cartilage on the one hand, and on the other with the coverings of the joint, which inflame, and acute symptoms are manifested. Certain it is, we may open a joint many times to remove a loose cartilage, without exciting inflammatory action; it is equally certain that when a joint is distended by synovia or pus, we cannot open it with the same impunity. We may perforate the pleura of a healthy animal twenty times, and, probably, pleuritis will not be developed in one, but previously inflame the pleura, in a single case, and when pleuritis is developed, make a similar perforation, and the chances are suffocation will follow in a few hours. I believe, therefore, that the action of atmospheric air is to be feared only when the tissues are already inflamed, or when a fluid which has undergone change is found in the joint.

Symptoms.—The first symptoms of penetrating wounds are often not different from those of ordinary wounds; the wound not being extensive, and the patient being unable to appreciate the importance of the escape of synovia, he uses the limb in fatal security. During the first two or three days there is nothing to alarm; but pass this period, in three, four, or six days after, symptoms are manifested which shew the gravity of the injury: there is itching about the wound, there is stiffness and some tumefaction, the edges are tumid, and a reddish serum escapes in considerable quantity: these symptoms may yield, if arthritis be not developed; but if inflammation set in, the pulse becomes strong, the skin hot, the face injected, the tongue white, with thirst, loss of appetite, and sleeplessness, if the joint be large; if it be small, the symptoms creep on in a more insidious manner, and gradually extend to contiguous structures, and often give rise to numerous abscesses, before attention has been directed to the mischief. Besides these consequences, contused or lacerated wounds of small joints are occasionally followed by tetanic symptoms: this is the general experience of military

surgeons. In the larger joints, when the symptoms of arthritis are set up, the patient keeps his bed, his limb is semi-flexed, the joint tumid, the colour of the skin covering it is often unchanged, though tense and glistening; the pain becomes more acute, increasing in proportion to the intensity of the inflammation, becoming more aggravated as it extends to the ligamentary and fibro-cartilaginous tissues. Often it extends beyond the joint, especially upwards; abscesses are formed so insidiously that until fluctuation is apparent they are often hardly suspected. It is singular, in many cases these abscesses are developed about the middle of the limb, apparently without direct connection with the joint, unless in some cases where the distended capsule has given way. Usually these abscesses are formed in the subcutaneous tissues and muscular interstices, and then the pus burrows with great facility.

Diagnosis.—The diagnosis of these wounds is usually easy; their situation, the tissues divided, the fluid which escapes, and the appearance of the parts, are usually sufficient to lead us to a right conclusion. In punctured wounds difficulties will arise; it is true these difficulties may be removed by the introduction of a probe, but as a probe may cause serious injury, it should not be wantonly used. If the wound be large the edges may be separated, so as to see the cartilages. The escape of synovia is an important circumstance, but it cannot be considered as pathognomonic, because it may follow the wound of a tendinous sheath, the joint itself being uninjured, or it may be so little, or so mixed with other fluids, as not to be recognized; and in a large wound, after twenty-four hours, inflammation would work a great change in its characters.

It is singular how long a tendency there seems to be, apparently from a kind of sympathy, when there is supuration at one point, to repeat a similar action in others, or even in serous sacs: how this happens I cannot tell; I merely record the fact.

Prognosis.—Formerly all wounds of joints were regarded with great apprehension, and unquestionably in most cases they are very serious injuries, but less fatal than our predecessors seemed to think. John Bell and Ledran stated that an opening made into a joint in a state of suppuration was necessarily mortal. If, instead of saying so, they had contented themselves with stating that complete cure was improbable, they would have been nearer the truth; for there would be no difficulty in mentioning a great number of cases of every variety of wounds of joints which have done well; and unquestionably, in many cases of great distention of joints from purulent or other collections, instant relief

may be obtained from a puncture or incision judiciously made. But we must inquire further; what we want to know is, when a joint, such as the knee, suppurates in consequence of a wound, what is likely to happen? I apprehend death almost inevitably, unless the limb be removed, and as a rule even in smaller joints.

The inflammation succeeding to a wound of a joint being the type of the *anatomical changes* produced by these from other causes, I shall here point them out. If the patient die soon after a joint is wounded, the only appreciable alteration is in the fluid contained in the joint; it is turbid, serous, and yellowish. If examined at a later period the internal synovial surface loses its polish; it is rough, and covered by a fibrino-albuminous coating; at a still later period, the synovial membrane may be thickened, the subjacent cellular tissue may be infiltrated, the contained fluid may be puriform, and, at a later period, purulent; the synovial membrane no longer retains the character of a serous tissue, but is more like a mucous surface streaked with blood; the cartilages may be thinned, softened, or destroyed; the ligaments lose their colour and consistency; the bones may be carious.

Treatment.—Inflammation of synovial surfaces being so serious, what should we do to prevent it? If the wound be simple, endeavour to heal it as quickly as possible, taking care that the position is easy, and the rest absolute. When the wound is brought together, some surgeons use bandages moistened with white of egg, to secure the exclusion of air. If the wound be irregular, contused, or lacerated, this may be impracticable, and we must then leave much to nature, arranging the position and apparatus so that the fluids which are secreted may find a ready exit. It may become necessary to moderate inflammatory action at the part; and for this purpose Schmucker thought there was no agent possessed of such efficacy as water. It is said that of sixty soldiers treated in this manner in 1792, at the convent of Cousarrebrouck, only four died, whilst in the French camp, of those similarly wounded, nearly all died. I have no doubt of its value, but I have already, more than once, stated my objections to it. The greater number of surgeons prefer local and general bleeding, with or without cold, with or without emeto-purgatives and rigid diet. Dorsey and Fleury liken synovial to pleural inflammation, and think repeated blistering upon the wound itself, or the point most acutely inflamed, the best mode of treatment. We have not had enough of experience of its results, in acute inflammations of joints,

to speak confidently on the subject, but as far as that experience goes, it is a most valuable agent. In Rust's Magazine is a proposition by Schrager, which consists in applying upon the wound nitric acid "to prevent morbid secretion." He mentions two cases of cure, which I fancy might have got well without it. In cases where the inflammation is not arrested, the tumefaction being considerable, and the pain great, it may be necessary to make warm emollient or narcotic applications to the part. If suppuration supervene, the communication with the exterior not being such as to allow of the escape of the purulent fluid, the fluctuation being evident and the distension distressing, it is proper to make an opening at as many points as collections of pus may be found: this is done to prevent the possibility of altered pus being pent up. It will be necessary to watch carefully the position of the limb, which the patient will always seek to flex, as a position which gives ease; motion should be absolutely prevented, and light warm emollient applications are then most comfortable. If the limb be much infiltrated, light equable bandaging will be proper, and the patient's strength must be kept up against the exhausting effects of suppuration.

ARTHRITIS.

Acute inflammation of joints, other than those produced by wounds, by gout, and rheumatism, we are also called upon to treat. It may be occasioned by blows, fractures, necrosis, sprains, dislocations, or other violence; by foreign bodies in the joints, by the action of cold, and by many other causes, such as gonorrhœa, parturition, or catheterism; but in these cases, when the inflammation is acute, the synovial apparatus is usually affected. The *symptoms* are very similar to those caused by wounds, and therefore it is unnecessary to recapitulate them here. In some cases the disease has been excessively painful, and has ended in gangrene. (Velpeau.)

When it occurs in persons suffering from gonorrhœa it is less painful, but it is sometimes developed with extreme rapidity; it has occasionally been seen in women after the use of astringent vaginal injections; in either case it often disappears quite as suddenly. It may, however, persist, becoming chronic, and ending in white swelling.

As a consequence of child-bearing, this affection is generally not very painful, neither does it light up severe general reaction; it may be developed quite as suddenly as that from gonorrhœa. Though it usually terminates favourably, it may,

like that from gonorrhoea, end in white swelling.

I know of five cases of arthritis following upon catheterism: of these two died, one recovered, but with ankylosis, the other two recovered, but after long suffering. In one, fever was developed after each attempt to introduce a bougie. The means which I have known to succeed best in gonorrhœal arthritis, are, cubebæ in large doses, compression, blisters, and purgatives; after, blood-letting and bathing. In these two varieties, mercurial and opium frictions have succeeded well, together with alterative doses of calomel.

WHITE SWELLING.

When a disease is manifested under a variety of circumstances and forms, it is not less difficult to assign to it a name to which an exact idea may be attached, than to give a general description which may include particular cases; such is the disease familiarly known as *white swelling*. This term has been applied to a particular form of articular inflammation, where the skin more or less perfectly retains its natural colour, and presents no evident external marks of inflammation. Under this term, the idea of chronic or subacute inflammation of joints, without change of colour in the skin, but with sensible tumefaction, is conveyed. The tumor may be hard and resistant, elastic, yielding or fluctuating, with or without effused fluid, sometimes indolent, but often painful, especially when moved. This inflammatory action may affect, at the same time, all, or severally, the tissues of a joint. Now it must be evident to all who have seen these affections that the simple enumeration of the principal symptoms is utterly insufficient to give any exact idea of a disease which presents so many and such varied differences, that scarcely are two patients presented in whom the progress of the disease is exactly similar.

Inflammatory action of joints is generally preceded by pain, varying in character and seat, sometimes limited to a point, sometimes extending to the whole joint, or beyond it; in other cases the affection is developed before any pain is felt. Where the cause is general, the disease is often manifested at night; it is not rare to see a person who went to bed well, awake in the morning with pain in the knee, and sometimes tumefaction. The tumor rarely extends to the whole joint; is almost always limited to a part: at the knee it is usually first perceived above the patella, and on either side of the ligamentum patellæ. This tumor is circumscribed, more or less hard and elastic, not retaining the print of the finger; giving sometimes a

sense of puffiness, at others of fluctuation. It is more or less painful on compression, but it is sometimes indolent; the temperature is not much increased, nor the colour of the skin changed; motion is impaired, and not accomplished without more or less severe pain. The position given to the limb is usually one of flexion, and extension cannot be made without much suffering. This constant flexion of the limb produces a state of fixed contraction in the flexors, and, in a comparatively short time, the joint becomes rigid and immovable. In this condition the joint may remain for some time, may even cease to be painful; but commonly the disease continues its onward course, with occasional exacerbations and remissions; it may, indeed, seem suspended for weeks, or months, and then, from a blow, or even without external cause, it continues its progress. The tumefaction increases, the pain is more severe at some particular point, is worse towards evening, when the temperature is variable, or when the limb is moved; but the extent of suffering is very changeable. The consistency of the tumor varies, generally it is as much greater as it is more advanced, but recent ones are sometimes very hard: this depends much upon the seat of the affection. The skin becomes paler, more glistening and thinner, the subcutaneous veins dilate, the muscles fall away; neighbouring lymphatic glands may be tumefied; the bones, when the disease is advanced, are softened and carious; the articular cartilages are destroyed, abscesses are formed, and are accompanied by much pain and fever; they may communicate with the joint, may open, or be opened externally, and an ill-elaborated sero-purulent, yellowish, whey-like, flocculent fluid, is poured out; sometimes its consistence is more like that of laudable pus, but it soon degenerates into a thin fetid sanious fluid. The escape of this fluid rarely makes any material change in the bulk of the tumor; sometimes the openings at one point are suddenly closed, and almost as soon produced in another; but usually all these openings remain fistulous.

Until the disease arrives at a certain stage, the general health does not materially suffer; then the suffering is occasioned partly by the severity of the pain, preventing sleep, and destroying appetite, and, probably, partly by the absorption of purulent matter into the economy; but it is after the abscess has opened that the general health principally suffers; then there is often developed low fever, night sweats, diarrhoea, and, unless amputation be performed, death.

If we examine the joint after death or

amputation, we see, In some cases, that the disease was primarily external to the joint, but that in its progress it extended to the cartilages and bones; in others that the extremities of the bones were tumid and softened, and that the disease had extended to the ligaments, and the other soft parts, at a later period. In those cases in which the disease has commenced external to the joint, if the limb be examined before the joint itself has suffered, the cellular tissue is infiltrated, spongy, and soft; but the skin may not participate in the disease: in some cases the tissues appear greatly thickened and indurated. In the midst of this mass purulent points may often be seen. At this time the synovial membrane may not have suffered, neither may the quantity of synovia have increased; in some cases, however, it may have increased in the knee joint, so as to press the patella forwards;—I recollect a case where it amounted to twenty ounces.—The bones and cartilages may remain unchanged; but if the disease have proceeded further, the bones may be tumid, yellowish, softened, and easily cut with a scalpel. If still farther advanced, a quantity of sanious matter may be found in the joint; the arthrodial cartilages may be softened or partially destroyed; the bones may be carious, and partially broken down.

In those cases where the bony structure has been principally and primarily affected, wherever we examine the joint we find their spongy extremities tumid, yellowish, softened, and easily cut into. At first, the soft parts are little altered, but at a more advanced period the ligaments and the cellular tissue are infiltrated with a viscous glairy matter. The bone itself is swelled, softened, carious, and here and there reduced into a sanious foetid matter, sometimes without the occurrence of any change in the cartilages.

Characters.—The characters of white swelling are sufficiently marked to enable us to distinguish between it and other diseases of joints; but when such a tumor is presented it is not so easy to determine the cause, which is of much importance in determining the treatment. To a certain extent it is sometimes possible, at an early period of the disease, to determine, not only the cause, but the tissue affected; but the shades of distinction are often very faint. The pain, swelling, and difficulty of movement, are characteristic; *dropsy* of the joint is sufficiently marked by the quantity of effusion, and the absence of pain and inflammation of the soft parts. If the inflammation be external to the joint, the pain is superficial, and motion of the joint does not increase suffering in proportion to the apparent intensity of the disease, and fever is usually absent. When

it is primarily seated in the hard parts, pain is singularly exasperated by any rubbing of the articular surfaces. This symptom coinciding with effusion, and moderate tumefaction, the external tissues still being susceptible of movement, and supporting pressure, enable us usually to affirm that the deep structures are affected. Great heat; prompt re-action; pain and tumefaction comprehending the entire joint; prominent points corresponding to intervals between ligaments, denote primary inflammation of the synovial apparatus. Where the disease occurs during the existence of the sequelæ of a *gonorrhœa*, it may begin with rigors and fever, but it is distinguished by its sudden development, and the bulk, without proportional redness, which it attains. Thus the absence of external violence, joined to those peculiarities, readily induces a suspicion of the cause. When it succeeds to child-bearing its progress is similar to the above, so that at first sight a differential diagnosis is not easily made out. The doughy feel; the apparent bulk of the heads of the bones, compared with the duration of the disease; the obscure fluctuation, and the regular form of the tumor, together with the absence of decided re-action, usually prevent mistake.

Prognosis.—Where the inflammation is external to the joint, and is properly treated, it usually ends favourably: where it is deep seated, but has extended to the joint, it is much less serious than where the inflammation primarily attacks the joint, and affecting a tolerably healthy person will often yield to appropriate means of treatment. That which succeeds to a penetrating wound too commonly ends at best in suppuration and ankylosis: in the other cases we are fortunate if we see discharges lessening and general irritation subsiding, so as to afford a chance of ankylosis, or an opportunity of excision of the joint or amputation of the limb: if this do not happen the patient lingers; new openings are formed; pus burrows above and below the joint; colliquative diarrhœas, with purulent infection, comes on, and death is not distant. That form of disease which commences with the bone or hard parts is generally chronic, but is not on that account, in many cases, less grave, though it leaves amputation as a resource. It is seldom that the gonorrhœal affection does not yield to well directed means; the same may be said of that which succeeds to child bearing. Nothing can exceed the danger of this affection when it arises under the influence of purulent infection; the cases of recovery are then extremely rare.

Treatment.—Over this formidable disease therapeutical agents exhibit little power; still that is no reason why it should be

abandoned. Local and general blood letting are only indicated when there is much pain and local reaction. In taking blood locally, Severinus thought the best plan was to open one or more of the distended varicose subcutaneous veins at the part. Some French surgeons of the present day follow the example, and speak highly of the results; others, such as Gama, apply a large number of leeches on the part. In England we are more disposed to use cupping as a surer means of attaining our object, and lessening the chances of erysipelas. If there be still much pain, it may be relieved in some cases by refrigerants; in others by warm fomentations or poultices. After the more direct antiphlogistics, pressure and counter irritation are often employed. In 1814, Balfour published a number of cases strongly favouring the efficacy of compression, but not sufficiently indicating the cases in which it should be employed. In 1827, Varlez, a Belgian surgeon, published many very painful cases of articular inflammation, in which the benefit derived from compression was very striking. The application of compression must be cautiously made, and this has not been found easy; probably it may be better applied in the shape of a starch bandage than by any other means: in this term Sentin has used it with great advantage. All these practitioners agree in one point, that it should not be used when the bone is principally affected. Refrigerants, emollients, bleeding, and compression failing, blisters have been much used, and, in my experience, with the best success. I think it is wrong to limit their use to purely chronic cases, and to blame so absolutely their employment in acute cases. I have seen the best effects to follow the use of large blisters in acute cases. *Mercurial* frictions have been strongly recommended by Bell and others; but I doubt their efficacy, except in cases of induration of the soft parts; and then probably Grosvenor's plan would succeed as well as mercury. The same may be said of iodine. Issues, moxas, and setons, are often very useful when the disease is deep-seated and indolent. The actual cautery was the remedy *par excellence* of Severinus; it is that of Rust and many others. Its effects vary with the mode of its application. If it be applied to make a large slough, it is less efficacious than caustic. If it be lightly passed over the joint in all directions every third day, the beneficial effects are sometimes very remarkable. Richerand recommended that the joint should be covered by silk plaister, so as to keep up around the part a continual bath. O'Beirn strongly advises that the system should be affected by mercury; and he has published many cases to illustrate the prompt efficacy of this

treatment. He administered calomel to the extent of ten, fifteen, twenty, or twenty-four grains a day, associated with from one to four grains of opium. The cases in which I have seen it used have not inspired me with confidence in its favour: where disorganization has commenced, but the inflammatory action has not ended in structural change, I dare say it may do what many other remedies will do as well.

When suppuration is developed, and the capsule is distended, should we open the joint? That depends on many circumstances. If distension excite great irritation, the course is clear; it must be done. The opening can do nothing worse than what already exists; and sometimes the irritation ceases as if by enchantment. If the reaction be confined to the joint, we should pause. In allowing the air to penetrate, we run the risk of exciting symptoms which we should wish to avoid. If the fluid be not absorbed, and the change of surfaces be manifest, amputation is the resource. Some people, in case of opening, when the joint is distended with pus, recommend that it should be small; such was the opinion of Petit; but the recommendation of David is the one to follow; open at any and every point where there is chance of pus lodging: this is the only means of neutralizing the deleterious effects of atmospheric air.

The different parts which enter into the composition of a joint are more or less intimately united together, so that when one becomes diseased the chances of another suffering are very great. In every joint we distinguish ligaments, synovial membrane, cartilages, and spongy extremities of bones. These different parts may be primarily and separately inflamed, and the disease may afterwards be extended to the others; and these circumstances cannot be viewed with indifference, because inflammation affecting the synovial membrane is different to that which principally affects the ligaments or the more external tissues.

If we admit that any of the tissues of the joint may be separately inflamed, do the symptoms enable us to distinguish the particular tissue affected? In some cases, at an early stage, it is possible; but, in the majority of cases, it cannot be done, because more than one tissue is suffering at the same time. Sir B. Brodie's work on Diseases of the Joints is the ablest in any language, and has done much to simplify the diagnosis, and, to his clear sight, the distinctions may be sufficient; but for you, gentlemen, I fear they will prove insufficient: however, it is my duty to give you the benefit of his great experience.

OBSERVATIONS

ON

THE VARIOLÆ VACCINÆ*.

By ROBERT CEELY, Esq.

Surgeon to the Buckinghamshire Infirmary.

THE *variolæ vaccinæ* seem to have been long known in the Vale of Aylesbury and its neighbourhood. They have been noticed at irregular intervals, most commonly appearing about the beginning or end of spring, and rarely during the height of summer; but I have seen them at all periods from August to May, and the beginning of June. By some it is presumed that cold and moisture favour their development; by others the hard winds of spring, after a wet winter, are supposed to have the same influence. I have, however, seen the disease in the autumn and middle of winter after a dry summer. The disease is occasionally epizootic, or prevalent at the same time in several farms at no great distance, more commonly sporadic or nearly solitary. It may be seen sometimes at several contiguous farms; at other times one or two farms, apparently under like circumstances of soil, situation, &c., amidst the prevailing disease entirely escape its visitation. Many years may elapse before it recurs at a given farm or vicinity, although all the animals may have been changed in the meantime; I have known it to occur twice in five years in a particular vicinity, and at two contiguous farms, while at a third adjoining dairy, in all respects similar in local and other circumstances, it had not been known to exist for forty years. It is sometimes introduced into a dairy by recently purchased cows. I have twice known it so introduced by milch heifers. It is considered that the disease is peculiar to the milch cow,—that it occurs primarily while the animal is in that condition,—and that it is casually propagated to others by the hands of the milkers. But considering the general mildness of the disease, the fact of its being at times in some individuals entirely overlooked, and that its topical severity depends almost wholly on the rude tractions of the milkers, it would perhaps be going too far to assert its invariable and exclusive origin under the circumstances just mentioned; yet I have frequently witnessed the fact that sturks, dry heifers, dry cows, and milch cows milked by other hands, grazing in the same pastures, feeding in the same sheds and in contiguous stalls, remain exempt from the disease. Many intelligent dairymen be-

lieve that it occurs more frequently as a primary disease among milch heifers; but I have not been able to confirm this remark by my own observation. It does not appear to be less frequent on the hills than in the Vale. It has been seen primarily on the stall-fed as well as on the grazing animal.

Origin of the Disease.—I have met with several intelligent dairymen whose relatives had seen good reason to ascribe its occurrence to the contagion of the equine vesicle, communicated by the hands of the attendant of both animals; but very little of that disease has been noticed of late years, though I know of several farriers who have been affected from the horse, and resisted subsequently variolation or vaccination, and have seen a few who distinguish between equine vesicle and the grease, a recurrent disease—eczema impetiginodes—as it appears to me. For many years past, however, the spontaneous origin of the *variolæ vaccinæ* in the cow has not been doubted here. In all the cases that I have noticed I never could discover the probability of any other source.

There is much difficulty in determining with precision, at all times, whether the disease arises primarily in one or more individuals in the same dairy; most commonly, however, it appears to be solitary.

The milkers pretend in general to point out the infecting individual; but as I have more than once detected the disease in a late stage on an animal not suspected of having it, I am not very prone to confide in their representations, unless my own inspection confirms or renders them probable.

In some animals the disease being mild and their tempers good, little notice is taken of tenderness in milking, which is of frequent occurrence; whereas an ill-tempered animal, with not more of the disease, being very troublesome to milk, is sure to be considered the infecting source. Moreover, in the same dairy, at the same time, with the true disease, some one or other of the spurious forms may occur in some individuals, causing difficulty in milking, and producing deep sores on the milkers' fingers, thus complicating the investigation and deceiving the indiscriminating milkers. The very frequent occurrence of inflamed, tender, and chapped nipples, in connexion with the time and mode of milking in closely arranged stalls, and in comparative darkness, renders these men in general unsuspicious of any specific disease till it has made pretty extensive progress through the shed. Their general incompetency to distinguish between the true and the false eruptive diseases, added to the above disadvantages, often creates insuperable difficulties in obtaining very important information, and frequently

* From the Transactions of the Provincial Medical and Surgical Association, Vol. VIII.

precludes implicit reliance on it when obtained. Hence another source of the numerous inherent difficulties which attend these investigations, and hence the cause of late intelligence precluding successful inquiries, and not unfrequently the loss of all knowledge of the fact of the existence of the disease; hence also the multitude of vexations, perplexities, and disappointments, which too often await the inquirer after facts, and the searcher after lymph. For the acquisition of a very moderate amount of real knowledge on this subject, much time and many sacrifices are required, since actual personal observation is indispensable; and even then it is only after extreme vigilance, quickened by repeated disappointments, with much inconvenience and considerable labour, that some of the objects sought can be obtained. The remote causes appear to be entirely unknown.

Condition of the animal primarily affected.—Here, again, the difficulties above mentioned often thwart inquiry, and the preliminary signs of the disorder are rarely noticed. Yet it must be admitted that this fact, though negative, justifies the presumption of the absence, in many instances at least, of any appreciable or very notable constitutional derangement. In the majority of instances I could not learn that food was refused, or any palpable febrile indications were noticed. In August, 1838, three cows were affected with the disease: the first was attacked two months after calving, and seven weeks after weaning. This animal was considered in good health, but to me appeared out of condition; it had heat and tenderness of teats and udder, as the first noted signs. The other two were affected in about ten days. In December, 1838, in a large dairy, a milch cow sired her calf, had heat and induration of the udder and teats, with vaccine eruption, and subsequent leucorrhœa and greatly impaired health; the whole of the dairy, consisting of forty cows, became subsequently affected, and some of the milkers. In another dairy, at the same time, it first appeared in a heifer soon after weaning, in about ten or twelve days extended to five other heifers and one cow milked in the same shed, affecting the milkers. In another dairy, at the same time, thirty cows were severely affected, and also one of the milkers. It appeared to arise in a cow two months after calving. The only symptoms noticed were that the udder and teats were tumid, tender, and hot, just before the disease appeared.

Condition of the animals casually affected.—There is rarely any manifestation of fever or constitutional disturbance. In some seasons it appears milder than at other seasons. In some animals it is less severe

than in others, depending on the state and condition of the skin of the parts affected, and the constitution of the animal. It is sometimes observed to diminish the secretion of milk, and in most cases commonly does actually affect the amount artificially obtained, beyond which, and the temporary trouble, plague, and accidents to the milk and milkers, little else is observed: the animal continues to feed and graze, apparently as well as before.

The topical effects vary much in different individuals, whether primarily or secondarily affected, the mildness or severity being greatly influenced by the temperament and condition of the animal, and especially by the state of the teats and udder, and the texture and vascularity of the skin of the parts affected. Where the udder is short, compact, and hairy, and the skin of the teats thick, smooth, tense, and entire, or scarcely at all cracked, chapped, or fissured, the animal may and often does escape with a mild affection, sometimes only a single vesicle. But where the udder is voluminous, flabby, pendulous, and naked, and the teats long and loose, and the skin corrugated, thin, fissured, rough, and unequal, then the animal scarcely ever escapes a copious eruption. Hence, in general, heifers suffer least and cows most from the milkers' vaccinations and manipulations. Dark red and red-spotted animals are often seen more affected than those of a lighter colour, as might be expected, from the occurrence in them of the respective conditions above mentioned.

Progress of the disease.—The variolæ vaccinæ once arising or introduced, and the necessary precaution not being adopted in time, appear in ten or twelve days on many more in succession, so that amongst twenty-five cows, perhaps by the third week nearly all may be affected; but five or six weeks or more are required to see the whole number perfectly free from the disease on the teats at least.

The facility with which the disease may be and often is propagated by the milkers is very remarkable. In December 1838, on a large dairy farm where there were three milking sheds, the variolæ vaccinæ first appeared in the home or lower shed. The cows in this shed being troublesome, the milker from the upper shed, after milking his own cows, came to assist in this for several days, morning and evening, when in about a week some of his own cows began to exhibit the disease. It appears that having chapped hands, he neglected washing them for three or four days at a time, and thus seemed to convey the disease from one shed to another. During the progress of the disease through this shed, one of the affected cows, which had been assailed by its fellows, was removed to the middle shed, where all the animals were per-

fectly well. This cow being in an advanced stage of the disease, and of course difficult to milk, and dangerous to the milk pail, was milked first in order by the juvenile milker, for three or four days only, when, becoming unmanageable by him, its former milker was called in to attend exclusively to it. In less than a week all the animals in this shed showed symptoms of the disease, though in a much milder degree than it had appeared in the other sheds, fewer manipulations having been performed by an infected hand.

The progress of the disease, however, is not always so readily or so satisfactorily traced; and I have felt induced to think sometimes that more than one animal has had the natural form in different parts of the same dairy. Nor is the disease necessarily communicated to all the animals milked by the same hand: not only do some older animals escape, but I have seen several times young milch heifers, exposed to all the circumstances favouring contagion amidst the rest of the herd, entirely escape.

Typical symptoms of the natural disease.—For these we are almost always, in the early stage, by reason of the circumstances above mentioned, compelled to depend on the observation and statements of the milkers. They state that for three or four days, without any apparent indisposition, they notice heat and tenderness of the teats and udder, which are followed by irregularity and pimply hardness of these parts, especially about the bases of the teats and adjoining vicinity of the udder; that these pimples, on skins not very dark, are of a red colour, and generally as large as a vetch or a pea, and quite hard; that in three or four days many of these having increased to the size of a horse bean, milking is generally very painful to the animal, the tumors rapidly increase in size and tenderness, and some appear to run into vesications on the teats, and are soon broken by their hands; milking now becomes a troublesome and occasionally a dangerous process. It is very seldom that any person competent to judge of the nature of the ailment has access to the animal before the appearance of the disease on others of the herd, when the cow first affected presents on the teats, acuminated, oval, or globular vesications, some entire, others broken, not unfrequently two or three confluent. Those broken have evidently a central depression with marginal induration; those entire, being punctured, effuse a more or less viscid amber-coloured fluid, collapse, and at once indicate the same kind of central and marginal character. They appear of various sizes, from that of a pin's head, evidently of later date, either acuminated or depressed,

to that of an almond, or a filbert, or even larger: dark brown or black, solid, uniform crusts, especially on the udder, near the base of the teats, are visible at the same time; some, much larger, are observed on the teats; these, however, are less regular in form, and less perfect: some are nearly detached, others quite removed, exhibiting a raw surface, with a slight central slough. The forms of the crusts on the udder are either circular or ovoid, slightly acuminated or depressed, and the crusts seem imbedded in or surrounded with more or less indurated integument. On the teats the crusts are circular, oval, oblong, or irregular; some flatter, others elevated and unguiform, several irregular; some thin and more translucent, being obviously secondary. The appearance of the disease in different stages, or at least the formation of a few vesicles at different periods, seems very evident. The swollen, raw, and encrusted teats seem to produce uneasiness to the animal only while subjected to the tractions of the milkers, which it would appear are often nearly as effective as usual.

Most commonly, however, the observer, instead of seeing the above phenomena, does not arrive at the dairy until the cicatrices are nearly healed on the animal first affected, when he commonly finds the greater part of the animals in the same house in different stages of the disease. When he is fortunate enough to have an opportunity of watching the disease in its progress through the different parts of a dairy, and can carefully and diligently inspect all the animals in succession, he may observe the

Typical symptoms of the casual Variolæ Vaccinæ.—It is very rarely that any indications of contagion, after undoubted exposure, are manifested before the sixth or seventh, sometimes not till the eighth or ninth day; but a vigilant observation of thin-skinned animals, with chaps and cracks on the teats, will exhibit small red, rather tender papulæ near the udder and on the body of the teats, about the fifth day. On the sixth and seventh day, in cows with white clear skins, on the lower parts of the udder are observed circumscribed indurations, generally of a reddish colour, and of a circular, ovoid, or lozenge shape, as large as a vetch or a pea; a few are still larger, six lines or more in diameter, and have a central depression very palpable to the finger, in which is visible a small, dirty, yellowish white discolouration, surrounding a still darker dot or line, sometimes angular, thus: — ◁; these indurations are often interspersed with minute red papulæ of a darker colour, rather acuminated, often with abraded summits. Some of the tumors contain within their centres

a slender amber-coloured, yellowish brown or brownish black crust, these being less tumid and prominent than those without the crusts; they are all very tender, even when slightly compressed. On the teats, especially on the lax and extensile skin of their base, similar tumors are observed, often in considerable numbers, generally circular, about the size of a vetch or a pea, some even smaller; on the bodies, and even to the apices of the teats, they are also numerous, and frequently ovoid, from ten to fifty or more. On all these parts of the teats the circumscribed intumescence and induration is less apparent and less defined than on the udder; but the pearly or glistening lustre of their margin and part of their centre is nearly as manifest. In animals with dark skins, at this period, the finger detects the intumescent indurations often better than the eye; but when closely examined, the tumors present at their margins and towards their centre a glistening metallic lustre or leaden hue; but this is not always the case, for occasionally they exhibit a yellowish or yellowish white appearance. Those in which a central crust has formed are readily detected, and on others which have been compressed, or had the cuticle abraded, there appears a crystalline amber-coloured translucent mass of concrete lymph on the surface, sides, and vicinity, leading to the detection of what might otherwise have been overlooked. On the eighth and ninth days, in animals with fair skins, on the udder, some of the tumors appear with more central depression, and more elevation of the margin, which is solid, uniform, tense, and shining, extending to seven or eight lines, of a glistening white, pearly, or silvery hue, and in the centre of many is observed a blueish or slate-coloured tint. Around the base is often apparent a narrow pale rose or light damask areola, not more than a line or two in width. In others the central crust is increased, and is yellow, brown, or black; a few appear a little pustular in their centres. On the teats corresponding changes have taken place in the tumors which remain entire; a few small conoidal vesicles also appear to have subsequently risen; some have a slight depression on the apex; they may be found from the size of a pin's head to that of a pea. But generally, the majority of the tumors are more or less abraded or otherwise injured, either by the animal while recumbent, or by the merciless manipulations of the milkers; hence is seen lymph exuding from the centres, with cuticle loose or partially detached, raw surfaces, brown or black crusts, either primary or secondary, and here and there the cuticle entirely raised from the centre of the tumor, forming a vesicle of a conoidal shape, often slightly depressed at its apex,

with a dark central spot, and distended with pellucid lymph, around which there is generally some appreciable intumescence and induration. Many tumors are found coalescent, and several vesicles interfluent. In very dark-skinned animals, instead of a blueish tint of the centre of the tumors, a leaden coloured or metallic glistening hue is apparent there and over the intumescent margin. In those less dark, with thin skins, a yellowish or dirty yellowish white, sometimes pustular appearance, is observed in the centre and on the margin, and instead of a well defined surrounding areola there is in some perhaps a reddish brown or tawny hue; but in all, heat and circumscribed induration, especially where the skin is thick, corresponding to the limit of the areola in others.

Between the tenth and eleventh days the disease in general reaches the acmé. On the udders the tumors are often from eight or ten lines in their largest diameter, and in white skins the centres and central edges of the intumescent margin are of a deeper blue or slate colour, and the areola, which is usually of a pale rose colour, is seldom more than 4 or 5 lines in extent, under which the integuments are deeply indurated. Lymph, which two days before was difficult to procure from beneath the cuticle of the central depression of some tumors, is now so copious that it raises the cuticle, forming a globular or conoidal vesicle, or freely flows out from its rupture. Other tumors have a greatly extended brown or black central crust, either slightly acuminate or depressed, encroaching on the marginal intumescence; others have become flatter, entirely encrusted, and perfectly passive. On the teats, the few which remain unbroken undergo similar changes, but appear to have less extent of areola, and less circumferential induration; the skin here being loose and extensile, the coalescent tumors are more or less abraded, and have primary brown or secondary black crusts, or a combination of both; the interfluent vesicles are more or less covered with brown or black, oblong, irregular, solid or unguiform, strong, compact crusts, or, denuded of cuticle, are raw, swollen, with elevated margins, discharging blood, lymph, and pus. On and after the twelfth day, on the udder nearly all is passive; the central brown or black crusts have rapidly increased, the marginal induration and intumescence proportionately subsided; the few remaining unbroken vesicles gradually acquire a brown or blackish hue, shrink, and desiccate within their subsiding induration. The central crusts above alluded to, if undisturbed, though they may become thicker and darker and more compact, seldom increase in breadth after the thirteenth or fourteenth day. The marginal indurations within which the

central and vesicular crusts are always enclosed, though they now and then, for a day or two, seem irregularly to renew their former elevation, gradually subside, and have nearly disappeared on the spontaneous separation of the crusts, which takes place on the twentieth or twenty-third day; but even then some traces of induration are left surrounding the cicatrix or pit, which is shallow, smooth, oval, or circular, of a pale rose, white, or whitish colour, according to the contrast of the surrounding pigment.

On the teats about this period—the twelfth day and onwards—around their base, the tumors and vesicles which are left entire exhibit the like appearance; central crusts of various sizes, brown or black, imbedded in less indurated marginal elevations; vesicles in various degrees of advancement towards desiccation; some with flaccid, flattened cuticle of the colour of the surrounding pigment; others, more advanced, with yellowish light brown, and others desiccated into dark brown and blackish, slightly acuminate or centrally depressed, oval, or circular uniform compact crusts. On other parts of the teats, out of the way of the milkers, and where the tumors or vesicles have been small, few, or solitary, the same may be observed; but most commonly, and always where these have been large, numerous, and coalescent or interfluent, the skin thin, loose, and vascular, and the animal inordinately irritable, a very different state of things is observed. Large black solid crusts, often more than an inch or two in length, are to be seen in different parts of these organs; some firmly adherent to a hard and elevated base; others partially detached from a raw, red, and bleeding surface; many denuded, florid red, ulcerated surfaces, with small central sloughs, secreting pus and exuding blood; the teats excessively tender, hot, and swollen. Not unfrequently one or more teats form a tumid mass of black crusts and naked red sores, secreting a discharge which imparts to the finger that touches it an odour strongly resembling that which emanates from a patient in the last stage of small pox. In some animals, under some circumstances, this state continues little altered till the third or fourth week, rendering the process of milking painful to the animal, and difficult and dangerous to the milker. In many, however, little uneasiness seems to exist: the parts gradually heal; the crusts, though often partially or entirely renewed and renewed, ultimately separate, leaving apparently but few deep, irregular cicatrices, some communicating with the tubuli lactiferi, the greater part being regular, smoothly depressed, circular, or oval. Occasionally warty or fungous growths succeed some of

the deeper ulcerations. It not unfrequently happens that the central deeper part of the depressed cicatrix, even when not very large, continues to remain a thin flimsy irregular incrustation, (secondary or tertiary,) as late as the end of the fifth week, or even longer.

[To be concluded in our next.]

EXCISION OF THE ELBOW-JOINT.

To the Editor of the Medical Gazette.

SIR,

THE ease of which I now forward a statement occurred some time ago, but as it is one the ultimate condition of which time only could declare, I have deferred giving an account of it, till I should have an opportunity of ascertaining the result of the operation, after the lapse of a sufficient period.

This opportunity having been afforded within the last few days, I am enabled to request insertion of the following history in the pages of your valuable journal.—I am, sir,

Your obedient servant,
GEORGE BUSK.

Dreadnought, July 14th, 1840.

JAMES LEWIS, æt. 25, was admitted into the Seamen's Hospital, September 7, 1837, with disease of the right elbow-joint. The joint was painful and much swelled, and its motion very limited. The swelling was principally on the sides of the olecranon and about the head of the radius. There was distinct fluctuation in that part of the swelling situated between the olecranon and head of the radius, and in this situation there was considerable tenderness. Any motion of the joint, and especially rotation of the hand, caused great pain, but no roughness attended the motion. The muscles of the arm were much wasted; the general health good. The history of the case was this:—In June 1833, the man was a patient in the hospital with abscess in one testicle, and periorchitis in the tibiæ, connected with syphilis. In July 1834 he was again admitted with an affection of the right elbow, which had commenced shortly after his previous discharge. The arm had been more or less affected ever since, but had not been so bad as to prevent him following his employment until the last three months. For some time previous

to his admission he had attended as an out-patient, and the usual applications had been resorted to without benefit. After his admission an issue was made in the neighbourhood of the joint, which was confined in pasteboard, and he took the hydriodate of potass: by these means the pain of the elbow was much relieved in eight or nine days, but he complained much of pain referred to the lower part of the radius. A grooved needle introduced into the fluctuating part of the swelling gave exit to some transparent fluid.

He continued to improve till about the end of the month, when he left the hospital.

He returned on the 31st of October. Since his discharge, he had been drinking, and living a very irregular life. He was very weak, and had a bad cough; slept ill, and vomited almost every thing he took. Pulse 120, sharp. The arm had become much wasted, which caused the elbow to appear large, although it was in fact but little swelled; there was only a soft puffiness on the sides of the olecranon. There was great tenderness over the radio-humeral articulation, and on the inner side of ulna. Flexion of the joint caused pain in both sides of it, but the most forcible attempts at extension did not cause any, unless the limb was jerked. When the limb was held so as to allow the forearm to hang inwards, great pain was felt on the inner side, and when the limb was bent outwards, the pain was felt in the radio-humeral articulation.

Rotation of the hand caused great pain in the elbow, and all down the arm.

There was no affection of any other joint. In the beginning of November his health was slightly improved, but there was no appearance of amendment in the elbow, and it did not seem probable that any would take place. There was evidently extensive ulceration of the articular cartilages, and probably caries of the bones. The parts surrounding the articulation were, however, in healthy condition, and the ligaments perfect. As the constitution was evidently affected by the local disease, its removal became a question of necessity. Under these circumstances the case appeared one well adapted for excision of the joint, and this proceeding was consequently determined upon, and carried into effect on the 12th of November, 1837,

in the following manner. An incision was made, on the posterior aspect of the arm, near its inner border, and immediately external to the course of the ulnar nerves. This incision was commenced about three inches above the articulation, and carried about two inches below it. A transverse incision was then made immediately above the olecranon, dividing the triceps, &c. down to the bone. The ulnar nerve was reflected over the inner condyloid protuberance. The angular flaps formed by the incisions were then reflected, and the lateral ligament of the elbow divided, the capsule of the joint opened, and the olecranon removed with the cutting forceps. An ivory paper knife was passed in front of the articular head of the humerus, and the whole of the articular surfaces removed with a saw. The coronoid process of the ulna was found to be carious, and the articular cartilages of the ulna and radius extensively ulcerated.

It was necessary to make another incision at right angles with the outer extremity of the former transverse one, downwards, over the head of the radius, to allow of the application of the cutting forceps to the neck of that bone, by which the whole of its head was removed with the saw. When the olecranon was removed with the forceps, its cancellated structure was observed to be filled with pus, but at the part at which the bone was afterwards sawed its texture was quite healthy.

The sharp projecting point of the inner condyloid protuberance was nipped off. A few small vessels were tied, and both ends of the ligature cut off—a measure I afterwards much regretted, as the knots became the cause of sinuses, which were open for some time, till the remains of the ligatures came away. The flaps of integument were brought together with sutures, and the wound covered with lint dipped in cold water, no plaster being used. The arm was placed in an easy posture on a curved splint.

The disease consisted in a gelatinous alteration of the articular cartilages of the humerus, and partial caries of that bone. Nearly the whole of the sigmoid cavity of the ulna was denuded of cartilage, and that bone extensively carious, and its cancellated structure filled with pus. The cartilage on the articular head of the radius extensively ulcerated,

and the bone superficially carious. The ligaments were barely distinguishable in the gelatinous looking-matter into which the capsule of the joint was converted. There was a small abscess external to the joint, immediately in front of the coronoid process of the ulna.

It is needless to record the daily reports: suffice it to say, that on the 16th, or four days after the operation, complete adhesion of the external wound had taken place, and the edges required separating a little at the lower angle, to allow of the escape of a small quantity of pus. He had suffered no pain since the operation. On the 18th he had an attack of severe pain in the side of the chest, which was considered to be pleurisy, and was removed by bleeding and leeching.

The arm went on very favourably, and on the 24th the limb was fixed on a splint, curved to an obtuse angle, and he was allowed to get up. By this time there was hardly any discharge, the wound being perfectly united throughout, except at the lower angle.

On the 3d of December, tin splints, having a joint at the elbow, were applied on the sides of the arm. These splints allowed of flexion and extension, but prevented lateral motion, and with them applied passive motion was frequently employed, which did not cause pain. On the 18th December he was able to write a letter.

In the middle of January the splints were left off, and he had considerable use of the arm. His general health was quite restored, and he was discharged from the hospital on the 1st of February. The last knots of the ligature did not come away till May or June, when the small sinuses which had been kept up by their presence finally closed. In June he had an attack of small-pox, on his recovery from which I saw him, when he had limited motion of the false joint, but it was very weak. He had, however, full power of supination and pronation of the hand, and was able to carry a pailful of water, with the arm extended.

About a year after the operation he returned to his employment as a seaman, and had very much recovered the use of his arm.

He presented himself to me on the 6th of this month, when I had an opportunity of fully examining the condition of the limb. Before removing his clothes

it required close observation to detect any difference between the limbs, and he stated that no one on board the vessel of which he had been mate for nearly twelve months was aware that he had anything the matter with his arm. On baring the arms, however, there was considerable difference in their size, although the muscles of the right had much increased since I had seen him last. The affected arm was altogether smaller than the other, but was not otherwise at all deformed. The shape of the elbow was so little altered that any one not aware of the fact would hardly have been able to convince himself that the articulation had been removed. The arm could not be flexed to more than a right angle, but could be perfectly extended. There was no lateral motion. The motions of supination and pronation of the hand were perfect. He had no pain, and found only that the right arm was not as strong as the left. He had become very stout, and appeared to enjoy the most robust health.

CASES OF SQUINTING.

To the Editor of the Medical Gazette.

SIR,

CASES of squinting cured by division of the internal rectus muscle have hitherto only been reported: as I have now had a few cases under my treatment where this proceeding proved insufficient, I beg to forward them to you for insertion in your valuable journal.

I remain, sir,

Your obedient servant,

A. FRANZ, M.D.

19, Golden Square, July, 14, 1840.

CASE I. — Eliza White, aged 29, a girl of weak constitution, with dark eyes, affected with squinting since her 6th year, which she had acquired by imitation, presented herself for operation on June 22d. On examination I found the left eye to be inverted and turned upwards, so that nearly one-half of the cornea was hidden by the inner canthus; that she could not turn the left eye outwards beyond the orbital axis; and that on closing the right eye she could only read very large print. I proceeded to the operation, and carefully and entirely divided the internal rectus muscle, as in all my former cases. I now removed the hook

from the conjunctiva, and, leaving the eye a little at rest, after the lapse of a few minutes I examined its state again, when I was not a little surprised to find that the division of the muscle had not proved efficient; for although the inversion was certainly modified, the eye was yet turned considerably upwards and slightly inwards. From the direction in which the eye now stood when at rest, and its movements obliquely upwards towards the glabella, I was induced to think that the present state of this eye, the internal rectus having been entirely divided, would be well adapted for an experiment to investigate the true action of the oblique muscles; and as the patient bore the operation with very little inconvenience to herself, I determined at once to divide first the superior oblique, in order to convince myself whether the present direction of the pupil depended actually on the action of the inferior oblique only, and then to divide the inferior oblique likewise, if the direction of the pupil should require it*.

I passed the hook again through the conjunctiva for drawing the eye outwards, and without enlarging the wound in the conjunctiva passed the curved scissors under this membrane, cutting through the adipose and cellular tissues with the blades of the scissors, so directed as to meet the tendon of the superior oblique, which I soon distinctly felt between the blades, and divided, as was proved by the resistance, and the peculiar sound with which the division of a tendon is accompanied. On removing the hook again from the conjunc-

tiva, and carefully examining the eye, I was not a little surprised to find that it was now perfectly straight, the pupil occupying its proper position. The division of the inferior oblique was therefore not requisite. The patient could not move the eye inwards, but in all other directions the movements were free. She was now dismissed, with directions for the after treatment, as in the former cases. No signs of inflammation made their appearance, and the case has proceeded favourably.

On the 11th of this month I saw her for the last time, when the wound was perfectly healed, and presented a smooth surface, and, with the exception of a slight redness in the inner angle of the eye, no trace of the operation was discernible: the pupil occupied the proper position, the movements of the eye operated upon were free and regular, and in perfect harmony with the motions of the other eye.

CASE II.—A young gentleman from Somersetshire, aged 17, in the enjoyment of good health, affected with congenital squinting of the left eye, arrived in London on June 29th, accompanied by his medical attendant, Dr. Cardew, of Weymouth, who placed him under my care for the treatment of this deformity. On examination I found the left eye turned considerably inwards and upwards, so that one-third of the cornea was concealed by the inner angle and the upper lid of the eye; that he could turn the left eye outwards to some distance beyond the orbital axis, but that he could not read print of a moderate size. I fixed the operation for the day following, when it was performed in the presence of Dr. Cardew. On removing the hook from the conjunctiva, after a perfect division of the internal rectus muscle, the eye, as in the former case, was yet drawn obliquely upwards towards the glabella. I therefore proceeded, with the concurrence of Dr. Cardew, to divide the superior oblique muscle, as above. After completing the operation, the eye occupied its proper position; its motions were free, except internally, and sufficed to bring the edges of the wound in the conjunctiva, which was very small, in contact. The same after-treatment was pursued; no inflammation followed; and on the 9th of this month he left town, perfectly cured: no trace of squinting could be detected,

* The physiology of the muscles of the eye has been certainly rendered far more clear by the observations "On the Muscles of the Eye," made by Sir Charles Bell in the *Philosophical Transactions*, 1823, but yet much remains to be said upon the functions of the oblique muscles, since a great diversity of opinion still exists amongst anatomists and physiologists in this respect. The inferior oblique muscle passes under and round the eyeball, to be inserted into the sclerotica posteriorly, and beyond the greatest diameter of the globe. We may therefore infer that its action would be to turn the eyeball so as to give the pupil a direction upwards and slightly inwards. From the peculiar arrangement of the superior oblique, and from its attachment to the sclerotica beneath the superior rectus, without passing over the greatest diameter of the globe, I am inclined to attribute to it the action of carrying the pupil inwards and slightly upwards, and thus to assist the inferior in a movement which is one of the most frequent of all motions of the eyes, as it occurs at every closure of the eye in the act of winking, during sleep, and as a diagnostic in the expression of the eye during various healthy and morbid conditions of both body and mind.

and both eyes moved harmoniously, the redness of the conjunctiva in the inner angle being confined to a space of about a quarter of an inch in extent.

On the 2d of July I have a third time divided these two muscles, in the case of a young gentleman from Birmingham, aged 9 years, in whom both eyes were affected with squinting to a great extent; but the description of this case, as it presents other peculiarities, I will defer until I have performed the operation on the other eye, which will take place in a few weeks.

In my latter cases I have somewhat altered the mode of operation, by which I am enabled to perform it with greater facility and ease both to myself and the patient. I use now but one retractor for the upper eyelid, and having fixed the eye, by means of the hook furnished with a sliding yard passed through the conjunctiva, I grasp the valvula semilunaris with a pair of fine forceps armed with teeth at their extremities, and drawing out a horizontal fold of the conjunctiva, between the hook and forceps, divide it with a pair of scissors, when the tendon of the rectus muscle is immediately brought into view, and the operation is completed in the manner formerly described.

In a letter, dated June the 9th, lately received by me from Professor Dieffenbach, he mentions an inveterate case of squinting, combined with amaurosis, where both affections were removed by the division of the internal rectus muscle, of which case he will give me a full account at a further period, which I shall then make known to the profession. He also further states that he has now performed this operation in 250 cases.

CASE OF SCROTAL HERNIA,

WITH EXTENSIVE ULCERATION AND PERFORATION OF THE INTESTINES.

To the Editor of the Medical Gazette.

SIR,

On the 18th of June, 1840, I was called upon to visit Mr. G —, a seaman, of a stout athletic habit of body, aged thirty-four. For more than twenty years he described himself as having been the subject of scrotal hernia, and which, from never having worn a truss, had acquired

a considerable size. On my arrival, I discovered that an increased portion of gut had descended, which, after a few hours, was replaced in its natural position. There was great distention of the abdominal parietes, of a tympanitic character. A diarrhoea had existed the previous day, but had ceased when I first saw him. He now complained of constant inclination to reject his food, a symptom to which he had been, more or less, accustomed for many years, and the slightest pressure on the left hypochondriac region would at all times enable him to vomit with ease. He had a full pulse, about 100 in a minute; firm pressure might be made over the whole of the abdomen, without producing the slightest pain; very little inconvenience was also experienced from effecting the return of the increased portion of intestine. The gastric irritation not being a new feature, I endeavoured to empty the bowels by castor oil, to remove the offending matter which had given rise to the diarrhoea, and attempted to allay the irritation of the stomach, by the use of effervescing salines, followed by the application of a blister, which remedies afforded considerable relief. A week elapsed from the time of my first visit without there being any alvine discharges, excepting a small quantity of mucus, although in the interim I had ordered a frequent repetition of enemata, together with active purgatives. At the expiration of this period, copious liquid discharges, with an abundant supply of bile, took place, followed by a considerable discharge of mucus. After the lapse of two or three days, the feculent discharges were again suspended; the gastric irritation and tympanitic symptoms now became more urgent, and on Saturday, July 4th, the attendance of Dr Symes was requested. At his suggestion, I abstracted twelve ounces of blood, the pulse continuing rapid, though with less force than at the commencement of the attack. The countenance at this time indicated great anxiety. The blood was neither bled nor cupped, nor was any relief obtained from the operation. A dose of calomel and opium at bed-time procured some hours of refreshing sleep: the following day, however, there was great increase of restlessness, and an anxiety of countenance, approaching to the facies hippocratica, was still more visible. From this period it would be needless to detail

the daily symptoms which continued unaltered (and wholly unrelieved by a variety of medicines,) till within a few hours of his death, when there supervened the most excruciating pain over the whole of the abdominal cavity. He expired on the night of the 8th inst.

Sectio cadaveris sixteen hours after death.—I began the dissection of the parts, as in the operation for strangulated hernia, and on opening the sac the first thing that presented itself was a portion of omentum, and behind it the sigmoid flexure of the colon, but no other portion of the intestine. No adhesions whatever were discovered in any part relating to the hernia, nor had there ever been any strangulation, which was proved by the finger being easily introduced between the intestine and the pillars of the abdominal ring. Farther dissection proved the hernia to have been congenital. The calibre of the bowel, as it emerged from the ring, was considerably diminished (the result of chronic inflammation), thereby obstructing the passage of any solid feculent matter; and (as was shewn by the subsequent dissection) in the portion of colon, above this contraction, were lodged several pounds weight of solid feces. On opening the abdomen, there was an abundant discharge of fœtid gas, and a sudden subsidence of the tympanitic swelling; and on farther reflecting the abdominal parietes, great displacement of the viscera immediately presented itself. The arch of the colon ran parallel with the descending branch of that intestine, and the cardiac extremity of the stomach lay in the left hypochondriac region. A small aperture was seen at the bottom of the descending colon, on which were lodged minute portions of feces; two large openings were also seen at the upper part of the descending colon, through which considerable quantities of feculent matter had escaped. The mucous membrane of the stomach, towards its cardiac extremity, was of a dark red colour: there was no other appearance of disease, either in the stomach itself, or at its pyloric orifice. The mucous surfaces of the duodenum and jejunum, and the two upper thirds of the ileum, presented no unusual appearance, but about the lower third of the latter increased vascularity and minute ulcers began to make their appearance, and these ulcers increased in size and frequency as we approached the colon (the ileo-colic

valve, however, remaining unaltered). The whole of the colon presented externally a livid appearance; internally, an almost uninterrupted surface of ulceration, more abundant immediately above the contracted part of the gut. These ulcers varied both in depth and size; two (as before described) had completely perforated the peritoneal coat, by openings nearly an inch in diameter; others had destroyed the mucous and muscular coats, leaving the peritoneum entire. The liver was considerably increased in size; the convex portion of the right lobe was of a purple hue, and most of this viscus much softened.

The post-mortem examination contained nothing farther worth relating.

Should this lengthened account appear sufficiently interesting for the pages of your valuable journal, I should be much obliged by your inserting it.

I remain, sir,

Your obedient servant,
JAMES SOUTHCOMB.

Bridport, July 13th, 1840.

DETACHED ABDOMINAL TUMOR.

To the Editor of the Medical Gazette

SIR,

YOUR number for June 5th, under the head of Medical and Chirurgical Society, contains a short description, by Mr. C. Hawkins, of a detached cartilaginous tumor found by him in the peritoneal cavity. In the number for June 19th, Mr. Douglas has published a letter, in which he agrees with Mr. Hawkins in his opinion as to the origin of the said tumor, and in which he mentions a few instances of similar excrescences growing from the cavity of the knee-joint and tunica vaginalis testis. No rational doubt can exist as to the origin of these tumors; and my only object in now addressing you is, to send you a short account of the discovery of a specimen similar to that of Mr. Hawkins. In the spring and summer of 1833, I attended William Green, a labouring man, aged about 50; he had been affected for a long time before with disease of the abdominal viscera, but had made no regular application for medical advice. It was clear at this time that, in addition to the abdominal disease, the heart had become extensively hypertrophied: as so often happens, in

similar cases, his death occurred suddenly, and a ready consent was given to my proposal of examining the body. The following is a pretty correct general account of the post-mortem appearances. The stomach was not much altered in structure; the intestines showed marks of chronic inflammation; there was great thickening of the peritoneum, without much serous effusion; the liver was enlarged, but presented no other morbid change; the heart was much hypertrophied, but the lungs were tolerably healthy. As I intended to detach the whole intestinal mass, for a more detailed examination, it was lifted up by one of the persons who assisted me, in order to pass a thread round the junction of the colon and rectum; and I then saw lying loose in the hypogastric region a substance which at first sight appeared like a piece of white wax; when taken up and examined, it was clearly a tumor, which had at some former time grown from the peritoneal surface, and had been detached. It was nearly triangular, about the size of a large walnut, and had a kind of a footstalk, which showed marks of having been abruptly broken, and from which it must have hung pendulous from the peritoneum. This discovery led me to conjecture that the man might have suffered, at some time, from a blow, or other external violence, and I questioned the widow minutely as to her recollection of any such occurrence: she said that two or three years before her husband had given himself a violent twist during some unusual exertion, and had complained of great pain in the abdomen for some time; in fact, his health, which was uniformly good before, had been more or less deranged ever since. I think there can hardly exist a difference of opinion as to the connection between the presence of this foreign body in the peritoneal cavity and the progressive and ultimately fatal disease of the abdominal and thoracic viscera. Being then in the habit of frequently seeing Mr. Stanley, I showed him the tumor, and he at once concurred in my opinion of its origin. At his desire I divided it into two equal parts with a very strong scalpel, and found that the outer two-thirds consisted of cartilage, and the inner one-third of osseous deposit. The only book on morbid anatomy to which I have ready access is that of Dr. Baillie; but the following extract from his work, relative

to the size of similar tumors discovered by him, will show the value, in a pathological sense, of this specimen and that of Mr. Hawkins:—"In one case I have seen a great many cartilaginous excrescences growing from the peritoneum;—they were of a small size, viz., most of them not larger than a garden pea, and grew from every part of the membrane. They were a little softer than the cartilages which cover the extremities of the bones, but had the true structure of cartilage." I am not aware that any account of this tumor has been given by Mr. Stanley to the profession at large, though I have no doubt it is still to be seen in his museum, and has been exhibited to his pupils. I shall not make any apology for sending you the above statement, because I am sure that we all equally value the advantages to be derived from the study of morbid anatomy; and because I consider that any addition to our stock of important pathological facts, however humble the person by whom it is made, must be acceptable to the great body of the profession. With a request for as early an insertion of this letter as suits your convenience, believe me, sir,

Your obedient servant,

WILLIAM ILOTT.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi i publicum sit, dicendi periculum non recuso."

CICERO.

HAVE OUR MEDICAL EXAMINATIONS IMPROVED?

In our article of July 3d we gave an impartial abstract of Mr. Carmichael's speech at the first anniversary meeting of the Medical Association of Ireland. In so doing, we animadverted on a strange mistake into which he fell, when he represented the eighteen medical examining bodies of these islands as engaged in an unworthy competition for diploma fees. He asserted, in the plainest terms, that they were outbidding

each other in lowness of qualifications and lowness of fees, and gave the name of Dutch auction to their proceedings : and a very good name it would be, if the facts were as he stated. The only instance, however, which he cited of this unseemly competition, was the Irish College of Surgeons, which, it seems, has lowered its examination, for fear of being deserted by candidates. Now, we volunteered no defence of the Irish College, but left it, and its supposed delinquencies, to the criticism of Mr. Carmichael, and the verdict of his Irish brethren. Our acquaintance with Dublin affairs was not sufficiently great to enable us to say whether the examination at the College of Surgeons was a commendable one, in its lowered state ; but we ventured to affirm, that so far from all the eighteen bodies being engaged in the Dutch auction, “ increase of severity, not of leniency, has been the general characteristic of the changes made of late years in medical examinations.” We quoted the University of Cambridge, and our three London corporations of Pall Mall, Lincoln’s Inn, and Blackfriars, as examples of corporate bodies which had rendered their examination more strict ; and the London University as one whose examination was certainly not fitted for the Dutch auction imagined by Mr. Carmichael. We should have thought that this appeal to the plainest facts must have persuaded every reader, prejudiced or unprejudiced, that Mr. Carmichael had been hurried away by the warmth incidental to public speaking, and had painted from his imagination rather than his memory.

Contrary to our expectation, however, our contemporary, the Dublin Medical Press, shows that there is at least one man in the three kingdoms whom we have not convinced ; for in its number of July 15th, it sets about defending the accuracy of Mr. Carmichael’s statement,

after the strangest fashion. Our first two exceptions are summarily disposed of. “ Even admitting that the examinations at Cambridge and the London College of Physicians have been improved, what is that to the point ? Of about five hundred candidates for medical practice let loose on the three kingdoms annually, about a dozen may, perhaps, be franked by these two bodies*.”

To us it seems most cuttingly to the point. If these two corporations were allowed, on account of their errors, to swell the list of eighteen delinquents, their amendment should not be passed over by professed reformers, on the plea of their insignificance. The first two on your list of culprits obtain a triumphant acquittal, and leave the court without any imputation to their characters : “ oh,” you cry, “ this does not affect our accusation at all—they were people of no consequence !”

Yet this, after all, is merely an *argument ad hominem*, though it is conclusive against the one-sided view of our contemporary ; but every friend to the profession must rejoice at the reform of the corporations in question. Had they remained in their pristine state, it might obviously have been objected that the higher walks of the profession were not swept with the same care as the lower ; but by these well-timed improvements the inlets to medicine have been rendered far more difficult on every side.

We might add Oxford to the catalogue of reformed corporations, as its regulations were thoroughly amended in 1833 ; but our contemporary would, of course, repeat, “ what is that to the point ?”

Come we now to the London College of Surgeons ; “ surely,” the reader will say, “ they ‘ let loose ’ an ample battalion of candidates every year upon the public, and their improvements must conse-

* Dublin Med. Press, July 15th, 1840, p. 46.

quently be to the point." Do not be too hasty, benevolent reader; there is an answer for that too. "As for the boasted improvements in Lincoln's-Inn-Fields, we challenge this avowed advocate of that institution—to prove that any of importance have taken place.*"

We willingly take up this challenge, though we protest against being called the avowed advocate of this or any other institution, at least, if our contemporary by "avowed advocate" means "indiscriminating eulogist."

In the first place, then, the College of Surgeons has from time to time altered its rules, and improved the education which it requires from its candidates, in accordance with the spirit of the age, or, in other words, in compliance with the expressed opinions of reasonable people.

Thus a set of new regulations was issued in October 1829; † regulations respecting certificates, &c., in October 1834; ‡ some very judicious regulations concerning teachers of anatomy in March 1836; § and new regulations for the education of students in June 1838. † Among other improvements, these regulations increase the minimum of surgical attendance at a hospital from twelve months to twenty-one. But, by the last regulations, dated August 20th, 1839, the candidate is required to have attended the practice of surgery, at a recognised hospital or hospitals in the United Kingdom, for three years; three months being allowed for a vacation in each year. In the second place, it is the common and well-founded opinion among the profession that the examination at Lincoln's Inn is a good one, as far as regards anatomy and surgery; and if we wished to confirm a general rule by a single example, we would refer to the judicious and sensi-

sible examination detailed by Mr. Gray in our number for June 12th; even though our Dublin contemporary cites this examination "as positive proof of the imperfection of the test to determine the qualifications of a person for practice."

In the third place, the sincerity of this belief in the soundness of the examinations at the College is shewn by the numbers who apply every year for their diploma, which is sought for, not from the terrors of the law, since unlicensed practitioners in surgery are not prosecuted, but from a wish for the distinction.

Lastly, that this distinction cannot be obtained by a mere formal compliance with the regulations is manifest from the number of rejections. We do not know what proportion they bear to the number of candidates, but we conjecture that they cannot be less than 1 in 12.

We have thus given a few reasons for believing that the College of Surgeons does not make one at the Dutch auction; but we are far from thinking that Utopia is situated in Lincoln's-Inn Fields, or that good sense and open discussion can fail to produce further amendments in their examinations. For instance, as they require attendance on medical lectures, lectures on the *materia medica*, and the medical practice of a hospital or dispensary, the examinations should touch upon these subjects, not only nominally, but really. Our contemporary, however, has discovered the truth, not at the bottom of a well, but floating on the top of one Dr. W——'s advertisement. This subtle grinder sticks his notices about the schools in Dublin, in which he engages to make his pupils unpluckable in London, within a few months. The Dublin Press knows that it is no vain boast, and that the doctor can perform what he undertakes. Nay, more; Dr. W—— engages to pass any pupil, "*no matter how limited his professional knowledge may be,*" and,

* Dublin Med. Press, July 15th, p. 40.

† Ibid. vol. v. p. 152.

‡ Ibid. vol. xv. p. 176.

§ Ibid. vol. xviii, p. 111.

|| Ibid. vol. xxii, p. 588.

if rejected, he will return the money. No wonder that our contemporary italicizes the line we have just quoted; it deserves to be in capitals. Why does not the doctor come to London, take pupils by the gross, and ultimately sell his secret to the other tutors for its weight in gold?

The third one of our London corporations, the Society of Apothecaries, is not noticed by the Dublin Press, but does not deserve to be passed over. Our readers need not be informed that the Worshipful Society has long and successfully laboured to raise the standard of medical education. It has gradually extended the period of attending lectures from a few months to two years and a half. Their regulations of the winter of 1827, on which we commented at the commencement of our career*, required only one course of lectures on the materia medica (including medical botany), one on chemistry, two on anatomy, and two on the practice of physic; while attendance on lectures upon midwifery and the diseases of children was merely recommended.

The regulations dated Sept. 25, 1828, extended the number of lectures considerably, two courses of chemistry being required, two on materia medica and botany, and two courses of anatomical demonstrations, besides two on anatomy and physiology†.

On a subsequent occasion, we gave the details of a very judicious examination which Mr. Henry Storer underwent at Apothecaries' Hall, in Dec. 1828‡, tending to show that the pupils were not required merely to have attended lectures, but to recollect what they had heard.

The regulations issued in April, 1835, are valid, with some slight alterations, at the present moment. They are indisputably an improvement on

the previous ones, though liable to the imputation of crowding too many subjects into too short a time. Either botany and forensic medicine should be struck out of the list of lectures, or, what would be better, six months should be added to the attendance on lectures, and subtracted from mere pounding and pouring.

Nor has there been a want of rigour in examining; such as could be exercised by experienced men who knew that it was their business to supply England with practitioners, and that they must rise their qualifications with caution. Thus, we showed on a former occasion, that from August 1st, 1815, to July 31st, 1834, the rejected were 795 out of 7,028, being rather more than one out of nine; and that the proportion increased in the latter years of the period, so that

in 1828-29 it was 1 in 6
in 1829-30 1 in 6
and in 1833-34 1 in 8 *

In 1820, the rejections were only one in twenty-three.

In England it will scarcely be necessary to quote these documents. To a man who mingles with medical society here, it would appear as superfluous to appeal to the Regulations of the College of Surgeons, and Apothecaries' Hall, to prove our argument, as it would seem useless to a Londoner to prove by parliamentary documents that the streets of the metropolis have been ornamented. Ask any practitioner of experience whether our corporations are outbidding each other in foolish lenity, and he will suppose that you have just dropped from the moon. Our contemporary tells us that he must needs laugh outright at our simplicity in believing that the examinations of our medical corporations have been improved; and we are quite sure that every English practitioner

* MED. GAZ., vol. i. p. 58.

† Ibid. vol. ii. p. 568.

‡ Ibid. z. vol. iv. p. 114.

• MED. GAZ. vol. xx. p. 696.

will more than smile at *his*, for not knowing the fact. We shall have at least 7000 laughers on our side, in London alone. The grey-headed practitioner of twenty or thirty years' standing will tell you how differently things were done in his youth; the staunchest praiser of the days that are gone will confess that, whether in the eager preparation of students, or the scientific rivalry of practitioners, the contrast is most gratifying between the medical England of 1810 and that of 1840; and he will not fail to attribute a great part of this increased energy to the zeal inculcated by our medical corporations. Few now imagine that their education is completed when they receive their diploma or their license; but they feel that their whole life must be a race for knowledge, a struggle for honour and for bread!

We suppose that in order to make out the list of eighteen examining bodies, we must take in the Army and Navy Medical Boards, and perhaps even the Examiner at the East India House: do these also contribute to "the number of unqualified persons annually forced into the profession, for the sake of the fees paid for certificates and diplomas?"

Thus, at this end of the island, there is no such very cheap and rapid way of getting into the profession as might be expected from Mr. Carmichael's speech. How are matters in the North? In Edinburgh the entrance into the profession does not seem to be dangerously facile. The College of Physicians scarcely counts 130 members; while the University and the College of Surgeons have improved their examinations, and shown no tendency to underbid their fellow corporations. The truth is, that in many places the march of severity has been so quick in these points, that the cautious have sometimes been afraid that the mark would be overshot, and either that candidates would shrink from

the examinations, or must, for the most part, be blackballed. This catastrophe, however, does not appear to have occurred anywhere but at the Irish College of Surgeons, so that our corporations have been more long-sighted than they had credit for being. Soon after the improvement of the Edinburgh University examination in 1833, a lugubrious pamphlet appeared, in which the author intimated his fears that the new rules would limit the profession "to a few physicians, polished up to the highest pitch of refinement in all the arts and sciences." Nevertheless, this euthanasia of the profession has not taken place. But we must conclude this long article, which we will do by observing, that if it is possible to find a couple of British Medical bodies that still ply for candidates, by dishonourable facilities, there are at least a dozen which show in the clearest manner that they shrink from the unworthy competition.

CLINICAL LECTURE
ON

POLYPUS OF THE NOSE,

Delivered at St. George's Hospital,

By CÆSAR HAWKINS, Esq.

GENTLEMEN,—So many questions have lately been asked by some among you, that I have thought a few observations on polypi of the nose would form an useful subject for to-day's lecture, particularly as you will often have cases of this disease under your care in private as well as in public practice.

Polypi are morbid growths of the mucous membranes, which are connected by a root or pedicle, more or less broad in proportion to the body of the tumor, which occur in various parts where these membranes are near their external communications, as in the rectum, the fauces or larynx, or the nose; and in the latter situation they may occur either in the nostrils or in the nasal cells; but it is to the former of these situations that I shall confine my remarks. You will find that polypi of some kind or other may be formed in any part of the higher portions of the nostrils, but they grow especially from the upper spongy bones and

middle passage of the nostrils, and generally the outer surface is selected: it has been denied that they originate on the septum; but here you may see a portion of the septum, with a polypus growing from it; they probably, however, never occur in the lower part of the partition of the nostrils. The situation of the tumor materially influences, as we shall presently see, its texture, but at the same time they possess some original differences in their nature. Their form will be given them, as you may see in these preparations, by the cavity in which they grow, so that, at first round or oval, they become flattened by the sides of the nostril, and when they reach the floor of the cavity they will expand in an irregular figure towards the front or back part of the nostrils; the nose being not unfrequently flattened or widened by their presence.

Symptoms.—The presence of polypi in the nose will cause some common symptoms whatever their kind may be; namely, the effects of obstruction of one or both nostrils, so that a person will not be able to breathe except with his mouth open; the voice will lose its tone or sonorousness, and there will be a degree of uneasiness in the nose, with the same sense of stoppage as in a cold; and there is also sometimes a similar discharge of watery mucus: the patient snores at night, and may be awakened by thirst and dryness of the mouth, from its being constantly open in his respiration: he cannot smell perfectly, if at all, because the air cannot be drawn through the nose, and for the same reason his taste is impaired, because that part of the sense which appreciates flavour is lost or impaired, though he still possesses the sense of common taste and touch in the tongue; sometimes the tears run over the face, though you will see large polypi, which do not at all obstruct the nasal ducts; sometimes again, if the polypus is far back in the nostril, deafness may be caused by its pressure on the eustachian tube, and occasionally deglutition is interfered with, as well as respiration, by the palate being pressed out of its proper position; finally, the effects of pressure may be of still more consequence upon the brain, by the polypus interfering with the circulation of blood, or affecting the base of the skull, so that heaviness, and sleepiness, and stupor, will take place, from which persons have been known to fall asleep on horseback, or a barber while shaving; and the unfortunate patient will have, as you have seen not long ago, rigors, delirium, or coma, or convulsions, by which a fatal result is occasioned. It is only to some kinds of polypi, however, that the latter symptoms belong, and it is only in them that the bones of the face expand and yield, so as to cause the frightful deformity, of which

examples have recently presented themselves to your notice, and which led a person, according to Alibert, to commit suicide after contemplating his own figure in the glass.

Diagnosis.—Many of the symptoms of polypi, therefore, being those of obstruction of the nostrils, may be occasioned by other disorders, *ozæna*, caries, and so on; and hence it is necessary to examine the nostrils, which may be expanded by a forceps or a speculum, so that the polypus may become visible, or if not, its existence may be ascertained by a probe or director; and in all cases you should endeavour to discover its form, and the situation of its root, by passing the probe round the body of the tumor. When visible, the polypus may sometimes be made to shift its position by blowing forcibly through the nostril; but if fixed, take care not to mistake serofulous thickening of the schneiderian membrane for polypus, and run the risk of extracting a portion of spongy bone; the opaque and white or pale colour of a polypus is very different from the red florid colour of inflamed and thickened membrane; and it is only in the malignant diseases of the part that much difficulty can exist, when a projection is visible. You have recently seen a man, a patient of Mr. Keate's, with a growth filling the aperture of each nostril; looking at first very like polypus, but on examination you found that it was confined to the lower part of the septum, which is not subject to polypus, and the red swelling on each side appeared to be the parietes of an abscess in consequence of a blow, of which I have occasionally seen instances; and he has left the hospital I believe nearly well after the discharge of matter. I have often known painful attempts to remove polypi, which really did not exist, by the use of forceps. We shall return to the malignant diseases presently; but besides them you will find that there are three forms of polypus of the nose of simple and innocent character.

I. *Vesicular polypi.*—In this kind of growth you will find the nostrils obstructed by a great number of grey or transparent vesicles, (sometimes erroneously called hydatids or hydatid polypi,) which are covered by the mucus of the nostrils in considerable quantity, and which contain a transparent watery fluid mixed with a small quantity of mucus, giving it a little tenacity. In this kind of polypi there is a copious discharge of liquid, as in cold, and they are excellent hygrometers, so that the patient will sometimes in dry weather be able to breathe pretty well, but in a damp atmosphere, interfering with the evaporation of the secretion, will find the cavities totally obstructed. Examine these polypi, and you find that they readily break down, discharging their con-

tents, and leaving in the forceps a few delicate shreds of fine transparent membrane; and the polypi are, in fact, great numbers of oval or pyriform bags hanging side by side, and continuing to form for a great length of time; fresh ones descending as fast as others are broken down. Sir A. Cooper, in speaking of these vesicular, (or as he calls them, hydatid polypi,) says they occur in young persons; but it so happens that the few instances I have seen have all been in adults, so that they may probably form at any age: it is however much less common than the next species of polyp. The softness of the vesicular polypi prevents their occasioning any severe symptoms by pressure, but their numbers give the patient a good deal of trouble.

Nature.—There are two opinions as to the nature of these vesicular bodies: some persons such as Portal and others, believing them to be enlargements of the mucous follicles, a kind of mucous encysted tumor; while Alibert and other authors believe the fluid to be in the common sub-mucous tissue. It is difficult to explain the occurrence in either way: it is not easy to see on the first supposition why such numbers should continue to form for so long a time; and if mere infiltration in the mucous tissue, there seems no reason why the swellings should be in the form of a number of separate and regular bags of half an inch long or more, hanging side by side, instead of having the usual appearance of œdema or puffiness. On the whole I am rather inclined to believe in the follicular origin, which is analogous to one form of polypus of the uterus, where the follicular vesicle attains a considerable magnitude, and the fine membranous bags are just what we should conceive these follicles would be when much distended in so delicate a tissue; at the same time I cannot say, as some assert they have done, that I have seen the orifices of the sacs. One thing I think is certain, that the occurrence of this form of disease depends on a constitutional cause. Mr. Abernethy, (speaking of polypi generally,) says that a person used to have some of them frequently extracted by Mr. Hunter and himself, till one day he gave him a lecture on his bowels, the consequence of which was that no more formed for several years, till a trifling return was caused by his being laid up by a broken leg. I cannot say that I think the general health has much to do with the formation of other polypi, but, with the vesicular species, I have always seen a pale muddy complexion, a kind of cachexia, which in other persons might have caused perhaps common œzæna, but in them occasioned this particular disease in the membrane of the upper part of the nostrils, in which part alone they are formed.

Treatment.—This being the case, their treatment must be constitutional in part; and the remedies which I have seen, I think, of much advantage in assisting the cure and preventing a relapse, have been sarsaparilla and liquor potassæ or hydriodate of potassæ, or, with both together; or, with small doses of bichloride of mercury. I have also administered small quantities of arsenic with apparent benefit; and bitters with alkalies and small alterative doses of blue pill.

With regard to local remedies, it is no use in general to extract these fine membranous substances; but the treatment is essentially the application of astringents: if, indeed, the nostrils are very much blocked up, you may first break down some of the vesicles to make your applications more readily act, but otherwise it is unnecessary to resort to a very painful, or, as Abernethy calls it, a blackguard operation. The best applications are the sulphates of zinc or alum, or copper, or the corrosive sublimate, which may be used of considerable strength as astringents in solution; they may be snuffed up the nostrils, or injected with an ivory syringe, or a piece of lint may be inserted into the nostril, and the solution dropped in while the patient's head is held back. The nitrated quicksilver ointment is of much service to the membrane after the polypi are destroyed, which may be applied by means of a little lint on a bougie as high as it can be inserted. You may also use the copper or zinc sulphate in powder on a piece of lint; and I have used burnt alum, alone, or mixed with a little savine powder, which the patient can snuff up the nostril; but on the whole I prefer the ointment and lotions, which I have mentioned. Some recommend the muriate of antimony or liquor potassæ; care being taken not to touch the sides of the nostrils, which are not ulcerated however by pretty strong solutions. These remedies must be continued for some time after the nostrils seem to be clear; and when the patient is careless I have known him come repeatedly to the hospital for many years, till he has tried all the surgeons in succession.

II. *Gelatinous polyp.*—The next form of polypus is a more solid growth of the mucous membrane, generally of the middle passage of the nose towards the outside, though I have also seen it in the cells and in the æthmoid bone: its appearance is seen in several preparations on the table, and you have also seen it in a patient who has just left the hospital. This was a man, Jesse Green, 50 years of age, admitted into the hospital on May 20th, in Wright Ward; and our notes say that he has had obstruction of the nostrils for thirteen months, and lately has had a yellow discharge from the nose. There are several gelatinous po-

lypi in each nostril, which appear to be attached high up, probably to the spongy bones, the nostrils are completely obstructed, and no air comes through the nose in blowing forcibly; he is also unable to smell or to speak freely. On the 21st I extracted a large mass of gelatinous polypus from the right nostril, and several portions from the left, and ordered a lotion containing sulphate of zinc $\mathfrak{z}\text{ss}$. to $\mathfrak{z}\text{viij}$. of water, which was afterwards increased to $\mathfrak{z}\text{ij}$. of zinc. This he was still unable to snuff up, and it was therefore injected. On the 23d some more fragments of the brittle polypi were extracted. On the 25th the right nostril seemed quite free, and some more was extracted from the left; one polypus of firmer texture than the rest coming away. On the 28th both nostrils seemed free, and he has since left the hospital apparently well.

You had then an opportunity of seeing the polypus in the living person as a dull white mass, covered by fine membrane with a yellow mucous secretion; and when extracted you perceived that it was a soft brittle substance, like firm jelly, consisting of infiltration of serum and lymph in the mucous and sub-mucous tissue, having a few delicate fibres running through its substance from the root to its circumference; and if these fibres are of unequal length they give an irregular or serrated appearance, to the surface of the tumor, which however, as you may perceive in the preparations, acquires its shape chiefly from pressure, and is therefore commonly broad and flat at the sides and expanded below, while in the early stage it is oval or globular before it has been compressed. In the interior of the polypus may also be seen a few delicate vessels seldom of much size. The gelatinous polypus is a solid mass of mucous membrane expanded by effusions in its tissue, not in separate bags like the vesicular polypi, and evidently not consisting of condensation of vesicular polypi, but different from its first origin, as well as in its usual situation; the vesicular polypi being only formed high up in the nostrils, and the gelatinous generally in the middle of the outer part. The gelatinous polypus is apparently a much more local disorder than the other, growing in healthy persons, frequently in children, though as you have seen it occurs also in adults. The gelatinous polypus is frequently single, so that if removed entirely with its root there will be no return of the disease: I extracted this, for instance, six years ago from a boy, and I know he has been quite well since that time. Sometimes there are thought to be more than there really are, in consequence of a single large polypus being extracted at several operations in separate portions, which are supposed to be distinct polypi; still, you must not too confidently promise a

cure, as two or three tumors may be present at once, or may successively appear, though it does not so much depend on a constitutional cause as the vesicular polypi.

Treatment.—The treatment of the gelatinous polypus is essentially mechanical; sometimes, indeed, if it is a soft one: some one of the astringent applications, before spoken of, for the vesicular kind, such as the strong solutions of zinc or copper, will effect a cure; but I have most frequently seen them fail: they are of great service, however, as you saw them used in Green, to assist the cure and prevent a return, and you may try them occasionally without operation, in which case you must use them stronger than the lotion employed in him, as they occasion less inflammation by themselves, than when used with the forceps. Green, you observed, had on one occasion a good deal of pain about the forehead and nose. You may dissolve as much a $\mathfrak{z}\text{j}$. of Sulphate of Zinc, or $\mathfrak{z}\text{ss}$. of Sulphate of Copper, in an ounce of water, if a weaker lotion has little influence.

The forceps should be rough, so that they may not slip off, and you should endeavour to place them as near the root as possible, the situation of which you will ascertain previously with the probe, and having laid hold of it, you twist the polypus off by turning the forceps, at the same time that you draw it down. In Green there was no bleeding to signify, nor is there in any case of gelatinous polypus; a little cold water, or a little piece of blue lint, will easily stop it, if there should be. The lotion, or ointment, or powder, which were before spoken of, are to be used when the bleeding has stopped; and in a day or two you examine the nostril again, and extract what may still appear to obstruct it, and let these applications be continued for some time, if there have been several polypi. In many cases, however, a single operation may be all that is required, and the root being perfect, nothing need be done subsequently. Sometimes, as you perceive in this preparation, a little piece of bone comes away with the root of the polypus; but as the bone has no share in its formation, it is quite as effectual to draw away the membrane from which it grows.

3. *Fibrous polypus.*—The fibrous, or sarcomatous, or fleshy polypus, is a more firm and solid, and a more highly organized tumor than the others; consisting of a fibrous tissue, with larger blood vessels, and with very little appearance of fluid effused in its interior. It is sometimes so solid as to cut with difficulty, and with a sound like that of fibrous cartilage, but it does not often attain so much density as this, and the pedicle is usually more condensed and fibrous than the expanded part of the

tumor. Like all fibrous tissue, it may undergo conversion in part into osseous matter, and I have seen one partly cartilage and partly bone, while another by its side has been of the usual texture. When you examine it in the living person it is seen to be of a reddish white or brownish colour, and is covered by a thin membrane, which is sometimes as smooth as a serous surface; its secretion also being more watery than what is commonly seen on the gelatinous polypus. Like the gelatinous polypus, it is generally situated on the outside of the nostril, but is more often seen further back, attached to some part of the posterior nares; perhaps it never grows on the softer structure of the æthmoid bone, but is now and then found in one of the cells. The fibrous polypus is often single, but there are sometimes several; it is, perhaps, always formed in adults, at least I have never seen one in a child.

Texture.—By many persons the fibrous polypus is distinguished from the other species, but not by all; by Sir A. Cooper, for instance, the fleshy polypus is spoken of with the gelatinous kind; by Boyer, whose description of polypus is on the whole the best I know, the vesicular and gelatinous species are included under the single name of mucous polypi, while fleshy polypi are spoken of separately, and divided into scirrhous and simple fleshy polypi, though curiously enough the characters of the two are exactly reversed. John Bell, and others, speak of these distinctions as imaginary, and thinks that the apparent differences are from different stages of the same tumor being separately described.

It appears to me that neither of these opinions is quite correct: sometimes, doubtless, the gelatinous polypus may gradually become more solid, till it is fibrous in texture; but in other cases a very small polypus is quite solid from its commencement. Sometimes, therefore, the fibrous polypus may be the sequel of the gelatinous; but in other cases it has no gelatinous condition, and in no instance can either form of disease be the sequel of the vesicular species. The difference between the fibrous and gelatinous polypus appears to me to arise from the textures which are affected; if only the mucous surface, then the gelatinous polypus will be the form of tumor; but if the whole thickness of the membrane is implicated, that is, the attached surface, which is the periosteum of the bones also, as well as the free mucous surface, then the polypus will be fibrous; sometimes, consequently, in the first instance; sometimes only in a later stage, when the diseased action has spread to the more firm tissue at its base. Thus, if a polypus grows from the upper parts

and middle of the nose, where the fibrous tissue is scanty, it is generally gelatinous; but if it be far back, towards the fauces, where there is a good deal of fibrous texture, the polypus is almost always fibrous: here, for instance, is a fibrous or fleshy polypus, removed by ligature from the back of the nostrils, in a patient from whom gelatinous polypi had previously been extracted from the anterior part of the cavity. Probably, from the same reason, the texture is softer in a polypus of rapid growth, and fibrous in one that has proceeded more slowly; and again the base is more fibrous than the pendulous part, being nearest to the fibrous tissue. The same causes may, therefore, give rise to both gelatinous and fibrous polypi, and the same patient may have both kinds at once: both are of the same nature, as far as malignancy is considered; but although both are of innocent nature, their difference of texture make the one a more important disease than the other.

Symptoms.—The fibrous polypus alone produces those severe and fatal effects which have been described, because it is only in this kind that there is firmness and vascularity enough to make the parietes of the nostrils yield to its pressure, in the way you can see has been done in this preparation. The bones, you perceive, are first expanded and altered in shape, the ossific deposit still going on in proportion to the interstitial absorption; then they are pushed aside and separated from each other, or the apertures of the nasal bones, or the cells, or the nasal canals, are widened and distended, and filled by projections of the tumor; then the growth is still more rapid, the bones are absorbed, but no fresh ossific material is allowed to form, and the polypus comes in contact with the skin or other textures in the face; the septum is absorbed, the nasal bones destroyed in part, or the orbit, or maxillary, or palate bones, are in great measure lost; finally, the skin becomes distended and discoloured: it is first of a dark red, then of a livid colour, then it is ulcerated, and the polypus fills up the ulcerated aperture, and the edges of the skin being everted and covered by thick florid granulations, and the projecting polypus being also vascular and fungous, and the surface bleeding as vessels are opened by ulceration and sloughing, the whole disease bears a very strong resemblance to a malignant tumor of fungous character. You have some of you had an excellent example of this fatal stage of the disease, in a patient under Sir Brodie's care, just a year ago, and you can here examine the nature of the tumor.

This was a man, 47 years of age, a gardener, who was admitted into the hospital, July 7th of last year, whose case was thus

described. His nose is much distended and enlarged by a tumor which fills the whole of the anterior nares. The tumor projects forwards from the face, stretching the parietes of the nose over it, and protrudes slightly through the anterior nasal openings; it is largest on the left side, and somewhat overlaps the eye. The nose has given way on the left side, and a fungous excrescence, of rather a brainlike appearance, about the size of a nutmeg, has protruded. The tumor is soft and elastic to the touch; the surface, where it is exposed, appears raw, and covered with irregular fungous granulations, disposed to bleed when touched, but not very painful. A probe can be passed round the tumor, between it and the parietes of the nose, in every direction, excepting on the left side; where it protrudes through the side of the nose, there are some adhesions between the tumor and the skin. The tumor does not extend far back, and cannot be felt from the palate; the septum nasi is perfect below, but perforated above, the tumor filling the right nostril from the perforation.

He states that twenty years ago he suffered from what was considered to be polypus of the left nostril: he was able at first to blow it out: it had the appearance of soft spongy flesh, the same nearly as at present protrudes through the nostril, and it would bleed when so blown out. Seven years after its first appearance, it was extracted with forceps, and has been so twelve or fourteen times since; it bled after the operation, and plugging the nose was once employed: the last operation was about two years ago, and two or three pieces of bone were then torn away. The tumor, before the last operation, was confined to one nostril, but has grown rapidly since, and increased greatly while he was ill and confined to bed, the early part of last spring (from March to April), with what he says was a violent purging. He is much reduced in flesh, and has been getting rapidly thinner. He has been in the Sheffield Infirmary since the tumor has been increasing, and has had lotions applied, but without benefit. No glands are enlarged. On the 20th, the tumor had increased, the ulcer of the skin had enlarged, and more fungus protruded, with much fever and irritation, and slight tendency to delirium. On the 23rd, he had severe rigors, with a pulse of 120, and the tongue became drier and browner. On the 26th, he was delirious again, with occasional rigors, and increasing debility. On the 28th, he had a fit of convulsions, succeeded by coma, and he died on the 29th, in this condition.

Thus, then, terminated a fatal case of polypus of the nose, which resembled very

much a malignant tumor before death; and you may see that the mass of disease is altered also, so as to be soft and brittle and more vascular, and to look like a malignant disease. It is said, indeed, by Alibert and Dupuytren, that this softening of a polypus in its later growth does not extend to its root, but you may see here that it reaches quite to the membrane from which it grows on the outer part of the nostril. Still, however, I believe that the resemblance is incidental only, and that the tumor was a single fibrous polypus, though I certainly thought that it must be malignant, till I had examined the disease thoroughly after death.

The essential characteristic of a malignant tumor is, its power of contaminating other structures contiguous to it; so that in several of these really malignant diseases you may see the bones converted into the same structure, the cells filled with new growth, and every texture nearly alike in appearance: examine the preparation on the contrary from the patient whose history I have just read to you, and you may perceive that notwithstanding its advanced stage, the disease is still entirely confined to the mucous texture and its fibrous outer part, so that you can separate the membrane from the bones, and they are seen to be perfectly unchanged in texture, though altered in shape, and in part absorbed by pressure: all the cells are perfectly healthy, though their shape is somewhat changed; and even the mucous tissue itself, except where the tumor originated, was quite healthy, being only thickened and more vascular, as might be expected; and at one point you may see a small gelatinous polypus attached to the thickened membrane.

Here, then, twenty years elapsed, and yet no other texture has been changed, and even a longer time has been known to have passed, at the end of which the polypus has still been simply fibrous. Some obscurity has been given to this subject by perversion of terms, such as that I have alluded to of Boyer, but still more from cases having been quoted again and again by different writers as examples of polypi, which were really instances of malignant tumors of other kinds. We shall return to them presently, after I have spoken to you of the treatment of fibrous polypi.

(To be concluded in our next.)

INOCULATION WITH THE MATTER OF "GREASE"

IN THE HORSE PRODUCING SYMPTOMS OF VACCINE IN THE HUMAN SUBJECT.

DR. STOKES presented two drawings of the appearances in a case which had recently occurred in Dublin, which was of

importance, as tending to corroborate the opinions of Jenner with respect to the origin of cowpock. For the opportunity of witnessing this case, Dr. Stokes was indebted to Mr. Pakenham, under whose care the patient had been placed. After quoting some passages from the works of Jenner, Dr. Stokes observed, that some had misunderstood Jenner's opinions on this subject, and believed that he had held that the direct inoculation with the matter of grease was capable of producing a disease the same as vaccine in man. This was not Jenner's doctrine. He says that the fluid of grease seems capable of generating a like vaccine, *after it has passed through the system of the cow*. But in speaking of the form of disease produced in man by inoculation with the matter of grease, Dr. Jenner was not distinct or accurate in his description. He speaks of ulcerated sores on the hands, inflamed lymphatics, and abscesses of the axilla, and says that many medical friends of his were aware of the similarity between the eruption on the hands after infection with grease, and that which succeeds cowpock, but he does not give any precise description of the appearances which result from inoculation with equine matter in the human subject. He states, however, that persons who have had sores on the hands from inoculation with grease, do not appear to be susceptible of small-pox, and alludes to the great difficulty frequently experienced in producing disease with variolous matters in farriers and persons who have been much engaged about horses. Dr. Stokes proceeded to read some notes of a case of equine infection, which occurred in 1793, and is detailed in Dr. Jenner's work. Three men, on receiving the infection of grease, got sores on the hands, with pains in the axillary glands, shivering, and lassitude; and two of them, who had previously gone through the small-pox, said that their sensations were similar to those they had experienced on the invasion of that malady. The whole duration of the febrile symptoms in these cases was about twenty-four hours. Dr. Stokes next exhibited a drawing of the pustule produced in a child by inoculation with matter taken from one of the men infected with grease. He also exhibited a drawing of the true vaccine pustule, and contrasted it with the former. The only apparent difference between them was, that there was a greater degree of lividity about the equine than the vaccine pustule. As a further proof of the close connexion between the two poisons, Dr. Jenner states that he has never been able to discover any instance of the prevalence of the vaccine pustule among cows, which

ld not be traced to cows originally in-

fected, or which had been milked by persons labouring under equine infection. The opinions put forward by Dr. Jenner on this subject were controverted by some of his contemporaries, among whom the principal was Dr. Woodville, who stated that he had made several experiments to try whether cowpock could be produced by grease, but had always failed, and that his friend, Mr. Coleman, of the Veterinary College, had made several experiments of the same kind with a similar result.

The case which had occurred to Mr. Pakenham was this: The servant of a gentleman residing near town, a man of good constitution and temperate habits, was in the daily habit of cleaning the hoofs of a horse labouring under grease. On one occasion the animal became restive, overturned the bucket in which the diseased limb was being washed, the edge of which cut the man over the upper lip. The groom immediately took up a sponge he had been using, and which was saturated with the matter of grease, and wiped his lip with it. He did the same the next day, and the day after, so that the matter was applied to the broken surface three, and perhaps four times. On the sixth day he became ill, complained of headache, lassitude, and loss of appetite. On the same evening a vesicle appeared on the upper lip, and next day another on the superior part of the cheek over the malar eminence; a third was placed more internally under the lower eyelid. Dr. Stokes saw him on the ninth day, and the appearances presented by the vesicles were such as were represented in the drawing he was about to exhibit. The drawing was taken on the tenth day. Dr. Stokes pointed out one of the pustules, and observed that on the ninth day it presented an appearance precisely similar to that of a vaccine vesicle, the areola being beautifully marked, and the vesicle so like that of a cowpock, that no distinction could be perceived. Around this vesicle there were several smaller and less regular ones. The original wound presented the appearance of a superficial eschar, and the cheek was swollen, but the constitutional symptoms were so slight, that the man was up and walking about. The case was seen by several medical men familiar with the phenomena of cowpock, and all agreed that nothing could be more like it. Dr. Stokes exhibited also another drawing of the parts taken on the 15th day, and observed that the appearance of the scab and of the retreating areola were very similar to those observed in the same stage of ordinary vaccinia. The chief interest of the case was, that it exhibited a form of disease originating in equine infection, and having certainly no connexion with glanders. He had hoped to be able to

procure a drawing of the horse's heel, but had not been so fortunate as to obtain it. The case shewed that a disease remarkably similar to vaccinia might be produced in the human subject by the matter of grease. The only points of apparent difference between them were, that in the latter the matter contained in the vesicle seemed more purulent, and the surrounding areola somewhat more livid.—*Dublin Journal of Medical Science.*

SMALL-POX STATISTICS.

To the Editor of the Medical Gazette.

SIR,

PERHAPS I ought to be frightened at the tone of Dr. Gregory's letter, and abstain from any allusion to it; but I hope I shall not repent my audacity if I venture two or three exculpatory lines. In your former volumes, and in the daily press of the present year, I have seen letters which convince me that enemies to vaccination still exist, who would rejoice to find an unfavourable statement; and I have no reason to think that they would be more successful in detecting the inaccuracy of such a statement, than your note to my former letter shewed yourself to be. I was therefore justified in calling attention to a material uncorrected error, which might be mischievously used. I am at a loss to know why Dr. Gregory should choose to notice that *manifest* is spelt *manifest* in my letter, unless he wishes to intimate that the difference between *vaccinated* and *unvaccinated* is equally unimportant; but if his notions are really so confused, it furnishes him with the best excuse for treating as identical assertions—your statement "that there is no proof whatever that with cow-pox any other disease can be communicated," &c. and the opinion which he groundlessly charges upon us, of "the impossibility of communicating any other disease along with cow-pox."

It is rather cruel on his part to say that I do not specify reasons for the manifest duty of selecting healthy lymph, since, had I done so, I might have been censured for needless prolixity or clumsy logic, in specifying reasons for a duty which I had just before declared to be manifest. There can be no doubt that the duty is manifest, since not even the atmosphere of the Small-Pox Hospital is murky enough to conceal the truth from Dr. Gregory, who advances two reasons in proof, of which the first is quite sufficient for every friend to vaccination. I might easily imitate him by pointing out what he has not said, as well as commenting upon what he has said; but he writes so loosely and unfairly

that no good could arise from following him up. Reply would beget rejoinder, and criticism be succeeded by explanation, until many of your valuable pages would be fruitlessly expended; and the only result would be, that when your patience was exhausted, your readers as well as yourself would heartily wish us both in that place where the "wash and rapidity" of small-pox statistics ought to be deposited.—I am, sir,

Your obedient servant,

HENRY COLES.

Cheltenham, July 20, 1840.

MR. OWEN AND HIS REVIEWER.

We subjoin a letter from our reviewer, in reply to Mr. Owen. On perusing it, we think that all will concur with us in regarding it as a document which alike by its brevity, moderation, and freedom from personalities, forms a striking contrast to the one which we had last week the pain of laying before our readers.

COURT APPOINTMENTS.

THE Queen has been pleased to appoint Charles Locock, Esq. M.D. to be first Physician-Accoucheur to her Majesty; Robert Ferguson, Esq. M.D., to be second Physician-Accoucheur; and Richard Blagden, Esq. to be Surgeon-Accoucheur.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, July 16.

R. J. P. Steel.—C. P. Keel, Southampton.—W. C. Walker.—J. Good, Lymington, Hants.—G. Goodwin, Ashbourne, Derbyshire.—J. W. Edmonds.—J. Davies, Colleshill.

METEOROLOGICAL JOURNAL.

Kept at EDMONTON, Latitude $51^{\circ} 37' 32''$ N.
Longitude $0^{\circ} 3' 51''$ W. of Greenwich.

Prevailing wind S.W.

On the 15th and two following days generally clear. The 18th cloudy, with rain. The 19th, noon clear, otherwise cloudy; rain in the morning and evening. The 20th, morning clear, otherwise cloudy, with rain. The 21st generally clear, except the afternoon, when rain fell.

Rain fallen, .145 of an inch.

CHARLES HENRY ADAMS.

WILSON & OGILVY, 57, Skinner Street, London.

STRUCTURE OF THE TEETH—REPLY TO MR. OWEN.

To the Editor of the Medical Gazette.

SIR,

WHEN, after a full discussion of the merits of a question, one of the parties to a controversy, in default of legitimate argument, resorts to abuse and misrepresentation, he signifies very efficiently that his cause is hopeless, and at the same time he spares a respectable adversary the necessity of replying. To Mr. Owen I shall not degrade myself by addressing one word on his letter appended to the *GAZETTE* of last week. I shall leave its coarse personalities—its repetition of already refuted arguments—its gratuitous assumptions—its confused and unintelligible statements—and its columns of irrelevant matter, to produce their natural effect upon the mind of the reader.

In my last article on this subject, I accused Mr. Owen of fabricating evidence by falsifying a quotation, and to this charge he has not found a word to say in reply. Indeed, so far from taking this warning, or disowning such an unworthy system of attack, he pursues it zealously. The following instance of veracity and fairness, in his letter of last week, speaks for itself:—

“As to the paragraphs,” (he says—*MEDICAL GAZETTE*, No. 43, p. 661*.) “which next follow in the *Literary Gazette* report, and which include the illustrations of Mr. Nasmyth’s notions of dental development by deposition of thin ossified layers of ivory, or the transition of peripheral layers of detached cells with central points on the pulp’s surface, and which illustrations he adduces from the known facts of the laminar decomposition of the mammoth’s tusks, and the alternate strata of red and white produced by Hunter’s experiments with madder, and which Mr. N. asserts to be a result incompatible with any other theory—as these paragraphs, I say, are too stubborn to be made to tell the new story by any process of transposition and mutilation, they are wholly omitted in the proof now in type in the published Abstract, prepared, despite his quibble, by Mr. N. himself; they occupy one column and a half of the closely printed page of the *Literary Gazette*, l. c. p. 598; thus we have the curious phenomenon of the abstract being longer than the memoir; the part greater than the whole.”

“I thought my conjecture, in my letter to Professor Phillips, as to the requisite extent of mutilation to produce conformity, somewhat hazardous; but the quantity of unsound parts in the original memoir,

which the author has found it essential to excise, surpasses all anticipation.”

The whole of this statement is utterly false. The passage in the *Literary Gazette*, referred to by Mr. Owen, occupies only half a column, and instead of being omitted in the memoir is there given as follows:

“The laminated cellularity of the ivory, which Mr. Nasmyth had shown was a natural consequence of the cellular structure of the pulp, was also borne out, he thought, by facts coming under daily observation, or recorded by scientific inquirers, which could not be explained by any other theory: viz., by the evidently laminated and concentric structure of the teeth of the mammoth, which is rendered directly evident during their decomposition by the experiments of Hunter on the teeth of animals fed on madder, by the circumstance that ivory is found to possess considerable strength, if cut parallel to the long axis of the tooth, and that it is weak if cut at the right angles; and also by many other phenomena of frequent occurrence. When a man persists in resorting to such a mode of warfare as this, I am sure the reader will excuse my declining the contest.

Again, the following extract from the *MED. GAZ.* of Jan. 17, 1840, will enable the reader to judge of the value of Mr. Owen’s latest discovery: viz. that Mr. Nasmyth is guilty of plagiarism from Schwann.

“We are requested by Mr. Nasmyth to state that the report of his paper on the structure of the teeth, read at the meeting of the British Association, in August last, and published in the *Literary Gazette* of Sept. 21st, from which we drew the materials for an article inserted in this journal on the 3d of the present month, errs in attributing to Mr. Nasmyth, instead of Mr. Schwann, a recent German writer, the comments on Purkinjé and Raschkow, given at the conclusion, in the summary of foreign authorities on the subject; and also the comparison between the ossification of cartilage and the formation of dental bone.” By this it appears that the passages adduced by Mr. Owen, as stolen from Schwann, had already been expressly pointed out by Mr. Nasmyth, as extracts from the German author.

The newly introduced absurdities regarding the translation of Retzius, and the capsular investment of the tooth, are too ridiculous to require notice.

Mr. Owen’s misrepresentations stand in no need of further comment; his repetitions require no fresh argument; and to his abuse I avow myself incapable of replying.

Your obedient servant,

THE REVIEWER OF MR. OWEN’S WORK.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

—
DISEASES OF JOINTS generally.—*Those of particular Tissues.*—The SYNOVIAL MEMBRANE.—The ARTICULAR CARTILAGES.—SCROFULOUS DISEASE.—DISEASES OF PARTICULAR JOINTS.—The HIP and the KNEE—their Characters, their Diagnosis, and their Treatment.

SYNOVIAL INFLAMMATION.

THIS affection may extend from adjoining parts, or begin in the membrane itself; but we confine ourselves here to the latter. It seldom attacks young children, is less rare towards puberty, is frequent in adults; this is the reverse of what happens with respect to some other of the diseases of the joints. Where it is a consequence of some constitutional cause, such as gout, rheumatism, syphilis, &c. it is usually not very severe. It may succeed to physical injuries, but the most frequent source of the disease is cold. It may leave the joint with its functions impaired, or may totally destroy it. For the most part it is a chronic or slow inflammation, which, while it impairs, does not altogether destroy the functions of the joint. Pain is at first usually referred particularly to one spot; it increases for a week or ten days, and even then may not be very great; sometimes, however, it is very distressing. In a day or two after the pain begins, swelling may be apparent; this swelling at first arises from a preternatural collection of fluid in the joint. When the inflammation has existed for some time,

the fluctuation is less perceptible, because the membrane becomes thickened. The form of the swelling is peculiar; it results from distension; the ligaments at certain points resist its progress, and give it a somewhat lobulated appearance. After synovial inflammation has subsided, the fluid is absorbed, and in some instances the joint regains its natural figure and mobility; in others the stiffness and swelling remain, and the patient is then very liable to a recurrence of the disease. In some cases the disease is more acute; the swelling is then almost coeval with pain, the skin is red, the pain severe, and greatly aggravated by motion at the part; with symptomatic fever. In a few days, if left to itself, the disease may assume a chronic form, or subside altogether.

Treatment.—When the disease is complicated with rheumatism, opium, combined with ipecacuanha, or other diaphoretics, colchicum and mercury, may be preferred. Where many joints are affected, colchicum wine, in doses of fifteen to thirty minims, three times a day, I prefer. Where only one or two joints suffer, calomel and opium, in such doses as to affect the system, may do best. Where syphilis has to do with it, a well regulated course of mercury will probably cause it to disappear. In most cases, however, our principal reliance must be on local remedies. In the acute form of the disease leeches and general bleeding may be required. If the swelling be sudden, and the pain be great, warm fomentations and poultices may relieve; otherwise, cold lotions do better. Chronic inflammation does not so easily subside: the joint must be kept perfectly quiet; blood must be abstracted locally by cupping or leeches (the former is the surer and preferable mode;) it may be necessary to repeat it two or three times; in the intervals cold lotion must be kept to the part. When the inflammation has subsided, one or a succession of large blisters may be used. If the joint be

much distended, it may be punctured. The puncture, if it be small, will give only present relief, for the joint will quickly fill again. If suppuration has taken place, a free opening into it will often be attended with the best effects. The most prudent method is first to puncture with a needle, and ascertain the nature of the fluid; if actual pus, the lancet may be used afterwards. When inflammation is in a great measure relieved, rubefacients are often useful. Issues and setons are useful in chronic cases. No other active remedies seem to be of much use; but much may be done by negative treatment, especially by absolute rest. Stiffness and thickening may be much relieved by slight moxas, by passing a red-hot iron very lightly and quickly over the surface, or by friction after the plan of Grosvenor; but this remedy should always be used with caution, as it has sometimes occasioned the return of inflammation. Warm douches are also useful, as well as the vapour bath, but all these methods require time and patience. It is often very difficult, without, or even with a previous history, to determine whether synovial inflammation, or "ulceration of cartilages," has been the primary affection; but this is of less importance, because, whatever the origin, when it has proceeded far the treatment is the same; and generally, when suppuration has taken place, removal of the limb alone promises much success.

THICKENING OF THE SYNOVIAL MEMBRANE.

As to *thickening* of the synovial membrane, in which that tissue loses its natural organization, and becomes converted into a thick pulpy substance, of a light brown, or sometimes of a reddish-brown colour, the disease, says Sir B. Brodie, generally takes place not long after puberty. In the origin of this disease there is a slight stiffness and tumefaction, without pain or much inconvenience. These symptoms gradually increase. In the greater number of cases, the joint at last scarcely admits of the smallest motion. The form of the swelling bears a certain resemblance to that of synovial inflammation, but it is less regular. The swelling is soft, elastic, and gives the sensation of a fluid. There is little or no pain till abscesses form, and the cartilages ulcerate; the abscesses heal more readily, and discharge less pus, than in the latter disease. At this period hectic is developed, and unless the limb be removed the patient gradually sinks. The progress of this disease is variable; generally two years elapse before it arrives at its last stage. The *diagnosis* is seldom difficult. The gradual progress of the enlargement, and stiffness

of the joint, without pain, and the soft elastic swelling without fluctuation, in the majority of cases enable us to distinguish it readily from all the other morbid affections to which the joints are liable, except those of chronic inflammation of the synovial membrane, with which it may be confounded.

Treatment.—We must not be sanguine that a remedy will be discovered for this affection; very many have been tried and failed. By means of rest and cold lotions, the progress of the disease may be somewhat checked. If there be much pain from ulceration of cartilages, some benefit may be derived from warm fomentations or poultices; but no method seems to be capable of more than checking somewhat the progress, and relieving symptoms. In every case, towards the termination, there is ulceration of cartilages, formation of abscesses, and consequent general disturbance, which render amputation necessary as a means of saving life.

Many illustrative cases of these several varieties of synovial disease may be found in his very able work. "A man was admitted into St. George's Hospital, with swelling of the knee, accompanied by pain, rigidity, and fluctuation. These symptoms yielded to the use of liniments and blisters. Two months after he died of fever. Upon examination, the synovial membrane was found distended, so that it was pushed out to about the extent of an inch and a half beyond its ordinary limits. Throughout, except where it covered the cartilages, it was of a dark colour, resulting from inflammation, and was as much injected as the conjunctiva in ophthalmia; at some points coagulable lymph lined the capsule. A young man felt a painful tumefaction in one knee, which he attributed to cold. Different remedies were employed; another disease of the leg required amputation, and the knee was examined. The bones, cartilages, and ligaments, were in a natural state; the synovial membrane was the eighth of an inch thick, and converted into a cartilaginous structure, and was strongly adherent to the cellular tissue around. A girl, of nine, fell on the hip; she suffered little inconvenience, walked out during the day, and danced at night, but felt a rigor which obliged her to return home and go to bed. The next day she complained a good deal of the hip, and of the knee of the same side; fever was developed, which increased, until she became delirious, and in a week she died. Twenty-four hours after death her body was examined: the viscera were healthy, but the hip-joint contained half an ounce of dark pus, and the synovial membrane, at the point where it is reflected upon the head of the femur, was ulcerated to the extent of a shilling. A

man having suffered a contusion of the shoulder, it was followed by tumefaction and severe pain at that joint. A nervous fever, which attacked him after the accident, destroyed life in a few days. Upon examination, half an ounce of pus was found in the shoulder joint. The synovial membrane was inflamed and ulcerated to the extent of a sixpence, at the point where it is reflected upon the neck of the humerus. In all these cases we see that this membrane alone was affected, presenting the different degrees of inflammation that we have admitted. Most commonly, however, the disease extends farther, invading other tissues of the joint, as we shall see hereafter.

Ulceration of Cartilages.—Can articular cartilages ulcerate? So great an authority as Brodie, we find, is of opinion that they can, at any period of life, but that the most frequent instances are found between the period of puberty and thirty five; that it usually affects a single joint, but may attack two or three; that it forms the great majority of those cases of caries of the hip-joint which occur in adult persons.

It is, and has long been, customary to describe inflammatory action, and the many changes it brings about, as affecting the synovial membrane, covering the articular cartilages. Nesbitt and Hunter first spoke of this covering, but never demonstrated it. Bichat and his disciples only admitted it analogically, and few persons have contradicted them. Gordon, many years ago, said that it was a mere anatomical refinement, but his opinion rested on assertion only. John Bell and Dorsey asserted that diseases never began in it; Cruveilhier and Magendie have reiterated it. Certainly the scalpel demonstrates that it terminates at the circumference of the articular facets. The transparent pellicle, which can be detached by separating, slowly, a slice of a diarthrodial surface, is, I apprehend, a portion of the cartilage itself, and has no relation with the adjacent synovial membrane. Exposed in a living animal, it may remain an indefinite time in contact with the air, may be touched and irritated, without ever becoming injected, reddened, tumefied, or in the least painful, whilst the proper synovial membrane is intensely inflamed. The general opinion is, that if the tissue of articular heads be injected, it is spongy easy to see that instead of expanding and diverging in the cartilage, the arteries and veins form arches in the osseous tissue itself; that cartilages are formed of perpendicular filaments, or superposed plates, if they be not homogeneous, containing neither vessels, nerves, nor cellular tissue, being in all things similar to the enamel of the teeth, from which, according to Cruveilhier and Larrey, they only differ in cohesion and hardness; that their appear-

ance is so fixed that nothing can change it; that in disease there is no mention of redness; that if they disappear during disease, it is by "erosion," solution, or molecular absorption; that, however much may be destroyed, what remains is unchanged; in fact, that it is physically altered, but not diseased. Morand found, in examining Madame Sapiot, in whom all the bones were softened, that the cartilages of the hip and the knee were perfectly healthy. This opinion Sir B. Brodie has long combated; and, to a certain extent, his views have lately received a kind of confirmation, which was previously wanting; Mr. Liston having, it is believed, succeeded in injecting cartilage. He very kindly allowed me to inspect his very beautiful specimens, and I am not prepared to say that the opinion of their being injected is incorrect. That injection passed along a canal in the inflamed cartilage I cannot doubt, but the injection did not seem to me to branch out or radiate from this canal through the cartilage; it passed along to the surface, and there was fairly extravasated between the cartilage and a layer of lymph, and partly, perhaps, penetrated that lymph. It is true that there are other tissues in which vascularity cannot be demonstrated in the state of health, though it can when they are inflamed; but in those cases vascularity is then very decided, which is not the case with cartilage.

Sir B. Brodie maintains that articular cartilages may be primarily inflamed and ulcerated; that the ulceration may and frequently does begin on its articular surface, and that the inflammation may extend to the other tissues of the joint; that the cartilages may here and there be changed into a fibrous mass, that they may be ulcerated at many points, and that the articulation may be filled with fetid pus; and that this affection is altogether different from ordinary inflammation of the synovial membrane, and the spongy extremity of bones. To this view of the case it is objected, that the so-called ulcerations were mechanical destruction, or a breaking down by caries: certainly, in most of the cases, there was a softened or carious or tubercular bone below the ulcer; the cartilage not being tumid or vascular.

It is said that this inflammation and ulceration may be seen at all ages, but that it is most frequently seen in young persons; most commonly in the hip and shoulder joint.

The only symptoms of this disease met with for some time, says Brodie, are pain; and if the articulations of the lower extremities be affected, pain and a slight degree of lameness in the lower limb. The pain at first is trifling and only occasional, afterwards severe and constant. It resembles

a good deal the pain of rheumatism, since it has often no certain seat, but is referred to different parts of the limb. As the disease advances, the pain becomes exceedingly severe, particularly at night, when the patient is continually aroused from sleep by painful starting of the limb. As the pain increases in intensity it is more confined in its situation. Wherever the pain is situated it is aggravated by the motion of the joint; but it is aggravated in a still greater degree by pressure of the articular surfaces one against another. This disease may be confounded with inflammation of the synovial membrane, the scrofulous affection having its origin in the bones; a painful nervous affection occurring in hysterical females; and certain affections of the sciatic nerve.

The principal *diagnostic* mark is the pain which is experienced at the beginning, unattended by swelling, and which is invariably increased by pressing the articular surfaces one against another. The pain is referred to the point which is the actual seat of the disease. Whatever joint is affected, the formation of abscess is always attended with an aggravation of the symptoms; but the degree in which the general system is disturbed when suppuration is established, depends on various circumstances—the age, the power of the patient, size of the joint, and its situation. In its progress the disease is generally tedious.

The *prognosis* is always unfavourable, for at its commencement the disease is frequently mistaken, and it rapidly brings about structural change in the constituents of the joint.

Treatment.—It is of course important to attend to the patient's general health. Undoubtedly there is no medicine of which it can be said that it exercises a specific influence over the disease; but Brodie cannot doubt that a course of sarsaparilla properly prepared and administered in full doses, is often productive of the greatest benefit. When the cartilages of a joint are ulcerated, it may well be supposed that the motion of their surfaces on each other must be favourable to the progress of ulceration. "I have known some cases in which rest alone was sufficient to produce a cure." I have employed caustic issues, and seen them employed in a great number of cases, and have found them usually to be productive of singular benefit when the cartilages are in a state of ulceration. Blisters and setons seem to act nearly in the same manner as caustic issues. Local and general bloodletting is in an early stage of the disease productive of advantage, and in the same stage the warm bath will be found serviceable. Friction is invariably injurious.

Scrofulous disease.—In scrofulous disease

of joints, the cancellous structure of the bones is the part primarily affected, "in consequence of which ulceration takes place in the cartilages covering the articular surfaces." The cartilages being ulcerated, the subsequent progress of the disease is in many respects the same as when the ulceration of the cartilage takes place in the first instance. I apprehend many of these cases in which the texture of the bones is softened, and yellow cheesy substance was deposited in their cancelli, were cases of tubercular deposition, such as I have already described. "This disease is frequent in children; rare after thirty: it may affect several joints together or in succession: it is rarely met with except in persons who have marks of a scrofulous diathesis. It is not unlikely to be confounded with ulceration of cartilages. Before the disease has extended beyond the cancellated structure, or any swelling is apparent, pain is experienced; generally however it is not severe: after a time parts external to the joint sympathise; tissues become infiltrated, and the joint appears swollen; the swelling is puffy and elastic. If no suspicion of disease existed before, it is always awoken by the swelling. It increases, but not uniformly, and especially after exercise. As the cartilages continue to ulcerate, pain is aggravated, but is not severe until abscess has formed: the abscess bursts, or is opened, and thin curdy pus discharged; it becomes gradually thicker, and very closely resembles the cheesy matter of scrofulous glands; other points give way, and continue fistulous. It may remain so for months without occasioning much disturbance: in some cases hectic comes on, and unless the limb be amputated the patient sinks; at other times the sinuses close, the œdema subsides, and the patient ultimately recovers with or without ankylosis.

Treatment.—In treating this condition it must be borne in mind that the system is at fault, and therefore general is almost as necessary as local treatment. I cannot say that the abstraction of blood from the part is never useful, but certainly it is seldom necessary. If there be an accidental supervention of inflammation, leeches and cold lotions may be employed with advantage. It rarely happens that good is obtained from blisters or liniments, or counter-irritation. I much doubt whether setons and issues are ever useful, except there be great pain and spasm. There is, however, one rule respecting local treatment, which is applicable to all cases, and which can never safely be disregarded. The diseased joint should be kept perfectly quiet, because motion is likely to promote ulceration, and hasten the formation of abscess. During the formation of abscess, fomentations and poultices should be used

to relieve pain. When, after the formation of several abscesses, the disposition to suppurate lessens, anchylosis, as a curative process, is about to commence; circular pressure around the limb will then be useful. As to constitutional treatment, a residence on the sea-coast is desirable; the diet should be plain, but nourishing. It appears to me preparations of steel are more useful than any other medicines; they must be continued, with slight intermissions, for a long time, until their exciting action may render it prudent to suspend them. In some cases, the liquor potassæ, with bitters, is useful; in others, iodine and its compounds will be found to act beneficially. When the organization of the joint is destroyed, and the health is failing, recourse must be had to amputation.

In the preceding description of articular inflammation affecting severally the tissues of a joint, I have adhered as closely as was compatible with the necessary condensation to the text of Sir B. Brodie, except as will have been seen, questions have arisen, as in ulceration of cartilages.

There are two joints where these affections are often seen, and where a more detailed consideration is necessary—the hip and the knee.

COXALGIA OR MORBUS COXARIVS,

is a complex affection of the hip joint, the nature of which is not unlike the so-called *white swelling* of other joints. Hippocrates speaks of it, (Aphor. sect. 6, Aph. 59 & 60;) and he even knew the actual cautery used for its cure. Asclepiades, the Bythnian, also speaks of two cases in which dislocation had occurred: Galen believed it to be owing to a relaxation of the ligamentum teres. The Arabs seem to have had more definite ideas of the disease. Albucasis points out a cause, which was indicated afterwards by Petit, in the first work of any importance on the subject: the Arab says that it sometimes happens that mucus accumulates in the hip-joint and causes luxation. We recognise it by the increased length of the diseased limb, and the void which is observed at the displaced point. Petit is the first person who well described the disease. It particularly affects children from three to fourteen, yet it may be seen at an earlier period: Camper has often seen it in children of eighteen months; Morgagni at a still earlier period; and Richter gives cases in which the disease was congenital. But it may be developed during adult life. Fieker met with it in a person of thirty-eight; Albers in one of forty-five; Paletta and Kraack in men of fifty.

The disease usually begins by a pain in the hip; more or less acute if it succeed to a blow over the trochanter; dull and deep

seated when not excited by accident; sometimes only felt at intervals, at others having an erratic, rheumatic character. It increases, however, becomes more fixed, is felt above or below, though sometimes at the level of the articulation, sometimes in the groin; it is increased by pressure and motion of the limb, and it is then usually very acute. Sometimes it is felt at the knee or along the whole limb. The pain at the knee or the ankle is often so severe as to mask the hip disease. The sign which Boyer pointed out, “that pressure on the knee does not increase the pain,” is, I believe, a theoretical idea, for instances to the contrary are often seen. The absence of tumefaction at the knee is not always a distinguishing sign. The pain is often accompanied by contraction of the flexor muscles, so as to oblige the patient to walk on his toes. There is usually developed about the same time a fulness of the superior part of the thigh. Still, although the patient is lame, there is no very decided change in the length of the limb; and it is not easy to state upon what this lameness depends: to a certain extent it may be owing to feebleness of the limb; to some extent to pain. If at this time the two limbs be measured, we shall probably find the diseased limb a trifle the longer.

Such are the three principal characters of this period of the disease—pain, elongation of the limb, and lameness. To these a new series of symptoms succeed: the elongation is replaced by a shortening, varying in extent with the age of the subject, and to circumstances to which we shall presently advert. The shortening is accompanied by all the symptoms of luxation upwards and outwards; that is, the knee and foot are rotated inwards; the great trochanter being directed upwards and forwards. It may occur suddenly: thus Desault has seen shortening occur to the extent of two inches in a single night. In many cases the great trochanter is drawn upwards by the glutæi muscles; then the shortening supervenes without any change in the direction of the limb. Again, in some cases there supervenes suddenly an elongation or increased elongation of the limb, sometimes assuming the appearance of luxation into the foramen ovale, by the contraction of the pectinæus and other muscles.

Inflammatory action goes on, and pus is formed in and around the articulation; it approaches the surface, and points. We recognise it by the more defined tumefaction, diminution of pain, and fluctuation. The most common situation of purulent collections, is the external part of the thigh; sometimes they are seen at the internal surface. When they are marked by in-

flammatory symptoms, they usually point in the buttocks. According to Dzondi, it is at this time the acute pain at the knee is felt. Whether we open these abscesses, or leave them alone to break, they pour out ill conditioned pus. The openings often close after a short time, and new ones are formed and become fistulous; the patient becomes emaciated, and sometimes sinks under the severity of the pain and the abundance of the suppuration, which produce hectic fever and death. I should mention that cases have occurred where abscess and death have supervened without any change in the length of the limb. In those cases Boyer believed that caries was limited to the circumference of the cotyloid cavity.

If we have opportunities of examining the bodies of those suffering from this disease at an early period of its existence, we shall find the soft parts external to the joint infiltrated with purulent serum; here and there it is collected in the form of abscess. Sometimes these collections are considerable before any external opening has been formed; the muscular tissue, through which this fluid is disseminated, is much changed, and the aponeurosis is perforated. If the abscesses have burst we shall see fistulous canals extending to the joint, the original seat of irritation. The articular capsule is often partially destroyed; sometimes it is not perforated; and there is occasionally a communication established by the breaking down of a part of the circumference of the cotyloid cavity. The fatty matter, termed synovial glands, and found at the fundus of the cavity, sometimes becomes tumid, and expands to such an extent as nearly to fill the cavity. The ligamentum teres is sometimes strained and elongated, but more frequently completely destroyed; the same fate attends the periosteum covering the neck of the femur and the border of the acetabulum. The cartilages covering the head of the femur and the cavity of the acetabulum are thickened and softened, according to some; strained and destroyed, according to others. However, we frequently find bones denuded, and, consecutively, caries is often developed in the contact with pus. Sometimes caries affects the fundus of the cavity, and the purulent matter may find its way into the pelvis; may even perforate the organs contained there. Sir A. Cooper refers to two cases in which it had found its way into the rectum. Often the head of the femur is the principal seat of alteration; at other times, in the midst of much disease of the cavity, it is little affected.

The relations of parts seem to be changed by the destruction of parts; the femur, shortened by the alteration of the head, sinks deeper into the cavity, also hollowed

by caries, so that the occasional shortening may be thus explained: indeed, Larrey believes this to be the ordinary explanation of it, and that displacement is exceptional. However, we find the head of the bone in the iliac fossa with sufficient frequency to establish that as a not very unfrequent cause of shortening.

When the bone is displaced, the limb shrinks; the muscles are enfeebled or atrophied by want of use. Nelaton believes that this atrophy is accompanied by a decrease in the length of the femur: this atrophy, which does not confine itself to the femur, but to a certain extent affects the leg, must not therefore be forgotten in making out the cause of shortening. Petit attributed this dislocation to an accumulation of synovial fluid, which distends the capsule, causes pain and relaxes the ligaments, so as to render them unable to resist the tendency to displacement upon motion. Sabatier, Desault, and Boyer, denied this dropsy, which they had never seen, but which others have. A case is described by Lesauvage, of Caen, in the *Archives Gen.* 2de serie, tome 9, which directly supports Petit's opinion: a case is also mentioned by Brodie. Those who do not deny the existence of dropsy of the joint, yet say, while the accumulation is going on there should be lengthening up to the moment of displacement, when the limb would be drawn up by muscular action. There can, however, be no question, I apprehend, that lengthening of the limb does occasionally happen, but I believe Sir B. Brodie's explanation will account for many cases of apparent lengthening. He believes that in all cases the lengthening is only apparent, not real, and that it is caused by obliquity of the pelvis. The body resting on the healthy side, the pelvis of that side becomes elevated, and the other side proportionably depressed. The inclination of the pelvis is necessarily accompanied by a lateral curvature of the spine, and then one shoulder is higher than the other. All these symptoms may disappear at the end of a few weeks, if the horizontal position be preserved, unless the deformity have existed long, and the patient be young. From this direction of the hip, an apparent lengthening of the limb is the necessary result. He believes that the shortening which is sometimes presented at an early period has nothing real in it; but putting aside both shortening and lengthening, he believes the disease to be an inflammation of the synovial tissue of the joint, or a scrofulous affection of the bone itself; that its most frequent cause is primary ulceration of the cartilages, progressive destruction of the osseous surfaces, and, as a consequence, a true shortening. Boyer admits as probable, that at the commencement of the

disease the cartilage which lines the cotyloid cavity, that which covers the head of the femur, the ligamentum teres, and the so called synovial gland, are tumefied; that this tumefaction, by destroying the proportion which ought to exist between the diameter and depth of the cavity and the head of the femur, produces that elongation which he thinks is almost always observed at this period. He mentions the case of a person who died from the consequences of luxation, consequent upon contusion; he discovered that the displacement resulted from the cartilaginous surfaces; that this tumefaction had almost effaced the cotyloid cavity, and elongated the head of the femur. The etiology of Petit having been abandoned, many persons have inclined to the opinion that luxation is commonly produced by inflammatory tumefaction of the diarthrodial cartilages, the synovial apparatus, and the ligamentum teres. Among the supporters of this opinion are Schwenke, Gorter, Vermandois, Van Swieten, Camper, Callisen, Plenck, Dehaen, Portal, and Boyer. If we find sarcomatous masses in the cotyloid cavity, certainly the displacement is easily explained. Yet these sarcomatous masses, and even the tumefaction of cartilages and the synovial apparatus, are not constantly met with, even after the dislocation has been effected. I recollect a case in which the head of the femur was entirely carious, and smaller than usual; it had escaped from the acetabulum and rested on the descending ramus of the ischium; there was no trace of round ligament, but the cotyloid cavity was very little changed. Observations like that induced Rust to seek other explanations; he sought to prove that the disease begins in the head of the femur; that it commences with inflammation of the medullary membrane, with a tendency to ulceration; that it ends by degenerating into a deep-seated central caries, and that this caries extends from the centre to the circumference; that at a later period the head of the femur, enormously swelled, obliges the great trochanter to direct itself downwards and outwards; that an elongation is thus produced, which may extend to four inches. At other times, on the contrary, the muscles draw the head upwards, as it is expelled, producing a shortening which may cease at intervals, and is never so complete as that which supervenes as a consequence of consecutive luxation. He adds, that if post-mortem inspections do not always support this view, it is because in those cases inflammation and caries of the cotyloid cavity were the consequences of disease previously existing in the pelvis.

A careful examination of a large number of specimens preserved in museums has

convinced me that the head of the femur is more frequently diseased than the cotyloid cavity: the head of the femur may unquestionably be attacked with central caries, and this caries may extend from the centre to the circumference. Still, I am far from thinking that the theory of Rust applies to all cases of hip disease. Caries of the head of the femur, or of the cotyloid cavity, only belong to one variety of the disease. How does the theory of Rust explain the dislocation, when the head of the femur, instead of being larger, is smaller than natural? atrophied. Berard saw the case of a grandson of Condoreet, in which the head of the femur on the diseased side was more than a third larger than the healthy one; the acetabulum had enlarged to contain it, and the articular cartilages were healthy. Dzondi, admitting the correctness of Boyer's reasoning as to lengthening, which he believed to be constant in the first period of the disease, maintains that the disease is always caused by rheumatic irritation, affecting the external surface of the capsule as well as the fibrous tissues connected with it, as well as the periosteum which surrounds the cavity and the superior part of the femur. Fricke maintains that two diseases have been confounded under one denomination: the one coxalgia, caused by relaxation of the muscles without disease of the joint; the other, a true inflammation of the articulation. In the first, elongation is constant; in the second, there is acute pain; and to ease that pain, there is vigorous muscular action, by which the head is firmly pressed upon the cavity so as to create a shortening.

In all these explanations two things must not be confounded, the facts and the explanations. Brodie, Bichat, and Rust's observations are incontestable, though different—but are their explanations equally incontestable? My own opinion is, that the lesion is complex, and, therefore, that the appearances upon examination are not identical. Now, with respect to the pathognomonic symptom, lengthening, it is certain that since attention has been directed to the inclination of the pelvis, it is rarely met with: we are, therefore, bound to admit that former observers overlooked the circumstance. It is clear, then, that the elongation of the first period may be simulated, by the depression of the pelvis on the diseased side; or being real, the cause remains to be determined; that in the second period the symptom may be real, and a consequence of luxation into the foramen ovale; that the shortening in the first period may be simulated by the elevation of the pelvis on that side or it may be real, and be owing to muscular contraction, which draws up the head of the bone, pushed out of the cavity,

by an accumulation of synovia, the tumefaction of the soft parts within the articulation, or other cause; that in the second period it is owing to the destruction of the articular surfaces; to a displacement into the iliac fossa, or, according to Dzondi, to a change in the direction of the neck of the femur. Many or all these causes may concur to produce this effect; for instance, we may find, in the same case, atrophy of the limb, ulceration of the articular surfaces, and a vicious inclination of the pelvis.

In making an examination for the purpose of determining whether there be any change in length, there are three positions in which the patient may be placed; first, lying on the back; then we put our thumbs on the anterior and superior iliac spines, mark their relation to an ideal horizontal line, and draw similar lines at the knees and the ankles. Sanson proceeds in the following way: from the upper part of the sternum he drops a line which represents the axis of the body; from one iliac spine to the other he draws a tape, which crosses the first: if the two spines be on a level, these tapes will fall perpendicular the one to the other; if, on the contrary, one hip is higher than the other, the angles will be unequal, and the most obtuse will be on the side where the hip is depressed. Brodie's method is, I think, hardly so exact as Sanson's: he extends the tape from the iliac spine to the superior margin of the patella of one side and the other. In case of elevation or depression of the pelvis, despite apparent change of length, the measure will be the same on both sides. Dzondi made the patient sit upon a chair, so that the lower part of the back shall touch the seat; the legs are carried forwards parallel to each other; the transverse line of the pelvis making a right angle with the thigh. At first he compares the two knees, then raising at the same time both feet, and flexing them strongly, the legs being in a right line with the thighs, both heels are then compared, and if they pass each other the case is clear. Whatever may be the advantages of examining the patient sitting and lying, the erect position is unquestionably useful; it enables us to judge of the inclination of the spine and the pelvis, and to observe the character of the buttocks, a matter of first rate importance; for, certainly, one of the most common signs of ulceration of the cartilages is a remarkable flattening of the corresponding buttock, which becomes flabby, and looks for this reason larger than that of the opposite side, though, usually, in reality, it is not so. This appearance seems to be owing to a falling away in the firmness and vigour of the glutei muscles; it is upon this sign that Brodie mainly relies, in determining whether the condition be one of ulceration of

the cartilages, or inflammation and tumefaction. But I do not think that this symptom can be relied on, to distinguish between these two affections. Again, Brodie relies upon the character of the pain, which according to him, is less acute in inflammation of the hip joint, and is not accompanied by the excruciating pain which accompanies ulceration of the cartilages; but of the decided value of this symptom I doubt. Still, I think the pain ought to be attentively considered; it is often only evident upon pressure, yet the absence of pain is not sufficient to affirm that there exists no alteration of the hip, for in some cases it is wanting.

It is important to consider what are the affections which we may confound with spontaneous luxations of the femur. I do not think it necessary to do more than caution you against confounding this disease with fracture of the neck of the femur, of the crest of the ilium, or luxation of the femur, though doubtful cases will occur; nor with congenital luxation: in that, lameness is coeval with the attempt to walk, and there is no pain. It is not, however, easy to distinguish this affection from certain chronic diseases. The pain in the knee may induce error, even when it is associated with pain in the hip, and change in the length of the limb; it may often induce mistake: it may be taken for disease of the coxo-femoral articulation, when it only affects the sacro-iliac symphysis. Again, it is not always easy to distinguish between coxalgia and rheumatism of the hip: indeed, the distinctions are not defined: the erratic character of the pain which, before affecting the hip, may have visited other parts, is an important sign; and may not rheumatism impress disease upon the synovial, fibrous, and osseous tissue of the hip? Again, sciatica is usually sufficiently marked by the course of the pain. Chronic suppuration developed in the vicinity of the hip, in consequence of caries or necrosis of the great trochanter, or of the crest of the ilium, should be distinguished from those which are a consequence of coxalgia; by the smaller quantity of pain attending motion of the thigh, and the absence of remission during repose; suppuration of psoas, presenting at the external part of the thigh, by the symptoms of psoas abscess, and by the absence of pain when the head of the femur is pressed down. Still difficulties will arise, such as when a chronic abscess opens into the acetabulum, either by perforating the fundus of the cavity, or in any other way.

There is nothing fixed or certain about the progress of coxalgia; it is sometimes very rapid, passing through all its stages in a few weeks; sometimes it may drag on

through months, or even years. The first period extends from the beginning of the disease to the displacement of the head, and is usually as much shorter as the disease has been excited by external violence, as it is more painful, and as the patient is more vigorous and plethoric. In children, it is usually rapid; possibly because of the comparative shallowness of the cavity: but where they are scrofulous, it may be prolonged for many months. It is, during this period, that we may hope to arrest the progress of the disease: we may see then the elongation, simulated or real, and the pain, disappear, and motion of the limb becoming practicable; yet there usually remains a certain rotation of the limb outwards.

The examination of a limb, made long after the cure, does not ordinarily shew any lesion; sometimes the diarthrodial cartilage is replaced by a complete eburnation of the osseous surfaces. During life, this eburnation is proved by a shock, experienced during the movement of the limb by the patient, and even perceptible to a bystander.

If medical assistance have been obtained too late; if by the carelessness of the patient, or the rapidity of the disease, it have been impotent, and displacement has occurred, the affection may proceed no farther; a false joint is formed, and the patient cured; presenting, as the case may be, a lengthening or shortening of the limb. This termination is not, however, the most common; oftener the pain persists, abscesses are formed, and fistulae established, the patient sinking under the disease. This duration of the period is very variable; it often extends to a year before death; sometimes even then the fistulae may close, and the limb become ankylosed: but, if this result is probable, care should be taken about the position of the limb. It is, therefore, evident that, in a case of this kind, the result must be very doubtful: it is also very uncertain what course a displacement may take.

If we examine the hip after a cure by ankylosis, we find the femur united to a point of the iliac fossa, or the cotyloid cavity: sometimes it forms a right angle with the trunk; sometimes it is parallel with the axis of the body, and the union is effected as in other cases of ankylosis.

After the cure by pseudo-arthritis, or false joint, we find, on the place where the femur rests, a depression; at the same time the head of the femur is diminished in size, and is flattened, so as to have contact with the ilium by a larger surface. The new joint is supported by muscular fibres, which take a fibrous appearance; the whole limb is atrophied, as a consequence of long inaction.

A point of great importance in the prognosis of this disease, as a means of determining whether any mode of reduction should be employed, is to ascertain what is the state of the cotyloid cavity. The generally received opinion is, that it becomes effaced, filled up, either by the tumefaction of the soft parts it contains, or by the production of exostosis. Boyer thought that the cavity abandoned by the head of the femur is more deformed by the pressure which the bone exercises on it from without inwards than by any other cause, but that the cavity is usually preserved.

There is much difference of opinion as to the causes of the disease. Some authors, with Petit, regarding it as the result of external causes—a fall upon the trochanter; others denying this cause in any case, and believing that this disease is always caused by constitutional means. I think there can be no doubt that constitutional causes exercise greater influence upon the development of the disease than those of an occasional nature; at least, they favour the action of the accidental cause: it is, however, true that a fall upon the great trochanter, the knee, or even the foot, the leg being in extension, frequently excites all the symptoms of the disease we are considering. Usually, however, no sufficient cause can be assigned for the existence of the disease. Some persons believe a scrofulous disposition to be the cause; others, rheumatic irritation: this Dzondi strenuously maintains. Larrey regards the disease as scrofulous in the earlier periods of life—rheumatismal in adult life. There are other debilitating causes, to which some men have given weight as occasional agents, masturbation, venereal excesses, arthritic diathesis, syphilis. Again, certain eruptive affections would seem to excite the disease; measles and small-pox; it sometimes follows bad fevers, parturition, and other causes.

Treatment.—This disease not being always identical in its nature or its progress, it is evident that its treatment cannot be identical; that it must be varied, not only with the periods of the disease, but with the nature of the cause, the constitution of the patient, and the intensity of the symptoms. I believe nothing to be of such paramount importance as absolute rest, prolonged through the treatment; and after the cure, or we may run considerable risk of relapse; but essential as this is to the success of the treatment, its attainment is not always easy: either we have to contend with the indocility of a child, or with the feelings of friends, who will not make up their minds to such a long confinement, for what they think a comparatively unimportant disease. Again, if

the limb be secured effectually, the ennuis of a child is often distressing. In consequence of this, many modes have been proposed for the purpose of obtaining the same result: by fixing the patient on a mattress, and when it is necessary to move at all, moving the entire trunk by means of a rope hanging from the bed head, the limb itself being rolled with junks, but I think the long splint is most effectual. When we have reason to expect a constitutional origin for the disease, the constitution should be modified by appropriate means. Bearing that in mind, the acute local symptoms which are often seen, should be energetically treated by antiphlogistics: they ought to be employed with a vigour proportioned to the intensity of those symptoms. The disease being set going by violence, the patient vigorous, the pains very acute, blood may be taken from the arm, and leeches or cupping glasses repeatedly applied to the part: at the same time the diet should be low. Baths have been recommended very strongly by Dzondi, but there is a serious objection inseparable from their use—motion of the limb. In fact, at an early stage of the disease, he holds that baths, hot flannels, a small blister just below the trochanter major, and tartar emetic, combined with opium, will cure nine cases out of ten. I apprehend, however, that the cases to which he alludes are the rheumatic ones. When inflammatory action is lessened, if the pain still persists, though blunted, revulsives should be employed around the joint; they may be applied at first if the disease be chronic. Among these agents we generally use tartar emetic ointment, croton oil, blisters, setons, moxas, caustics, and the red-hot iron. Boyer employed a succession of blisters, placed upon the anterior, superior, and external sides of the thigh. These are used so long as the pain is present. He was accustomed to apply, in succession, from three to a dozen; sometimes, at first, they will be very beneficial, and then suddenly will seem to increase the pain of the articulation; they should then be suspended, and antiphlogistics should be substituted for them until the new irritation subsides. Some surgeons prefer to a succession of blisters a less effective plan, a single one, upon which they keep up suppuration by means of savine ointment; some prefer a seton external to the aponeurosis of the thigh; this often lessens the pain in the knee, which is occasionally very distressing: this seton should be large, and placed over the tensor vaginæ femoris muscle. Cauteries are also applied around the joint, but though more powerful in their effect than blisters, they cannot be

compared to moxas: those should vary in size with the age of the patient. When the eschar is detached, it may be dressed with some stimulant to keep up suppuration. As soon as one is about to cicatrise we make a second, a third, and so on until the desired result is obtained. Professor Rust holds that none of these agents can be compared with iron, heated to whiteness; he does not, however, use it in acute cases until after blood-letting. He heats the iron or irons (for he employs as many irons as he requires lines) to whiteness; the cauterising extremity is three inches long by nine lines broad, and in form like a reversed prism. If the patient be young, three rays are enough; if older and vigorous, five; these rays converge from above downwards, and are placed an inch distant from each other. The first passes through the centre of the buttock for six inches, and in the direction of the sciatic nerve; the second is not so long, it follows the depression which the trochanter major leaves behind it; the third may pass over the trochanter itself. They should remain in contact with the integument some seconds whenever we wish an eschar of a certain extent. Rust, who admits a constant elongation of the thigh, states that he has observed often after the employment of the cauteries, that the limb resumed its natural length. There can be no question of the great efficacy of this treatment in a large number of cases. Still, as it is more painful, and the patient's fears are alarmed by it, it may be a question whether we should use it before the failure of moxas; and these even should not be used until milder means are tried. Certain it is, however, that transcurent cauterisation and moxas are the means to be employed in the last period of the disease; the effects must be maintained by rest as absolute as can be obtained, the limb being extended. When abscesses are formed and opened, the cure is rare, especially where the abscesses are large; still it is not impossible. It is much more unfrequently that such abscesses disappear without opening, or are followed by cure. Again, it is to moxas that we owe such cures, but then they must be applied in much greater numbers than in the first period. Larrey has applied with success as many as twenty in a period of between fifteen and sixteen months. We may also use with success very large blisters, such as have been recently recommended by Velpeau. If, however, the abscesses present an acute character, antiphlogistic means must be used, and it may be necessary to open them to lessen the irritation. If the abscess seems to be caused by caries, if counter-irritants do not repress it, an opening must be

made, but as to the time and mode of doing so, much difference of opinion exists. Some persons who are strongly impressed with the bad consequences produced by purulent collections, recommend an opening to be made as soon as the formation can with certainty be detected; most men, however, wait until the quantity of pus collected is very considerable, raising the skin and producing pain. As much inconvenience would attend one course as the other; if opened very early we give counter-irritants no chance to excite the absorbents; if left to collect in great quantity, the muscles are damaged, the integument is thinned, and the chances of cure remote, whether it be left to open itself or it be done artificially. We usually open them by a simple puncture, either with a trocar or a bistoury; in the latter case with or without a valvular opening: the opening is closed by means of adhesive straps, the puncture will commonly have to be repeated; at last it remains fistulous, and the patient sinks under the profuse suppuration and accompanying hectic. The hectic is attributed by some persons to the contact of air with the interior of the abscess; by others it is maintained that it occurs more quickly if we largely open them by means of the potential cautery and the bistoury. Rust believes that whether the opening be large or small the same quantity of air is admitted. To avoid these effects, he recommends that before opening an abscess, we should strongly irritate the skin which covers it, by passing over it, two or three times, a red hot iron; and when the tension and pain caused by the burn are passed, we incise one of the eschars through its whole length, for the purpose of evacuating the fluid. In this way, he seeks to produce an inflammatory condition, analogous to that which nature sets up before an abscess is opened spontaneously, and which favours the tendency of the parietes to coalesce when the pus has escaped, and produces in them a state predisposing to adhesion. When the abscess is very large, and the patient very feeble, he passes the trocar, heated to redness, through the tumor, carries a seton through the openings, and leaves it there thirty six hours. Larrey follows the method of Petit, of Lyons, opening the abscess by a small knife heated to redness, and afterwards applying the cupping glass. Whatever method is adopted, the result is often fatal; occasionally, the suppuration lessens, the fistulæ are healed, and the case does well. Whatever may be the period of the disease when the cure is obtained, or the means by which it has been brought about, great precautions are neces-

sary to prevent relapse; the horizontal position should be long maintained, and when the patients get up they should move about on crutches; and much care must be devoted to the first attempts to rest the body on the diseased limb. Such are the means which may be employed in the treatment of coxalgia: these means may often succeed in the first period, rarely in the second; indeed, until of late years, the efforts of the surgeon were limited to obtain a cure by ankylosis, or, in a still more favourable case, to the formation of an artificial joint. Certainly, when caries is extensive, the most favourable termination that can be looked for is ankylosis, the limb being in extension; otherwise the limb will not only be useless, but inconvenient.

Dislocation, by these means, has until lately been deemed incurable, and the patient has been doomed to perpetual lameness. In 1835, Humbert, after maturely examining the condition of the limb, became convinced that the cotyloid cavity persisted, that its contraction was inconsiderable, that the new adhesions formed with the head of the femur might be destroyed; he proposed that attempts should be made to reduce the luxation: those attempts were made, and were successful. In six cases, after graduated extension, maintained during a time varying between five days and several months, he has procured reduction; but when reduction was accomplished, no relaxation of the extension was permitted for many days, indeed, not until the parts were supposed to be accustomed to their restored condition, and then only very gradually. This reduction, however, does not appear to bring the limb to its proper length on all occasions: disease of the spine or deformity of the pelvis may be the cause of this, and there may be atrophy of the limb, which will be incurable, but the patient may be able to walk without difficulty. In speaking of congenital luxation, this point was considered.

OBSERVATIONS

ON

THE VARIOLÆ VACCINÆ.

BY ROBERT CEELY, ESQ.

Surgeon to the Buckinghamshire Infirmary.

[Concluded from page 687.]

Varieties, Anomalies, and Analogies.—Although the medical observer, practically acquainted with the varieties and anomalies of the vaccine disease in man, will

neither be much surprised nor long perplexed at less obvious though strictly analogous occurrences in the cow, yet there are some particulars connected with this part of the subject which appear to me not unworthy of remark.

The normal course of the natural and casual disease is completed in about twenty or twenty-three days, viz., four days, in the natural form, from the probable period of invasion (in the casual, three or four from the presumed period of incubation,) to the appearance of the eruption; six or seven from this period to the full development and perfect maturation of the vesicle; five or six from its decline to perfect desiccation; five or six from this period to the spontaneous separation of the crust, and the formation of the cicatrix. Irregularities, however, both real and apparent, are observed. In the natural disease the first two stages often seem materially abridged. In the casual the first seems prolonged, and the second proportionately abridged; or the first is prolonged, and the second and subsequent stages are normal. In both forms the third stage seems often abridged, sometimes prolonged. Lastly, the eruption is not always simultaneously developed. All these irregularities do occur, some more frequently than others; but some of them are very often merely apparent anomalies.

It will frequently appear, from the representations of the milkers, that the eruption in both forms of the disease reaches its acmé in four days; and this would be perfectly correct if we could admit that the period of detection was coeval with the period of eruption; but in very few instances, on their parts, does this appear to be the case. It has been already stated that these men rarely, if ever, detect any precursory fever; they often disregard the first occurrence of topical heat, and as seldom notice the first period of papulation. Nor is this in the least to be wondered at: it is, in truth, very difficult for an experienced observer at all times to escape error in this latter particular, and oversights will occur to the most vigilant from various causes, especially from peculiarity of colour, vascularity, and texture of skin, as well as temperament of the individual. It is indeed surprising, at times, to observe with what suddenness and rapidity the second stage appears to be completed, seeming scarcely to occupy more than three or four days. In this, of course, we see nothing more than what is occasionally observed in man from various causes. Greater difficulty in detecting the commencement of papulation in the cow, however, is the fruitful source of apparent anomalies of this kind; but vigilant observation, I am persuaded, by leading to the earlier detection of the obscure indications

of this stage, will materially diminish their number. Topical heat, slight discoloration, slight tenderness, some induration, will often exist three or four days before any well-defined circumscribed tumefaction is perceptible. When the corium and epidermis are thin and vascular, the pigment not very dark, and the examinations are carefully and repeatedly made in a good light, the respective stages are better observed, and fewer irregularities are apparent. Although the exact period of incubation of the casual disease cannot always be positively determined, yet there seems good reason to believe that it is occasionally prolonged from five to eight days, the subsequent stages being perfectly regular.

The abridgment of the third stage, or the too early appearance of turbidity in the lymph, or the premature occurrence of vesicular desiccation, and the circumstances upon which these and other real and apparent anomalies depend, are well deserving of consideration. In order that they may be more correctly appreciated, and better understood, it seems necessary to furnish an analysis of the principal phenomena of the eruption in connection with some of the varied circumstances under which they arise; and this I shall proceed to attempt, although it must necessarily involve some repetition, which to many, I fear, will prove tedious, and be deemed superfluous. The eruption commences in papulæ, which have their seat in the corium. They are not always simultaneously developed, either in the natural or casual form. In size and colour the papulæ differ according to their age, the thickness and colour of the skin. In thin, fair, and vascular skins, at a very early period, they resemble flea or bug bites, and are of a deep rose red; they become in a day or two as large as a pea, and have frequently a dark damask or even livid hue; which gradually diminishes as they acquire their vesicular character. In very dark skins of this texture, at this period some degree of redness, a coppery-reddish brown, or a tawny hue, is observable. In thick skins, though fair, the colour is much paler, and is, of course, sooner lost. In dark thick skins, and even in flesh-coloured skins, if very thick, the red colour is often entirely wanting, or is scarcely appreciable. Here, therefore, the papulæ are seldom noticed till they have acquired the size of a vetch or a pea. They feel hard, raised, more or less round, are hot and tender. Many of these varieties may occur at the same time in different parts of the same animal,

In three or four days from their first appearance, the papulæ acquire their vesicular character, and have more or less of

central depression: continuing gradually to increase, in three or four days more they arrive at their fullest degree of development, and sometimes are surrounded with an areola, and always imbedded in a circumscribed induration of the adjacent skin and subjacent cellular tissue. The first change in the pimple is indicated by the appearance at its apex of a dull or dusky yellowish point; the circumference gradually increases in substance and extent, and the centre becomes wider and deeper; at length a flattened vesicle is formed, with a dimple or depressed centre. The degree of central depression differs not only in different stages of the vesicle, but also in different animals, and in different parts of the same animal at the same time. It is in general more considerable about the fifth or sixth day of its formation. In very fair skins, (especially on the udder,) just before the appearance of the areola, and in very dark skins of a slate, blue, or black colour, where no areola appears, the depression is better felt than seen; but in the former a dirty ochre or dusty spot in the centre is rarely ever absent to aid the eye. The depression is sometimes wanting in some small vesicles on the teats at their early stage; but it appears in the middle or termination of their course, and is again entirely lost. An anatomical examination of the structure of the vesicle, just before it attains maturity, shows that its colour, indurated margin, and central depression, depend on the existence of an adventitious membrane formed in the corium and secreted by the papillæ. It is raised in the form of a zone, and is intimately connected with the epidermis. It has cellular structure, in which is secreted and contained a clear viscid lymph. The cells appear to be arranged in two concentric rows, and are separated from each other by whitish radiating partitions, which, at their converging extremities, are united by a central membranous band. The dusky central spot which marked the first change of the pimple into the vesicle, and which has now become darker and more distinct, seems to be caused by a greater or less degree of separation and desiccation of the epidermis, stretched over a crypt-like recess, which contains a small quantity of semi-concrete lymph-like matter, occasionally a turbid opaque fluid. This cellular, adventitious, membranous conformation, though differing in texture and amount in different vesicles, is invariably present, and is not less essential than diagnostic. About the fourth or fifth day of the eruption, or two days before the decline of the vesicle, there often appears at its base a red circle, which gradually increases in extent till that event

occurs. During this period the lymph within the cells, having become more abundant and less viscid, and somewhat opaque, bursts and breaks up the cells and their connecting band, separates the epidermis from its attachment to the subjacent adventitious membrane, and the vesicle, losing its central depression, becomes more or less acuminate, presenting a conoidal or semi-globular form. The lymph soon acquires a pale straw colour or light amber hue, and speedily becomes more serous, turbid, and opaque. Acumination of the vesicle, however, is not always confined to this period. It takes place earlier, later, or never occurs. It is earliest in small, comparatively superficial vesicles, which seem to resemble the supernumerary vesicles in children; is later in thick skins, not very vascular, being postponed till the tenth, eleventh, or twelfth day of the disease. It is earlier on the teats where the cellular tissue is more lax, than on the udder, where it is more compact. There are different degrees of acumination: in some vesicles it is barely visible, especially on the udder; but on the teats it is very often strongly marked.

The quantity and quality of the lymph varies, not only at different stages, but also in different parts of the same subject. It is generally more abundant and less viscid on the teats than on the udder; more copious commonly in the cow than the heifer. In the early stages of some vesicles, chiefly those which are comparatively superficial, and often others which have been irritated, the lymph is occasionally turbid, and even bloody, without any impairment of its efficiency. In these vesicles, too, are often observed pustular or vesicated margins, analogous to those seen in the puffed irregular vesicles of adults, or the vesicles of irritable habits, either with or without local irritation. They are more apt to occur on the teats, but happen in thin skins, or on the udder, from the slightest irritation. Here the cuticle appears sodden and rumpled, and is soon removed. A premature decadence of the vesicle sometimes occurs from an accidental escape of its contents; it is then covered with concrete lymph. An irregular escape of lymph will give rise to alternate decline and revival. When the escape is slight and progressive, it constitutes another form of vesicle—the vesicle with a central crust, which, being liable to be mistaken for a desiccated vesicle, deserves notices. This vesicle or “vesicular tumor” assumes its characteristic form at various periods, most commonly at an early stage. It depends generally on a deep fissure in the epidermis and corium, through which the lymph slowly oozes, and concret-

ing, exhibits a central crust. The fissure may not have completely closed before the formation of lymph: it may have re-opened during any part of that process, therefore the characteristic form may be acquired at different periods. When it exists at an early period, the dusky yellowish spot of the centre of the vesicle is absent, its place is occupied by concrete lymph, and the vesicle commonly has more central depression, and more elevation and induration of the margin.

The crust gradually changes from an amber to a yellowish brown or black; sometimes, from an admixture of blood, it is black at an early stage. It partakes of the form of the vesicle, though sometimes it is irregular. As the vesicle enlarges, the central crust in the same ratio increases in breadth and thickness, advancing towards the circumference, and resting upon the epidermis until the tenth or eleventh day, when the elevated margin beginning to decline, the central crust having become darker, thicker, and larger, in all directions, often reaches its inner circle, occasionally partially overtops it, about the thirteenth or fourteenth day. The epidermis around and beneath this crust, if punctured at any part except the immediate centre, yields nothing but blood. It often has a rumpled and pustular appearance. These vesicles, and a few others scantily supplied with lymph, never acuminate.

The areola differs in colour and extent, and is often entirely absent. In thick white skins, at its acmé, it is of a pale rose-colour, and seldom when the vesicles are distinct more than three or four lines in diameter. In dark skins it is entirely absent, except when they are very thin: in that case it will appear as a circular line of a dull vermilion, a reddish brown, a tawny or a coppery hue. When absent, the erythematous inflammation of the superficial, surrounding, and subjacent tissues, of which it is one of the signs, is still indicated by others, viz., heat, tenderness, and circumscribed induration. This induration is greater where the tissues are thick and compact, though more circumscribed and better defined. Where they are thin and lax, it is less regular and more diffuse. The former is the case on the udder, the latter on the teats.

Seat of the Vesicles.—The vesicles are found principally on the teats, but are often seen on the udder, especially on the lower and naked part. They are very frequent around the base and neck of the teat, and also on the body; now and then on the apex. The number varies considerably—occasionally one or two; not unfrequently twenty, thirty, or even sixty, dispersed about the teats and udder.

Size and form of the Vesicles.—Perfect vesicles may be seen scarcely much larger than a pin's head, and not unfrequently as large as sixpence, sometimes even larger. On the same animal they often appear as large as a vetch, a pea, a horse-bean; the latter is a common size. In general the more numerous they are, the smaller they are. The form of the vesicles is circular or oval; now and then, in some parts, somewhat irregular; almost invariably circular around the base and neck of the teats. The oval form is to be found on the udder, but principally on the body of the teats. Its axis seems to be determined, as well as its form, by a fissure or furrow in the skin. Where the skin is thin, vascular, and much furrowed and corrugated, which is often the case on the teats of red cows, the form is irregular, more especially when the vesicles are coalescent.

The colour of the Vesicles.—This varies according to the age of the vesicle, and is again modified by the colour and texture of the skin. At an early period, from the first to the third day, where the skin is thin and vascular and the colour fair, that of the vesicles varies from a florid red to a deep damask or purple. At a corresponding period, in thick skins of a light colour, that of the vesicles is less intense, but often bluish. In thin skins, very dark, a degree of redness is still visible, often a light damask or bright rose; but when the skin is thick and dark, the colour is more obscure. In general the vesicle is lighter in colour than the surrounding pigment; but in all cases there is presented a striking metallic glistening aspect. As the vesicles advance, the depth of their colour proportionately diminishes. It is, however, always darker at the base than on the surface, especially on the elevated border, where it is also more glistening. In the fairer skins, the glistening lustre resembles that of silver or pearl; and some vesicles, where the skin appears diaphanous, have a bluish white or pale slate colour, particularly towards their centre. In very dark thin skins, the colour of the vesicles is occasionally reddish at their base, and they have their surface much lighter than their ground, glistening with the lustre of mica or of lead. When fully developed on the light-coloured skins, the vesicles vary from a bright to a pale rose or flesh colour, which is deeper at the base, and blends softly with the varying tint of the areola, when present, or terminates in a narrow rose-coloured ring when that is absent. At this period, even in the dark reddish brown skins, the raised and tense margin of the vesicles have a rosy hue, which increases towards the base, where it terminates, except in very thin skins, insensibly in a deep tawny hue. The bluish, bluish white, grey or slate-coloured

tint of the depressed surfaces of some vesicles is most apparent, and the metallic lustre is most conspicuous in all. But these are not all the variations of colour met with; there are others, some of which are not unfrequent. On white skins, when very thick, and at the same time much corrugated, the vesicles have a dull white or cream colour. This will also appear when some vesicles have been injured and a portion of their contents has escaped, diminishing their tension and plumpness. A recovery of tension restores their former warmth of colour and glistening aspect. On light brown thin skins, especially when the vesicles are not deeply seated, the depressed centre is of a dirty yellowish white. These and other superficial vesicles, which resemble more the human vaccine vesicle, have a tendency to become pustular on their surface, and, at their margin, often vesiculate.

After the tenth day the vesicle loses its plumpness, its warmth of colour, its glistening aspect, its areola, and its indurated base, and in general, when undisturbed, rapidly subsides. Those which early exhibit the central crust, in a day or two after this period have their centres completely occupied with its oval, or circular, or irregular form, and scabrous substance. By the thirteenth or fourteenth day this crust is at its greatest magnitude, is of a brownish black colour, and adheres more or less tenaciously to the epidermis and skin beneath, and is bounded almost always by some traces of indurated margin, even at the twentieth or twenty-third day, when it separates and leaves a smooth cicatrix, slightly depressed, of a white colour on dark skins, but often of a pale rose on lighter coloured and thin skins. The acuminate vesicles frequently spontaneously burst, are often broken, or slowly collapse, and, with others which have little or no acumination, gradually desiccate from the centre to the circumference, changing their colour, which is dull and rather paler than that of the surrounding skin, to a yellowish, yellowish brown, and black, and forming at length a thick laminated, partly diaphanous crust, of a horny and glistening aspect, but brittle texture. The small crusts are often slightly acuminate, the larger more or less depressed in the centre, both retaining the form of the vesicle, but being, of course, less in diameter. These crusts fall about the same time as those above mentioned, leaving a similar cicatrix.

On the teats, especially about their bodies, the crusts are often large, being conjoint and often compound, two or more crusts of coalescent vesicles being directly united or intermediately connected by thin, dirty yellowish opaque, or black irregular

incrustation, left by pre-existing marginal or intervening erysipelatous vesications, which have been attended with sanguineous exudation or puriform secretion. Here the cicatrices are often deep and irregular, jagged or cruciform; but the greater part of the ulceration in general appears to have been superficial, in the central parts of which the specific and deeper erosions of the cutis are very conspicuous. In some animals, however, where the eruption has been interfluent, and much local irritation inflicted, deep and irregular seams succeed the more profound and protracted ulcerations. The appearance of the natural and casual disease, not unfrequently in different stages, at the same time in the same subject, is too obvious to be overlooked by even superficial observers. Papular or tubercular elevation—papulæ, more or less advanced to the vesicular form—vesicles, more or less dimpled or depressed—vesicles more or less acuminate, conoidal, or semi-globular—vesicles, more or less desiccated—varying in size from a mere point to eight or ten lines or more in diameter, certainly may be seen at times co-existent. Some of the causes are sufficiently obvious. No sooner is lymph produced, than by pressure in the recumbent posture, self-vaccination may occur; but a more frequent and more efficient cause are the reiterated manipulations of the milkers. These men, night and morning, in the performance of another task, unconsciously but most effectually perform on an extensive scale a very important process—a series of *re-vaccinations*, both from the infecting and infected animals. Hence many of the apparent anomalies and incongruities above alluded to. Some papulæ, appearing late, never pass into the other stages; others of earlier date, possess some of the vesicular attributes; others, still earlier, exhibit them all, and hasten on with rapid but unequal steps to the final stage of desiccation.

A due consideration of all these phenomena and their associated circumstances would make it appear, therefore, that the disease in the cow has few if any anomalies by which it may be distinguished from the disease observed in man. The phenomena in man called supernumerary vesicles, and those produced by what has been called Bryce's test, seem as strictly analogous to those appertaining to the cow as can well be desired. It is in the supernumerary vesicles alone of man, whether eruptive or not, that we are able to trace the corresponding changes from the papular to the vesicular state. The inoculated vesicle in him, of course, will not suffice for that purpose any more than the casual vesicle in the cow, palpably induced by the manual application of lymph to a visibly abraded

or fissured surface. The two kinds of vesicle in the cow, it has been seen, exhibit some striking differences from the supernumerary and inoculated vesicle in man. In the supernumerary vesicle, though the tendency suddenly to acuminate does exist, as in the cow, yet it always possesses more obvious indications of the vesicular character on its surface and at its margin than is ever seen before acumination in that animal, where an indurated and more or less elevated solid substantial margin alone appears. This remark applies also to the vesicular tumor, or the vesicle with a central crust; its margin is solid, indurated, tense, and shining, but the epidermis is not raised by distended cells giving an obvious vesicular appearance as in man. The central crust of this vesicle, of course, has its analogy in man, and in him depends on a corresponding though artificial cause. It is always progressive and more obvious in the cow. The lymph in man has not that tendency to escape, in the form of a crust, from a deep puncture or accidental fissure; the containing cells, readily distending, elevate the yielding and thinner cuticle; whereas, in the cow, the lymph is slowly and scantily secreted for a time, the cuticle is thick and resisting, and an epidermic fissure affords the readiest outlet. A near approach to this tumor-like form sometimes, it is true, is found in children in particular states of the health, or in those of phlegmatic habits, otherwise healthy, with thick skins, where the vesicle, of a rose or damask hue, rises boldly and in a solid form above the level of the skin, covered with an ash-coloured or bluish epidermis, which being punctured, like that on the cow, yields scarcely any thing but blood, even till the tenth day. In form, size, colour, &c., the analogies, exceptions, and their causes, are too obvious to need particular description. In the irregular appearance of the eruption, hitherto, I have seen nothing essentially different from what occasionally occurs or may be induced in man, as above alluded to; and as I have never yet succeeded, after numerous attempts to revaccinate the cow, subsequently to the development of the areola or its attendant phenomena, I shall look with suspicion and some distrust on vesicles apparently evolved after the twelfth day.

The cow, like children, and the young of other animals, particularly high-bred dogs, is subject to a purely vesicular eruption, consequent upon vaccine fever, which often bears a striking resemblance to vesicular varicella. This commonly occurs about the ninth or tenth day of the vaccine, in the form of erythematous-papular elevations of different sizes, solitary or in groups, evidently of sub-epidermic origin, which, within twenty-four hours, contain a pellu-

cid serous fluid, raising the epidermis. This fluid being more or less imbibed by the cuticle, gives, in the white skins, an early appearance of opacity to the vesicle; in the darker skins, a yellowish brown or dirty yellowish white colour is soon apparent. On the second day the fluid is straw-coloured, and becomes speedily turbid; the vesicles desiccate with brown and black, bid; the cuticle collapses or bursts, turns yellowish brown, and before the fifth day thin, flimsy, brittle crusts, which speedily fall. They vary in size from a mere point to that of a vetch or small pea, or are even larger, may occur on any part, but most commonly appear on parts void of hair; sometimes they arise later, and not unfrequently continue to form and desiccate for three or four weeks.

Besides this vesicular and other occasional co-existent eczematous and ecthy-matous eruptions, less likely to be mistaken, it must be borne in mind that the state of the teats and udder, during and after the specific eruption, is very favourable for the generation and reception of other contagious eruptions, which are sometimes seen to occur in the same dairy. Hence it is no uncommon thing for cows which have recently passed through the former to become the subjects of the spurious pocks. In the winter of 1838-9, I witnessed this phenomenon most satisfactorily. In a dairy farm, containing several sheds, the animals in one shed, scarcely recovered from the true disease, became affected with the white vesicle, (to be hereafter figured and described,) from the introduction of an affected cow from another shed, and several of them continued under its influence for two and three weeks longer. The character of the eruption of genuine vaccine, its seat, its cellular structure, its hard and knotty feel, its glistening aspect, its tardy and progressive change to the vesicular form, its central depression, its late acumination, afford in general broad and palpable grounds of distinction. Difficulties in the way of prompt and accurate discrimination, especially in solitary vesicles, will be better indicated and more appropriately discussed in a special account of the spurious pocks.

Recurrence of the disease.—At what period the disease may recur in a cow, and with what amount of modification, I have had no opportunity of personally observing. Here the animal is rarely kept for daily purposes after the fourth or fifth period of calving, often not so long; and as it is not very common to notice the disease in the same dairy more than once within that time, recurrent or modified cases are not likely to be met with.

ON THE TREATMENT
OF
CERTAIN INJURIES OF THE EYE,
OCCURRING IN INFANTS AND YOUNG
PERSONS.

By RICHARD MIDDLEMORE,
Surgeon to the Birmingham Eye Infirmary.

[For the Medical Gazette.]

I PURPOSE, in my present communication, to place before the readers of the MEDICAL GAZETTE the result of my experience in the treatment of cataract occurring in early life, whether congenital, the result of local injury, or taking place from any circumstance not distinctly ascertained.

If ordinary congenital cataract be allowed to continue until the subject of this defect has arrived at or towards adult age, certain important changes take place; for instance, the lens is absorbed, the anterior and posterior hemispheres of the capsule become thick and opaque, and either fall into apposition, or become united by an organized medium.

Concussion of the eye or head, wound of the lens and its capsule, and a variety of other accidents, may occasion cataract, and, if such an event take place in early life from any of these circumstances, and no attempt be made to relieve it, thick, tough, capsular cataract is likely to remain, and is especially prone to contract adhesions to the iris, and to diminish the pupillary aperture.

It will be perceived from this statement, that if, in early life, the lens and its capsule become opaque from any cause, and no prompt surgical efforts be employed to procure the disappearance of the opaque matter, a secondary, and far more troublesome, and less manageable form of disease will almost certainly occur. Hence, it may be laid down as a rule of practice, admitting of scarcely any exception,* that operative proceedings should be employed soon after the distinct establishment of the cataractous malady, *whenever it occurs in early life*. I say *in early life*, because, when the same malady occurs at an after period, the same reasons for removing it by operation do not exist. For instance—1, if, then (at a late period of life), the disease continue for very many years, it is not by any means so liable to be converted into a more unmanage-

able description of malady, so that a time of choice is, as it were, allowed us; on this account it would be manifestly improper to select, for the purpose of performing an operation, the period of inflammation, just when the eye is very unfavourably situated for such a proceeding; 2, the eye is perfectly developed, and its growth cannot, therefore, be arrested, as it may be if an operation be too long delayed, as in the case of congenital cataract; 3, the sensibility of the retina *has been* perfect, and *has been* exercised, so that atony of that important part is not likely to take place from the oftentimes temporary, and always partial, discontinuance of its natural stimulus*, as occurs in the instance of cataract (traumatic or otherwise), affecting only one eye, in elderly persons; 4, the question of personal appearance is comparatively of little importance, &c.

Cataract occurring in young persons is now generally treated by the anterior or posterior operation of solution. In performing either of these operations, we are very properly directed to destroy the anterior capsule to an extent at least equal to the size of the natural pupil; but I am convinced this important direction is by no means sufficiently attended to. In the operation of keratonyxis, owing to the difficulty of moving the needle about in a texture like that of the cornea, without causing the escape of the aqueous humour, the capsule is sometimes merely divided; a portion of the cataract escapes into the chambers of the eye, and perhaps a small quantity of the soft flocculent lens is interposed between the lips of the incision in the capsule. So, also, in the posterior operation of solution, the needle, having passed through the lens towards its margin, is, indeed, pushed through the anterior capsule, if that membrane be healthy, but, if unusually thick and tough, it may be *raised upon* and *pushed before* its point; but in depressing its point, with a view of lacerating the capsule, it will, very often I fear, pass nearly through the same aperture at which it entered, into the substance of the lens, where it may be moved about with much apparent, but little really useful, effect. Now, in

* The reader will be so good as to bear in mind that I am not professing to discuss at all in detail the propriety of operating for cataract, when existing only in one eye, in persons at an advanced period of life.

such cases, what is the result of these proceedings? The wound of the capsule heals very readily, if no portion of the lens be interposed between its edges, and there is scarcely any vestige of the puncture; but if any portion of the lens protrude through the opening, it is gradually absorbed, and there remains an opacity of the capsule of a greater or less extent. The capsule being not at all, or only very slightly, opaque, proceeds to the absorption of the lens, which it generally accomplishes; it then becomes opaque; its two layers meet, or they become united, and constitute a thick, tough, opaque texture, which is, in fact, worse than the original disease. Sometimes, when the posterior operation of solution has been performed, the injury to the capsule may have been more extensive than I have now stated, but still not sufficiently great to permit the discharge of the whole of its contents, nor to destroy its opacity until it has completely absorbed the lens, when, having become, as it oftentimes will do, inflamed, it generally secretes a lymphatic matter, by means of which the capsules, the iris, and an intervening mass of lymph, are united, and remain as a future obstacle to vision. Hence, then, arises the necessity—and the fact cannot be too frequently presented to the notice of junior practitioners—of making a free laceration, and extensive comminution of the anterior hemisphere of the capsule, at a *first operation*, namely, to prevent the occurrence of that form of disease in which the two layers of the capsule meet or become united, form adhesions to the iris, and constitute an obstacle to vision which nothing short of extraction can entirely remove. The importance of preventing the *secondary* disease, by a due attention to the treatment necessary for the perfect cure of the *primary* affection, is manifestly very great; and, on this account, I hope to be excused for referring to the subject in a manner which to some may bear the appearance of needless repetition.

If, however, the disease take place in the eye of a young person, from injury—for example, a slight wound of the cornea and capsule—what are the measures best adapted to secure to the patient the best chance of the restoration of sight?

If the injury be unattended with displacement of the lens, or any material

wound of the cornea, or any severe inflammatory symptoms, the plan of treatment I am about to propose, and which has not been previously stated by any author with whose labours I am acquainted, appears to possess many advantages. On referring to the ophthalmic articles in the *Surgical Dictionary* of Samuel Cooper,* and the *Treatise* of W. Lawrence,†—works which are characterized by fulness of detail, accuracy of statement, and extent of research—I find the treatment of such injuries is represented to consist in the employment of purgatives, the application of leeches, blisters, &c.; no mention being made of an early operation with a view of preventing the formation of tough capsular cataract. The only allusion to the subject I can find is in a communication by Mr. Barton,‡ in which, sanctioning the recommendation and practice of St. Yves,§ Warren,|| Beer,¶ and others, he advises the early extraction of the lens, in cases where it has been accidentally displaced; ** and likewise, though some-

§ A Treatise on the Diseases of the Eyes, translated from the French, by J. Stockton, M.D. London, 1744.

|| New England Journal.

¶ Lehre von den Augenkrankheiten, b. 2, Wein, 1813—1817.

** The following quotation, from the ingenious *Treatise* of St. Yves, may not be uninteresting:—"When the eye receives a violent stroke, the crystalline is loosed immediately, and, in two or three days, it becomes opaque, so that the patients can only perceive the light" (p. 228). After having stated that the lens, when so displaced, may have two situations, which he describes, he proceeds as follows:—"The *third* place is when the cataract passes altogether into the anterior chamber, and is placed between the *cornea transparens* and the iris; from whence it must be taken out in the manner that shall be described in the sequel of this *Treatise*" (p. 229). The "manner" consists in making a section of the cornea, introducing a scoop, and *canting* the lens through the opening. The author's words are: "When you design to perform this operation, to draw out the crystalline which has passed in the foregoing manner (that is, into the anterior chamber), the patient must be seated in a chair, with his eye fronting the light; open both his eye-lids with your thumb and fore-finger, then, with a sharp-edged lancet, divide the *cornea transparens* a little below the middle of the pupil. You must continue your incision transversely, from one side of the cornea to the other, in such a manner that you do not leave unsevered, on each side, above half a line's breadth of the *cornea transparens*. Then introduce a fine small scoop through the orifice, convey it behind the crystalline, and, with it, draw out that humour, through the incision made in the cornea." (P. 262.) I shall still further extend this foot note, for the purpose of introducing the following curious quotations:—"Three sorts of cataracts pass through the hole of the pupil. In

what vaguely, recommends the extraction of the lens when rendered opaque by accidental violence, without being displaced. But I do not know that this advice is intended to apply to young children, as the only examples brought forward, in proof of the utility of the practice suggested, are, the cases of "a country gentleman" and "a mechanic." I apprehend, however, it is *not* intended to apply to very young children, inasmuch as the only operation proposed is that of extraction, an operation, which, although I will not go so far as to assert it is not possible to perform on a child two or three years old, yet I may safely affirm it is so difficult of performance, (the iris being convex, the lens soft, the eye, as it will be under the circumstances in question, inflamed, the patient very young, &c.) in a manner which may justify the expectation of a successful result—successful as regards the appearance of the eye, and the restoration of

the first, the consistence of the crystalline is soft; in the second, it is hard and concrete, like a stone; in the third, it is partly soft and partly petrified. When it is soft, the aqueous humour which lies behind this body thrusts it forwards and fixes it *in the pupil*; but, when this body is hard, it passes at once through the hole of the pupil, upon the least effort made in bending the head." (p. 262) "Whatever passes during the operation (of couching), through the hole of the pupil, if it be of sufficient solidity, the point of the needle must be pushed through the hole of the pupil, without touching the iris; then pierce the body of the cataract with the point of your needle, and place it where it is usually placed (that is, in the vitreous humour), p. 271." The reader of these extracts will not fail to remark that St. Yves understood the nature of dislocation of the lens into the anterior chamber; was aware of the inconvenience its presence occasioned; and practised and advised its extraction, with a view of relieving them. He was also aware that, when the lens was somewhat soft, it would occasionally press against the iris, (he calls this passing *into*—and who can say this is incorrect—not *through* the pupil) and that the extraction of this soft lens was necessary not only to restore vision but also to relieve pain and inflammation. Mr. Gibson of Manchester, has received much credit for suggesting the removal of soft cataract, by making a small incision of the cornea; and the justly celebrated Dupuytren has been infinitely lauded for recommending the introduction of a needle through the sclerótica into the anterior chamber, with a view of depressing the crystalline when dislocated into the anterior chamber; but I much question if any impartial reader can give either of them much credit for *pure* originality, as far as these questions are concerned, after having perused the work of St. Yves. The subject of dislocation of the lens is somewhat fully discussed by Dr. Warren, of Boston, and its treatment illustrated by the recital of cases; and I am rather astonished his remarks have been so little referred to. [They were re-published in the Medical and Physical Journal, vol. xxvi. p. 386.] He advises the early extraction of the lens when displaced, even although it may not have passed into the anterior chamber, but makes no reference to the disease when occurring in infants and children.

vision—as to be *almost* impossible. Perhaps, however, the question is set at rest by Mr. Hunt, who, in the course of an interesting communication, "On extraction of the lens, in some injuries of the eye," (which appears to be a further development of the views of his able and experienced colleague, Mr. Barton,) makes the following statement: "Before concluding, it may, perhaps, be advisable to mention some restrictions which may be necessary in the employment of the proposed method: as circumstances may occasionally occur which would render the operation inapplicable, attention must be given to the age of the individual; for if the patient be so young as to render the fixing of the eye, without the aid of a speculum, impossible, or of such an advanced age as would contra-indicate the performance of any operation, extraction of the lens would, in both instances, be improper. And as a farther objection to the operation at an early age, it must be considered that absorption of an injured lens, like most other reparative processes, proceeds more rapidly, and with much greater certainty, in children than in adults." (*North of England Medical and Surgical Journal*, p. 495. London, 1831.) The latter part of this statement is perfectly true, but the question is, can we, by omitting an operation, *certainly prevent* the formation of the capsular disease, which is admitted, on all hands, to be so difficult of management? If this cannot be done, then, I apprehend, an operation is far more needful in early life than at any other period of existence: and that a suitable and efficient operation can be performed, and ought to be performed with but little delay, it is the object of my present communication to prove.

I now proceed to explain the operative proceedings it is the main object of this communication to recommend; and it will be understood they are adapted to those cases of traumatic, or other forms of cataract, occurring in infants or young persons. For, if traumatic cataract, not attended with displacement of the lens, occur after the latter age, the necessity for an operation is much less than at an earlier period, chiefly because the lens is less prone to become absorbed, and the capsule to undergo those changes which so generally occur in younger subjects. And here I beg to state that, on one or two important

points, I entirely differ from preceding writers. First, in pointing out that, when the lens is rendered opaque in infants and very young persons by the application of accidental violence, it is *absolutely necessary* to cause its removal by a surgical operation, unless, indeed, it be at the same time displaced, or associated with other injury necessarily destructive to vision; and secondly, in stating that when this accident occurs in early life its cure should be attempted, not by the operation of extraction, which, for ought I know to the contrary, some persons may be injudicious enough to perform, but by that of solution.

Operation.—If a child have sustained an injury of this description—the cornea not being much injured; the inflammation produced by the accident not being severe; the lens opaque, but not displaced;—I prepare the eye for operation, by applying belladonna to the eyelids, and bind up the healthy organ. Having steadied the eye by means of the fingers of an assistant, (I scarcely ever use a speculum) if operating upon the left eye, and by the agency of my own if operating upon the right eye, I introduce the needle through the sclerotica, as for the posterior operation of solution,* and, by continued and varying movements, lacerate the capsule as freely as possible, to an extent equal, at least, to the size of the pupil in its ordinary state of dilatation. Having done this, bearing in mind that the needle is slightly curved, I very gently withdraw it, keep the patient in a darkened apartment, and employ any antiphlogistic or other measures the after course of the case may render necessary. The daily application of belladonna is requisite, with a view of facilitating and rendering more perfect the solution and absorption of the comminuted lens and its capsule.

Let it be remembered that, as the

* I do not advise the performance of keratonyxis, because the cornea has, in many of these cases, already sustained injury; the eye is irritable from the existence of a slight degree of inflammation; and, on these accounts, the necessary manipulations through the cornea would be more than commonly difficult. The needle employed is small and round, being slightly curved at its point. It is introduced with its point downwards (towards the lower part of the cornea), so that neither its concave nor its convex surface is opposed to the iris. As soon as the needle is perceived within the pupil, its point is directed, by a slight rotation of the handle, towards the

object of this operation is to prevent the establishment of a secondary form of disease (tough capsular cataract), which usually occupies in its development several months, it is not imperative to perform it so soon as the opacity of the lens appears; neither is it advisable to do so until all acute inflammation has been subdued; in this respect differing from some cases of dislocation of the lens, which may demand the prompt performance of a surgical operation.

Sometimes it is necessary to perform a second operation, but this seldom happens if the first operation is practised with the necessary care, except in those cases where the lens has become opaque independently of any local injury, which has caused the laceration of the capsule. So that a first and single operation for congenital cataract affecting the whole lenticular substance would not be so likely to be perfectly effective as would the same operation performed upon the eye of an infant suffering from traumatic cataract. In fact, in the case of congenital cataract, a single operation will not, by any means always, effect the entire removal of the disease, however carefully and perfectly performed.

I shall conclude with the following condensed summary of the more material statements contained in the preceding remarks:—

1. *Proposed operation.*—Posterior operation of solution, with very free laceration of the capsule.

2. *State of disease or injury to which the proposed operation is adapted.*—Any injury of the eye, occurring in infants or persons not more than thirty years old, and producing opacity of the lens *in situ*, but not occasioning any extensive wound or injury of the cornea, or other part of the globe, necessarily destructive to vision. Should the soft lens, uncovered by its capsule, (which has been extensively torn by the accident,) be thrown from its natural situation, either into the pupil or the anterior chamber, the operation is not required; first, because the supposed free laceration of the capsule protects the patient from the occurrence of capsular cataract; and, secondly, because the youthfulness of the patient, and the softness of the lens, render almost certain the disappearance of the cataract without the performance of a surgical operation.

3. *Time at which an operation should be performed.*—As soon as acute inflam-

mation has subsided, and any inflammation the globe, or any injury the cornea has sustained, has been either much moderated or altogether subdued. Just as, in other instances, when about to perform a surgical operation, we get the parts, upon which we propose to operate, in as quiet and tranquil a condition as possible beforehand, so here we act on the same principle, and, by freeing the eye from inflammation, place it in the most favourable state we can to sustain the irritation occasioned by the operation we propose to perform. The operation is not suggested with a view of relieving pain or inflammation, or with the intention of preserving the vision of the opposite eye; for it is presumed that a somewhat slight wound of the cornea, and opacity, without displacement of the lens, will neither produce serious inflammation or severe pain of the affected eye, nor endanger the vision of its fellow. It is performed with a view of restoring the sight of the injured eye, and of preventing the establishment of that form of capsular cataract which, as I have previously explained, is always difficult of management*.

I could readily append to this communication a number—a very large number—of cases which have occurred in my own practice, and which forcibly illustrate the advantages of the plan of treatment now suggested, but am unwilling to lengthen this communication, and apprehend the explanations I have given, which embrace principles rather than details, render this measure in some sort unnecessary.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

An Essay on the Treatment and Cure of Pulmonary Consumption, &c. By GEO. BODINGTON, Surgeon. London, 1840.

MR. BODINGTON believes phthisis to be a nervous rather than an inflammatory disease; and accordingly treats it with a tonic diet, fresh air, and sedative medicines. He protests against beef-steaks

and porter, on account of their grossness and unfitness for a consumptive patient; but he gives “a glass of good Sherry or Madeira in the forenoon, with an egg, another glass of wine after dinner, fresh meat for dinner, some nourishing food for supper, such as sago, boiled milk, according to the taste and digestive powers of the patient.” (p. 14.)

He narrates six cases treated in this manner, five of which, he says, were cured, and the remaining one, though ultimately fatal, was arrested in its progress. Mr. Bodington allows that local bleeding may be necessary to relieve congestion of the vessels in phthisis, though the disease is cured by restoring the nervous energy. In support of this distinction he cites Magendie's experiment, where the division of the orbital branch of the fifth pair of nerves within the cranium caused intense inflammation of the eye. “It is plain that the whole course of antiphlogistic treatment, carried to its full extent, would fail in such a case to cure the eye; but a restoration of the nervous power, by reunion of the divided branch, if that could have been effected, would have cured it; the antiphlogistic means would have assisted, by unloading the distended vessels, and facilitating their restoration to their natural calibre.” (p. 51-2.)

If Mr. Bodington republishes his essay, we think that he ought previously to read more of what has been already written on the disease, particularly the admirable work of Dr. Thomas Young.

A Manual on the Bowels, and the Treatment of their principal Disorders, from Infancy to Old Age. By JAMES BLACK, M.D. of the Royal College of Physicians, London, &c. &c. London, 1840.

This work is intended partly for young practitioners, and partly for the general reader, and may furnish both with some useful hints. Yet we think it would have been better had the author divided his book into two separate treatises, the one addressed to the profession, and the other to the laity; for he might thus have entered more into details, without danger of being misunderstood, or of the valetudinarian attempting to put into practice the precepts addressed to the physician.

* I may as well remark that it was for the removal of this capsular disease that I invented the needle-forceps described in the number of this journal for April 7, 1838.

A Treatise on the Physiological and Moral Management of Infancy. By ANDREW COMBE, M.D., Fellow of the Royal College of Physicians of Edinburgh, &c. Edinburgh and London. 1840.

THIS book is by the author of 'The Principles of Physiology applied to the Preservation of Health,' &c., and is characterised by the quiet good sense which pervaded that useful publication.

Dr. Combe has divided his work into fifteen chapters. The first contains an introductory explanation, and the others are on the extent of mortality in infancy; the sources of disease in infancy; delicacy of constitution in infancy; conditions in the mother affecting the health of the child; the constitution of the infant at birth; the nursery, and conditions required in it; the management of the infant immediately after birth; food of the infant at birth; the choice, properties, and regimen of a nurse; artificial nursing and weaning; cleanliness, exercise, and sleep in early infancy; management of the infant during teething; management from the time of weaning to the end of the second year; and, lastly, on the moral management of infancy.

At p. 103 he supposes that the change of temperature from 98° to 60° , or 65° , is the chief agent in exciting respiration in the new-born infant. But does not the child breathe equally well in those climates where it is born into an atmosphere at 90° or 95° ?

Dr. Combe's work does him great credit, and will not only be an excellent manual for private families, but afford many useful hints to practitioners.

The Transactions of the Provincial Medical and Surgical Association. Instituted, 1832. Vol. xiii. London: Churchill, 1840.

THIS volume, independently of being a record of the proceedings of the Association, contains several articles on medical topics of interest. One of these is the report of the section appointed to inquire into the present state of vaccination; a report which has already been the subject of much discussion in this journal. We also have a general retrospective address, by Dr. Symonds, of the Bristol Hospital; and one on surgery, by Mr. James, of Exeter: these are interesting, and highly creditable to their respective authors. But the chief

interest of the volume depends upon the observations on the variolæ vaccinae, by Mr. Ceely, of the Buckinghamshire Infirmary. We regard this as a very valuable addition to the pathology of the disease, and we have taken the liberty of extracting a considerable portion of it in another department of our journal. In the original, it is accompanied by above 30 coloured engravings.

MEDICAL GAZETTE.

Friday, July 31, 1840.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL REFORM IN FRANCE.

WE should apologize to our readers for directing their attention a second time to the question of medical reform in a foreign country, did we deem the topic itself a purely foreign one. But the truth is, that the grand spring of the question is the same in France as in England. The natural discontent of the profession with its social position is as strong in Brittany as in Britain; and on both sides of the water the hope is loudly expressed that every difficulty may be got over by improvements touching diplomas and examinations.

The correspondent of the *Gazette Médicale*, on whose communications we commented a short time since*, endeavoured to show that the Medical Faculty proposed to be erected at Rennes was wholly superfluous, the three already existing in France being amply sufficient. He observed, that even the Parisian Faculty was far from overworked by its labours in examining candidates for the doctor's degree, and that the Faculties of Montpellier and Strasburgh had but little to do. Moreover, if this easy work of one, and comparative idleness of two, existed under the old system, when the number of

* MED. GAZETTE, July 10, 1840.

medical students was constantly on the increase, what will they be under the new regulations? For, besides the degree of bachelor of letters, the University of France now requires the degree of bachelor of sciences from the candidates for the doctorship. Hence the young men who aspire to this honour in future, must not only have gone through their *humanités*, *i. e.* belles-lettres and rhetoric, and have a knowledge of the ancient languages, but they must have studied the different sciences with which medicine comes in contact. These regulations have produced the effect which the University intended. It appears, from a report of M. Orfila, that in 1835 there were 1522 new pupils in the three Faculties of Medicine, and the eighteen secondary schools; but in 1837, when the bachelorship of science was required, the number was only 744; in November, 1839, it was only 596; being a diminution of nearly two-thirds.

Two possibilities, however, have been mentioned, says A.M.P., as likely to augment the labour of the Faculties in the examination of doctors. The first is the abolition of the *officiers de santé*, when it is supposed that those who now are contented with this grade will aspire to the dignity of M.D.; and the second is an increase in the number of examinations for the doctor's degree.

The Parisian critic is of opinion, in the first place, that the abolition of the *officiers de santé* would be extremely unadvisable, and we perfectly agree with him. An entire suppression of this inferior grade, combined with so sudden an increase of rigour in bestowing the degree of M. D., would be a bounty on quackery, if ever bounty there was. It does not appear that there is a general overflow of practitioners throughout France, whatever there may be in great towns; and if the *officiers de santé* are taken away from those who cannot

afford to pay for scientific doctors, lay medicine in all its queer varieties must rule the roast in village and hamlet. It is difficult to criticize foreign arrangements with accuracy, yet it seems to us that the University has rather overshot the mark by driving away two-thirds of its medical students; especially when we know that if M. D.'s grow too scarce in France, *officiers de santé* are the only alternative—a genus of practitioner, who are not held in high esteem, though, of course, infinitely superior to unlicensed and amateur practitioners of every denomination.

But even if the grade of *officiers de santé* was blotted out, it is argued by A. M. P., and very reasonably, few would be added to the doctoral ranks, as the *officiers* are mostly unlettered men. The labours, therefore, of the Faculties are not likely to be much augmented from this quarter.

But, it is said, the examinations passed by the candidates ought to be more numerous, which would give the Faculties more to do. True, says the correspondent, they ought to be more numerous; but, then, the years spent in medical education ought to be more numerous also; and, therefore, argues A. M. P., being here glaringly deserted by his organ of arithmetic, a greater number of examinations being spread over a greater number of years, the trouble of the Faculties in each year would not be increased.

The answer to this arithmetical fallacy is, that if the years of education are increased from four to five, or six, the Faculty will annually examine a longer series of pupils than at present, though the number of examinations which a pupil passes in a single year may remain the same.

In spite of this oversight, however, it is quite clear that A. M. P. is right in alleging that there is no want of fresh Faculties for the purpose of creating doc-

tors, as far as the quantum of work is concerned, which the members of those Faculties have to go through. There is another, however, which he touches on very lightly, but which may have had great influence with M. Cousin, when he proposed the establishment of a new Faculty at Rennes. The inhabitants of a great part of Brittany are more than a hundred leagues from Paris, the nearest Faculty; and if he was aware how the number of medical students has fallen off in late years, he might be willing to make up in some degree for the increased severity of the regulations by the convenience of a Faculty within the province.

It is to be observed that the state in France contributes part of the expense of medical education; for each pupil pays only 1000 francs (£40) for his education and his diploma (*droits d'inscription et de réception*); and as this is insufficient to keep up three Faculties and eighteen secondary schools, the former are assisted from the funds of the University of France, and the latter by the towns and departments in which they are situated. Considering the difference in the scale of prices and expenses between France and England, it might seem, at first, as if a thousand francs were a tolerably large sum, and required no further addition from the state. But we suppose that in France it is thought that if a man is of sufficient note to be allowed to lecture on any branch of medicine, he ought to derive an income for his exertions; while, in England, where the matter finds its own level, as we say, by private competition, the lecturer is often too happy if the fees enable him to pay the rent of his room, which is the arena of his glory! Even in France, the professors at some of the secondary schools must be badly off, unless the department contributes handsomely; for, according to A. M. P., this year there were only thirteen new

pupils at the secondary school at Nantes, seven at Rennes, and six at Angers.

The great problem which lies at the bottom of all these details, is, how can medical advice, of the best possible quality, be provided gratis for the poor, and at a very low price for those who are just above the poor? If the state is anxious only concerning the quality of the advice, and suddenly demands a great increase of knowledge from medical candidates, the candidates become few, as we have just seen in France, and interlopers will become many. If cheapness alone is desired, while literature and science are wholly neglected, the practitioner loses his position in society, and with it his moral influence, which is quite as bad for his patient as himself. How are we to steer clear of this Scylla on one side, and that Charybdis on the other? We attempt to do so in England by gradually raising the standard of medical qualifications, and by paying those practitioners who attend the poor. Something more remains to be done. In the place, medicine must be taught more as a practical art, and examinations, instead of consisting only of words, must be enlivened by a tangible reference to things.

Secondly, our surgeons must be encouraged to attend on the poor by real salaries instead of nominal ones; and it should be publicly acknowledged by the legislature, as well as the philanthropist, that medical, like clerical, succour must be provided for the indigent at the expense of the state; and that the live-long labour of the cottager is not over-rewarded by these additions to his nine shillings a week.

Thirdly, those classes who, though above the necessity of accepting gratuitous medical aid, are yet unable to give a doctor's fee, or face an apothecary's bill, should be taught how a burden may be borne in common by each member of a small community, and

should secure themselves against loss by disease, as they do against loss by fire.

PUBLIC HYGIENE.

It has ever been a subject of regret to the enlightened philanthropist, that the duties on French wines are so high, as to reduce their consumption in England to a very trifling quantity.

The unfortunate predilection for acrid and intoxicating wines, which is the characteristic of this country, was fostered by the Methuen* treaty, concluded in 1703, by which we bound ourselves to impose 50 per cent. higher duties on French than on Portuguese wines. It is true, that even previously to this agreement, the consumption of Portuguese and Spanish wines was far greater than that of French; but the Methuen treaty naturally added to the growing love of alcohol; so that in 1830, while the consumption of Portuguese and Spanish wines was nearly double that of 1702, the consumption of French wines had actually diminished, in spite of the immense increase of population.

But, on taking the increase of population into account, we find that the consumption of all wines per head has materially diminished; so that while the nation has been growing in wealth with a rapidity beyond all precedent, the consumption of wines, especially of the most wholesome ones, has fallen off. Hence it appears with the clearness of a mathematical result—

1. That the duties on wines generally were too high.

2. That the duties on French wines, specially, were far too high.

In 1831 the Methuen treaty was hap-

pily annulled, and all foreign wines were admitted at a duty of 5s. 6d. per imperial gallon; and this remains the tax, excepting, indeed, that a small addition has been made this session to this, as to other duties. That this duty is much too high is obvious to any one who consults the records of the Custom House, or better still, who is acquainted with the habits of the middle classes. According to a sensible essay, published four years ago*, the French make nearly a thousand millions of imperial gallons of wine annually; and “we purchase from France not more than one part in 2,500 of the wine made in that country, not taking into account that part which is converted into brandy.”

As an excuse for discouraging French wines, it is sometimes alleged that the French will not buy our cottons; but surely this is a second edition of Dr. Johnson's story of the idiot, who, when his friends affronted him, used to lie all night upon the bridge! If the French like to dress shabbily, must we, in revenge, drink unpleasantly?

It is often urged, in addition, that claret is too cold for our stomachs. Pshaw! Just read the following figures; they are taken from the book above quoted, and represent the gallons of wine exported from France to different countries in 1832:—

The Hanse Towns (chiefly for the supply of the interior of Germany).....	4,666,676
Holland	2,162,769
Prussia	2,110,026
Belgium	1,899,157
Russia	1,127,448
England	530,164

Is the climate of Holland so broiling, and are Dutch stomachs so hot, that four times the quantity of French wine is

* It is a curious coincidence that the word Methuen in Greek (*μεθυεν*) signifies “the drunken thing;” will not some explainer in a future age say that the whole is an allegory, and that the treaty was merely prompted by the love of strong drink?

* Commercial History of Wine, in the Household Year-book for 1836.

required for a population so much smaller than ours?

It is worthy of remark, that long after the Methuen treaty, Scotland and Ireland, under the genial influence of low duties, were still famous for claret: so erroneous is the vulgar opinion that it is a wine only suited for hot weather! But custom-house officers, so potent is their spell, might banish claret from Bourdeaux! There is a humorous epigram by Home, the author of Douglas, in which he attributes the fiscal regulations which introduced the heavier wine of Portugal into Scotland, to a settled design to break down the spirit of the people.

Firm and erect the Caledonian stood,
Old was his mutton, and his claret good;
"Let him drink port," an English statesman
cried;
He drank the poison, and his spirit died!

It is a great mistake in public hygiene to consider wine as a luxury for a few only, and to drive the middle classes to spirits by prohibitory duties. The late Mr. Jefferson, President of the United States, expresses his gratification, in his Memoirs, at the introduction of a very cheap wine (St. George) into his neighbourhood, which had already quadrupled the number of those who kept wine. In the same work he says, "I rejoice, as a moralist, at the prospect of a reduction of the duties on wine by our national legislature. It is an error to view a tax on that liquor as merely a tax on the rich. It is a prohibition of its use to the middling class of our citizens, and a condemnation of them to the poison of whiskey, which is desolating their houses. No nation is drunken where wine is cheap; and none sober where the dearness of wine substitutes ardent spirits as the common beverage."

We, too, have a better prospect before us. A commercial treaty is all but concluded with France, and we may

hope, in a few months, to have the best and wholesomest wine in the world at a very reduced price*.

CLINICAL LECTURE

ON

POLYPUS OF THE NOSE,

Delivered at St. George's Hospital,

By CÆSAR HAWKINS, ESQ.

[Concluded from p. 702.]

Treatment.—You could not expect that so solid a body as a fibrous polypus would be much under the influence of external applications, and therefore the cure is simply removal of the tumor by some means or other; and because not malignant a cure may always be anticipated, when the whole disease can be eradicated. The astringents before spoken of may, however, be here also used after the operation, to lessen the chance of the return of the polypus. The means of removal of a fibrous polypus are either extraction by the forceps, or its excision by knife or scissors, or its destruction by ligature; and the one you select must depend on the size and consistence and situation of the tumor. There is one precaution, however, which you should adopt, when you are going to operate on a fibrous polypus, which is unnecessary with the gelatinous kind; it is, always to have ligatures and lint, and a bougie, or other apparatus ready, that you may immediately resort to plugging of the nostril, if you find that there is any alarming hæmorrhage. Usually, indeed, the bleeding readily ceases by the use of a little cold water, or pressure by the finger or the forceps, for a short time, with a little plain lint, or lint dipped in solution of sulphate of copper; and it is said by Mr. Pott that he never knew any bleeding

where the polypus was at all fit for removal; nevertheless, as there are several cases on record, where the polypus was evidently only fibrous, and yet the bleeding is described as having been alarming or frightful, it is prudent to be prepared for it beforehand, though it is not necessary (as some have recommended) to pass a ligature for this purpose through the nose in all cases before proceeding to extraction or division of the tumor.

1. *Extraction by Forceps.*—In the greater number of fibrous polypi, that is to say in those of moderate size, and of not very firm consistence, and without any broad attachments, the forceps will be the best means of removing the tumor, which may be reached in various ways, according as the root is accessible, and the tumor easily moveable or otherwise. Sometimes it may be torn away in the usual manner from the front; sometimes, although separated by the forceps introduced from the nostril, it is more easily pushed back, and then seized by the fingers or forceps from the fauces: if, for instance, the body of the polypus is rather large, and expands backwards, this is the best way. Sometimes, when wedged in the nostril, the finger passed behind the palate has been found to assist the forceps introduced from the front; sometimes the polypus can be more easily laid hold of by a pair of very much curved forceps, passed from the mouth behind the palate. In some cases two pair of forceps have been found useful, by which means the tumor, drawn forwards to a certain extent by one pair, has been more advantageously seized higher up by the second pair. When very large, Richter has recommended a divided pair of forceps, the blades of which may be passed separately on opposite sides of the tumor, and afterwards joined together. When the polypus has been of very large size, and the nostril has yielded with difficulty, Dupuytren and other surgeons have divided the ala nasi with a bistoury, to prevent its laceration, and to facilitate the passage of the polypus—a proceeding, however, which can certainly be very seldom necessary.

2. *Excision.*—The fibrous polypus has frequently been found to be too firm to yield to the forceps, or its attachment too broad, or the polypus too large, to be embraced by the forceps; and, in such cases, it has often been cut off by scissors, or a knife. Here are some complicated instruments of Whateley's, to convey a ligature round the tumor previous to its division, which must (if possible,) be quite unnecessary; and a common probe pointed scissors, curved or straight, will do just as well, or a probe-pointed bistoury, part of which is covered with lint, or made like a hernia knife, in some measure, so as to cut only towards the end. The scissors can,

of course, only be used towards either end of the nostrils, as they cannot be opened in the higher part of a narrow cavity; the knife can be employed for the higher parts; in either case, the polypus, after division, as near to the root as possible, is to be drawn forwards with forceps, or pushed back into the fauces, according to its situation and figure. When thus divided, the root has been described as being as hard as cartilage, so as to require much force to cut through it; and, in one of the cases for which Wheateley had this sheathed knife constructed, he found the root two inches wide where he cut it off. Where a polypus has been situated far back, an operator has divided the palate longitudinally, in order to extract it, which must be looked upon as quite unjustifiable, since the division of the tumor in more than one piece, which has also been done, would be a preferable plan. Sometimes the hæmorrhage has been found free from danger in cases of excision, but has been alarming in other cases; and in all operations by this plan on large fibrous polypi, it would probably be right to pass a silk previously, in order to plug the nose directly if the bleeding appears dangerous.

The knife or scissors have been employed in several cases after the forceps and ligatures have been tried in vain; but I have never done it myself; and I think the plan is inferior to the others, and is only to be tried when other means have failed, as it is probably open to the objection given by Sir Astley Cooper, of a return being more likely when the tumor is simply cut off than when torn or tied, besides the greater risk of bleeding.

3. *Ligature*.—The third plan, which is applicable to fibrous polypi, is the strangulation of its root by ligature; but you may readily imagine that this is by no means an easy operation in a deep and narrow cavity with unyielding parietes: it is, therefore, most easily done when the polypus is far back in the fauces, or near the anterior opening. Here is a polypus, which was tied by the simplest means, namely, the passage of a bougie into the mouth from the front, by means of which the silk was passed round the root: the polypus itself was the size of a walnut before its removal. When passed round the root the wire or silk may be tightened by means of these common tubes, till it is separated, and if large, much pain and fœtor are occasioned, requiring the use of opium, and of chlorine or other lotions. It is, however, the passage of the ligature round the tumor which is the difficult part of the operation, and it would take me too long to explain the numerous plans which have been proposed for this purpose; for a description of which I will refer you to Boyer's works, and Malgaigne's Operative Surgery. You can

examine after lecture the latest invention for this purpose, a somewhat complicated instrument, by Mr. Beaumont, which I fear, although easily used near the opening of the nostril, must be scarcely applicable to large tumors situated far up in so narrow a cavity; in which cases only is there difficulty in the operation.

It appears to me on the whole, that of these methods the extraction by the forceps is the best and easiest; but if the tumor does not yield, then that it may be tied, if far up, as the next best means, or cut off by scissors, if easily accessible, so as to ensure the root not being removed, or destroyed by caustic afterwards; and that if the ligature cannot be applied in some way or other, that the tumor may then be cut off by the knife, though the most dangerous and uncertain plan.

Malignant polypi.—Under the term malignant polypus, as you find cases described in a variety of works, there appear to be included two different forms of disease.

4. *Cancer of the mucous membrane*.—The first is comparatively a rare disease, being a growth of a number of red vascular projections from the mucous membrane, not in the form of a polypus, but of an extensive growth from the surface, something like warts, though soft and spongy; it is analogous to cancer of the skin, in which the warty form is more distinct than in mucous membranes. It is a disease of old persons, and may affect any part of the nose or its cells, and may go on for several years without occasioning extensive destruction or contamination of the glands. In this preparation it affected the membrane of the antrum, and yet after five years spent in much suffering, with some swelling of the cheek, the cavity was scarcely filled by the tumor, and the bone scarcely at all affected. If the red projecting substance in the nostril is considerable, it nearly blocks up the cavity, by meeting from the opposite sides; and I have known the septum destroyed with cancerous ulceration, which spread up to the upper portions of the æthmoid and sphenoid bones, and occasioned a fatal influence on the brain. In the same manner, in the antrum, ulceration may spread into the nose or through the cheek, with the usual course of cancerous disease, but without much growth of fungous substance.

Palliatives are all the means that you can employ for a disease the eradication of which is in this situation scarcely a possible proceeding, after its nature has been discovered. If extracted on the supposition of its being polypus there is some hæmorrhage, and the new growth only proceeds the more rapidly from abortive attempts to effect a cure, and even caustics aggravate the pain and suffering of the patient,

without being able to reach every part which is affected.

5. *Medullary or fungous disease.*—A much more common form of malignant disease of the nose is the fungous or medullary kind of tumor, which is not confined to any age; you have lately, for instance, seen one at the age of four years, and another in a woman of forty; it is, however, more common in young persons than in those advanced in life. Its progress, to a certain extent, was seen in the woman I have just alluded to, a patient of Mr. Keate's, in whom the disease appeared first, about a year ago, like a polypus in the nostril, and was extracted two or three times with some hæmorrhage, and it used to bleed of itself when it first came. This ceased after a time, and lately the growth of the disease has been in other directions. You see it at the present time forming a tumor on the left side of the nose, just below the inside of the orbit, the inner canthus being not an unfrequent situation for its growth; it reaches a little way across the lower part of the orbit, being firm and hard, except in the centre, where some whiter substance has formed like cheesy matter, while the rest is of a dark red colour; it has pushed the eye-ball outwards and deranged the sight, though it is not yet entirely lost. It is not clear whether the tumor has yet filled the antrum, as the cheek has not yet bulged outwards, as it will do, perhaps, by and by, in the same manner as the upper part of the bone is already affected; but the bony palate is beginning to be pushed downwards by the tumor, and is a little altered in appearance. The other surgeons were asked to see her, and we decided that the disease had made too much progress to justify an operation, which could scarcely by possibility remove the whole, and would, therefore, increase the rapidity of its growth. The future progress of the case will probably be, that it will increase in various directions in the face and mouth, then it will soften and ulcerate, and bleeding will take place with unhealthy fungus, where the skin gives way: the patient's health is not yet much affected, but she will, probably, soon become thinner, and will lose her appetite and sleep; she will have rigors, or perspirations, and die exhausted by irritation, or will have some affection of the sensorium by the disease spreading inwards, and occasioning convulsions and coma, as in our former patient with the fibrous polypus; in short, it will run the course of fungous disease in any part of the body, changing the surrounding textures, and, probably, occasioning a similar disease in other parts of the body.

In most cases of malignant disease of this character in the nose, the disease is not properly a growth of the mucous membrane, like a polypus, but it begins in some other

texture, and reaching the interior, and being covered by mucous membrane, it assumes something of the appearance of that structure, from the usual laws of growth affecting tumors. Thus, in this preparation of fibrous tumor of the upper maxillary bone, you may see the external part firm and fibrous, and looking exactly like the gum in which it grew; the middle of the tumor is in great measure osseous, and the interior, growing into the cavity of the antrum, is soft, and exactly like a gelatinous or soft fibrous polypus projecting inwards with a narrow neck. Cancerous or fungous diseases may thus spread into the nose from any of the surrounding parts; in this case you see a fungous growth filling the nostril, from cancer of the upper part of the nose; here you may see all the cells and cavities of the nose filled with fungous matter from similar disease of the cheek, the æthmoid and sphenoid bones changed, and the dura mater and even the brain beginning to be altered in their texture; and the fungus may even grow from the orbit, as in this preparation, where the medullary tumor filling that cavity has altered the bones of the nose; and you may see especially the upper spongy bone altered and enlarged, so that it might easily have been taken for polypus growing in that situation, and this also has extended to the dura mater and brain. Most frequently the disease commences in the maxillary bone or its periosteum, and the tumor grows in the antrum, and thence extends to the nose or inside of the cheek and orbit; first, where there is least resistance, and afterwards to the cheek and palate, where the parts are harder in texture. If the tumor grows in this manner from the antrum or bone, it immediately expands in the nostril, as if it grew from a pedicle like a polypus, because its growth is under no restraint, and its texture becomes also from the same reason softer and more vascular. I do not wish to deny altogether the existence of a fungous or medullary polypus, growing from the mucous membrane alone in the first instance, because I know no reason why it should not form there, as it does in the skin, but I have never seen one in its early growth, so as to be certain of the fact; and it is impossible to say, in a later stage, when all the other textures are altered, as in many of these preparations, in which of them the morbid action may have originated, though I believe it to be generally, as I have just remarked, in the bone or periosteum.

Diagnosis.—When a fungous tumor projects into the nostril, it is very often difficult to distinguish it from the fibrous tumor; it is usually softer and redder, and less smooth and shining on the surface, looking more like granulations; and it also bleeds more spontaneously, and the hæmor-

rhage is greater if it is meddled with, which circumstances seldom occur with a fibrous polypus till it has occasioned much distortion, and has begun to change its own nature by softening, while they may be observed very early in the malignant fungus: later in the progress of the fibrous polypus, as we have already seen, it is very difficult to know one disease from the other till after death, when we may be tolerably confident, if the alteration is confined to the mucous membrane, and there is no sign of contamination, of which there is plenty of evidence in many of the published cases of supposed fibrous polypus, but really fungous disease of the bones.

Treatment.—In almost every instance you will do wrong to meddle with medullary disease in the nose, as, among the delicate and intricate textures in the nostril, you will scarcely ever recognise the nature of the tumor early enough to insulate it by removal from the uncontaminated parts; and if any operation of this kind is unsuccessful, it is almost certain to accelerate the growth of what remains, by the local and general irritation which it excites. Where you are doubtful of the nature of the apparently polypos growth, it will be right to extract it on the supposition of its innocent nature, and not to repeat the operation if there is reason to alter this opinion. Sometimes this is not followed by much hæmorrhage, as in the woman under Mr. Keate's care, whom you have seen; but this bleeding is sometimes enormous, and should at once be considered as strong evidence of the destructive nature of the disease. I have known a boy nearly destroyed in another hospital by the loss of blood after two unsuccessful attempts to extirpate a soft growth by forceps, after which my friend who was the operator tried to tie the external carotid artery, but was obliged by the boy to withdraw the ligature after it had been passed under the vessel; he meant after this to have removed what bone seemed implicated through an incision in the nose, but I believe the operation was never performed.

Where there seems fair ground to hope that every diseased part could be removed, it would doubtless be proper to attempt the removal of the tumor, which some of you have had an opportunity of seeing done in the child from whom some of the preparations on the table were taken, an account of whose case I will read to you. The child, four years of age, was admitted under Sir B. Brodie's care, October 30th, 1839, with a firm inelastic tumor, larger than a walnut, distending the left nostril, and extending nearly as high as the inner canthus of the eye, and inferiorly as far as the alveolar process, and laterally there is an indistinct sulcus felt between the tumor and the malar prominence, as if the tumor

had extended itself under the ala nasi over the maxillary bone, as far as the bicuspid tooth. The tumor does not project through the nostril, and the small portion that is visible at that opening is of a dark reddish ash colour. The probe may be passed between the tumor and the septum, and between it and the floor of the nostril, but on the outer side of the tumor, between it and the maxillary bone, it cannot be passed, as if prevented either by its attachment to the inside of that bone, or by its projecting from the antrum. The skin covering this side of the nose is tense, shining, and slightly reddened, but not otherwise altered in appearance. There is a little purulent secretion from the inner canthus of the eye, and the tears run over the cheek; the right nostril is quite free, and the tumor does not extend so far back as to reach the fauces: the child is cheerful, and its health does not appear to have suffered.

The mother states that the first thing she perceived was "a small pimple" between three and four months ago, and that a short time afterwards a boy struck him, and his nose bled very much, and that this, which she calls a pimple, has gradually enlarged ever since, but the enlargement has been more rapid lately, and it has bled occasionally, and in the week previous to the operation the increase was very perceptible.

Now in this case the nature of the tumor scarcely admitted of any doubt, but as it was perhaps confined to the front of the nose, and there was no apparent disease of the antrum, it was thought right on consultation to afford the only possible chance of saving the child's life by endeavouring to remove the diseased parts, together with the bone, if it seemed affected. The tumor was therefore removed on the 9th of Nov., together with a portion of skin which was attached to the tumor where it most distended the ala nasi, and chloride of zinc was afterwards applied to the surface of bone, from which it appeared to grow on the outside of the nostril.

The part continued free from any return of disease for some months, and on the whole I think the operation prolonged the child's life, although it was ultimately unsuccessful, by removing for a time the local irritation of the tumor. Its structure, as you may see in the preparation, was that of a firm cartilaginous or gristly substance, like ordinary scirrhus, or like fibrous cartilage to a certain degree.

From the end of November to the end of January, when the child left the hospital, he continued to improve in health, and the nose appeared free from disease, except that there was a portion of bone to exfoliate from the action of the caustic. On February 19th he was readmitted, looking pale and anxious, and scarcely able to

move any of his limbs, and he complained of much pain in them; the abdomen was large and tender; the skin hot and dry, and the tongue furred; and the nostril was full of tenacious mucus, with some coagulated blood. The friends stated that he had a fall a fortnight previously, since which time his nose has bled profusely on several occasions, and he has rapidly declined in health.

After this the paraplegia increased, and sloughing took place in the nose and cheek, with a return of morbid structure in the part; and towards the end of March the glands about the left ear enlarged, and a tumor was felt at the extremity of the sternum; and on the 12th of May he died.

On examination of the body it was found, as these preparations show you, that the tumor, wherever it may have originated, had produced a good deal of alteration in the parts around the nose. You may see the maxillary bone softened, and the antrum filled with morbid growth; the sphænoid and æthmoid bones are similarly affected, with the dura mater lining them, and the cells are lost in the new growth, which fills all the upper part of the nose. The palate and left side of the mouth are in a state of gangrene. You may perceive some solid white matter extending in the sphænoid fossa to the temple, under the zygoma, and a little piece coming in contact with the sphænoid bone has produced a hole through it, so that the tumor formed a prominence in the interior of the cranium; every structure in this way yields before such a growth, and is implicated in it. The tumor at the end of the sternum is a firm, semi-cartilaginous mass, growing from the covering of the ensiform cartilage, and entirely surrounding the cartilage itself, which is not yet altered. This tumor is only one out of many others, I might almost say hundreds, which are formed on the bones: one of large size was formed on the periosteum of the inside of the ilium, but they were most numerous along the whole line of the vertebræ, and along almost all the ribs, and you will see in the preparation that from the periosteum the disease has, in several vertebræ in this section, contaminated the osseous texture of the bodies of the bones, while the intervertebral cartilages have hitherto resisted the morbid influence. These tumors around and in the bones, gave rise, no doubt, to the paralysis of all the limbs. The vertebræ most affected were those of the back, and from their front part a great mass of the same hard substance, like cartilage or scirrhus, has projected forwards in the centre of the chest, whence it extended some way into the roots and centre of the lungs, and in some parts of the lungs there are separate tubercles under the pleura, of exactly the same appearance.

I am not aware that any tubercles were found in any of the other viscera.

It is singular that the malignant influence should have been nearly confined to the bones, or rather to the periosteum of the bones, and also that even in those parts which were not immediately joined to the bones, so as to acquire their form of structure from this contiguity, the new formation should yet have been of a cartilaginous nature. It shows you, however, that because such new structures are cartilaginous, and bear much resemblance to the natural tissue, they are not therefore to be considered as belonging to a particular genus of tumors, lately spoken of by Müller under the name of enchondroma. There are, no doubt, some diseases of the bones in which cartilage forms a large part, but while some of these are innocent cartilaginous tumors, others, as in this child, will possess other characters, and run through the usual course of malignant disease.

More frequently, when fungous disease appears in the nose, it has the usual characters of medullary or hæmatoid tumors, instead of the firm structure seen in this case. But whatever the variety, the operation is usually impossible, or else the tumor is sure to return, and frequently several other parts of the body have the same disease developed in them. Some years ago Mr. Earle made a similar attempt, by incision into the nose, to remove what was considered a polypus, and had been previously operated on by forceps no less than 23 times in eighteen months, during which the tumor had been growing; but the disease returned in less than two months, and almost every viscus of the chest and abdomen, as well as many parts of the internal cellular texture, was found to be the seat of malignant tumors of medullary character.

I need hardly observe, in conclusion, that besides the injurious effects of repeated losses of blood to considerable amount, such injudicious attempts to eradicate what cannot be got rid of by forceps will only serve to hasten the fatal termination of the case, and that there are scarcely any cases in which the more complete removal by incision can be thought of as likely to afford a chance of success; the result will usually be such as you have seen, even when done early, as in the little child whose case you watched.

LITERARY ANNOUNCEMENT.

A Discourse on the Pendulous Belly, showing it to be a Visceral Affection, and attended with many important consequences in the Human Economy; with Cursory Observations on Diet, Exercise, and the general Management of Health: for the Use of the Dyspeptic. By Richard Frankum, Consulting Surgeon.

MR. TOMES ON THE STRUCTURE OF THE TEETH

IN REPLY TO MR. OWEN.

To the Editor of the Medical Gazette.

SIR,

IN the GAZETTE for July 17th, 1840, is a long letter from Mr. Owen, relating principally to a controversy between himself and Mr. Nasmyth, but containing in the latter part some statements bearing upon a letter of mine, published in the Gazette of the previous week. Mr. Owen there says, that upon my first interview with him, he shewed me sections of *Megatherium* and *Acerodus* tooth, as supporting the analogy of dental and osseous structure. This is not a true statement.

The only specimens he showed me were the two spoken of in my letter, neither of which were specimens of fossil teeth: moreover, he denied the analogy of the dental and osseous tissues, and it was not till I had shown him many specimens, demonstrating that dental tubuli often enlarge laterally into a more or less oblong cavity, from which, sending off numerous delicate tubuli in various directions—in fact, the tubuli taking the form of osseous corpuscles—specimens also in which the teeth were naturally ankylosed to the jaw as in some fish, demonstrating that in a section the precise points of junction of the jaw and teeth could not be shown, the structures were so like each other—it was not till I had shown him these, that he acknowledged the intimate relations of the two structures.

At this same interview, Mr. Owen, instead of showing me specimens of *Megatherium* and *Acerodus* teeth, gave me a large fragment of *Megatherium* tooth to examine, and asked me to make him a section from it. That he shewed a section of this same tooth is quite true, but it was some three or four months after the above date, and then the section he showed me was one of my own preparing. It was at a date even later than this, that he gave me the fragment of *Acerodus* tooth.

At this same first interview, as stated in my letter, Mr. Owen told me of Retzius's discoveries, which Mr. Owen

denies my having acknowledged, though the acknowledgment was printed in the Gazette of the week previous to the one which contains Mr. Owen's letter. At the same time, Mr. Owen showed me the engravings of dental structure, taken from Retzius's plates, and contained in Müller's Arch.; but I must also add that, upon my asking Mr. Owen several questions relating to Retzius's discoveries, he acknowledged that he had not read the account carefully, but said he would do so, and he then told me he was having the plates copied on an enlarged scale, and one plate had been so copied. Mr. Owen says in his letter, that he had more than a hundred specimens of teeth for the microscope, before I became known to him. This he did not tell me; indeed he only spoke of the two specimens which he then showed me, as stated in my letter.

The sections of teeth exhibited with the microscope, by Mr. Clift, at the College of Surgeons, by Mr. Owen's order, some days subsequent to his lecture on the subject, were almost exclusively mine, or made by me, excepting the two of which Mr. Clift gave the history narrated in my letter. Again, Mr. Owen, before this exhibition, borrowed of me numerous specimens, upon several occasions, to show at parties. Upon one of these occasions, Mr. Owen took my specimens to the Bishop of Norwich's Linnæan *soirée*, and there exhibited them. Mr. Owen may, perhaps, recollect this, especially as they were recognized as mine by a friend; before which recognition Mr. Owen seemed to be regarding them as his own.

I am quite aware that Mr. Owen had many specimens made, but I believe they were all made subsequent to his having seen mine, and subsequent to his having received many of mine as presents. If Mr. Owen had so many specimens it was strange he did not show them, and it was still more strange he should borrow mine to show.

This, and my previous letter, is but a plain and honest statement of facts

which can in no way be disproved; not that I doubt Mr. Owen's ability so to confuse the subject, by the style of writing which he has chosen, that it may be difficult for any person to form a fair judgment of the matter; for which reasons I shall decline any further communication on the subject.

Sir, may I beg you will insert the following letter, which I received from an old and valued friend who lived with me at the time to which my letters refer.

I am, sir,

Your obedient servant,

JOHN TOMES.

41, Mortimer Street,
Cavendish Square,

Gay Street, Bath,
July 22, 1840.

MY DEAR TOMES,

ON carefully reading and collating the GAZETTE of July 17, with the previous one, there appear several misstatements on both sides, which, from my living with you for many months both before and after the time mentioned, I can rectify; so would now recal the facts to you so far as my memory serves me. You began the study late in the year 1837, having been excited thereto (I think) from seeing the sections of bone exhibited at Dr. Todd's lectures. After many trials you made some sections of teeth, which were shown to the class in the earlier part of the course; a syllabus of the course would give almost the exact period: you then worked at little else for some months, and at length obtained that beautifully injected rabbit's incisor, and was persuaded to show it, with many others, to Mr. Bell. The subject was so commonly known among the King's College students that one of the physiological prize questions was on the dental microscopic structure. My firm impression is, that Mr. Owen, when lecturing on the teeth in 1838, did not mention his having at all personally confirmed Retzius' views, (though the diagrams then displayed were copied

from Retzius,) but most positively he mentioned you had done so. Of the specimens exhibited by Mr. Clift in the little room looking into Portugal Street, *much the larger number*, if not all, except the two which he said were given to him by Retzius, had been prepared by you; each of them was well known to me, who could not mistake those I had seen cut and put up, besides knowing their microscopic appearances.

You seem to have forgotten your coming home and narrating several conversations between Mr. Owen and yourself, on the analogy between teeth and bone, of which analogy you said you had much difficulty to persuade him, until you shewed him some sections of maxillary or palatine teeth of fish, that were naturally ankylosed with the bone: the names I know not. I am sure Mr. Owen's memory misleads him when he states that he shewed you preparations of the Megatherium and Acrodus teeth, at least preparations fitted for microscope, since you, on the receipt of some fragments, at once made him sections. Shortly afterwards Mr. Owen said that he should himself follow out the structure of fossil teeth, upon which you then ceased to work at this branch of the subject, considering that, in honour, you could do nothing with it. Mr. Owen treats you unjustly in trying to show that you kept back his having told you of Retzius's investigations, whereas you expressly mention it at the top of page 633 of the GAZETTE of July 10th, 1840, and also state that to Mr. Owen you were indebted for your first knowledge of the researches of Retzius. At any rate, you have the satisfaction of knowing, that to these investigations you were impelled by a pure desire of knowledge, and derived no ideas from any one else till you found that your observations were confirmed by Retzius, who, like yourself, was an independent observer.

I am, yours most faithfully,

JOHN S. BARTRUM.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF JOINTS, *continued.* The KNEE JOINT—ANCHYLOSIS—LOOSE CARTILAGES—INJURIES of the HEAD—WOUNDS of the SCALP.—*Their Nature and Treatment.*

THE KNEE JOINT.

As the knee is the joint where we are most familiar with *white swelling*, it is necessary to make a few observations on this particular form of disease. Again, we say that the disease may commence in the hard or the soft tissues. In the latter, it mainly consists of chronic inflammation of the fibro-synovial capsule: to this tissue it may have extended from within, or without the joint. A disease of the tibial bursa, or inflammation at the sides of the patella, between the end of the triceps and the femur, may irritate the interior of the joint; an abscess, a fracture, or an amputation, may produce a similar effect; but the opposite course of proceeding is most frequent. The disease generally commences within the fibrous capsule, and the reason is obvious. Placed between the front of the tibia and the ligamentum patellæ, the cellulo-adipose mass, constituting the adipose ligament, is exposed to pressure in almost every motion of the joint; the sub-condyloid synovial membrane is similarly exposed; the fibro-cartilages and ligaments are constantly compressed, dragged or twisted; each of these may serve as a primary seat of irritation or inflammation. It may, however, arise upon the free surfaces, or deeper parts of the joint. A blow,

a fall, a long walk, or irregular motion, may excite irritation in the synovial membrane, or the cartilages. If the disease commence in the bone, it may be consequent upon caries, necrosis, tubercular masses, abscesses, or osteitis. The cartilages may be separated, and fungous granulations may spring up from the bony surfaces; a fetid purulent fluid may fill the joint, and abscesses may be developed around it.

Symptoms.—When this disease is confined to the soft parts, we recognise it by the following characters:—the pain is rarely very acute; neither is motion impossible: the patient has noticed swelling, stiffness, and weakness in the joint, before he has suffered much pain: persons may remain in this condition for weeks or even months without seeking for advice, and may continue their ordinary occupation. When we examine the knee, we find it larger than that of the opposite side; pressure upon it is sometimes painful: it may be extended and flexed without much aggravation of suffering; the patella is moveable, but is raised in front of the condyles; and the swelling appears irregular, in consequence of being bound down by ligaments; it is elastic, but, if carefully examined, fluctuation cannot be distinguished: this condition constitutes the *fungus articulorum* of Raymer. If the cartilages have suffered first, pain has preceded the swelling; at first, however, only during motion. The severity of the pain keeps pace with the progress of the disease; at last it is so severe, that the patient cries out upon the slightest motion of the joint. If there be much swelling we do not always find an irregular projection on each side of the patella; if we do, and if it comprehend the whole joint, fluctuation may be felt, and the general health has then usually suffered. If the disease commence in the sub-cartilaginous surface of the bone, it very much resembles the preceding form; except that the pain, at first, is less acute, more extended, and less aggravated by

slight motion; the intra-articular effusion and the tumefaction of the soft parts are less rapidly developed. Caries, necrosis, and purulent, or cheesy, deposits in the structure of bone, are known by obtuse deep-seated pain, which at first is not increased by pressure or motion. The tumefaction, which supervenes slowly, is unequal; it is sometimes manifested at the extremity of the femur; at other times, of the tibia, whose bulk is sensibly increased: the patella is soon fixed.

In a case I lately observed after death, the knee was in extreme flexion; both condyles of the femur were sensibly enlarged; the articular capsule had become adherent to the diarthrodial cartilages; the patella was adherent to the outer condyle. The cartilages were softened and thinned; they could be torn off from the osseous surfaces. The semi-lunar cartilages and crucial ligaments were converted into a homogeneous lard-like mass; pus was found at several points, external to the joint, and fistulous canals communicated with the surface.

Prognosis.—When very little advanced, these affections of the knee are extremely serious. Those comparatively superficial, the least so; the more deep-seated are rarely cured, except by ankylosis. If left to itself, and motion be not prevented, general reaction comes on, the viscera suffer, and death is almost inevitable.

Treatment.—In the treatment of this affection, what we have already said of blood-letting, as well as large blisters, perfectly applies; but I may add, that to lessen the chances of strangury, after the application of blisters, the surface may be powdered with camphor. The actual cautery may be applied at any point with advantage; but as the angles of bones are here near the surface, we must employ it with more reserve than at the hip joint. Again, in making caustic issues, care must be taken to place them where there is a sufficient cushion of soft parts to keep up an abundant suppuration. In applying compression care must be taken to fill up all the hollows with cotton, otherwise prominent points will suffer. Of all these means *large blisters*, moxas, cauterisation, and compression, properly employed, will most often arrest the progress of white swelling confined to the soft parts, while blood-letting and caustic issues will exercise the most beneficial influence upon the affection of the hard parts. Nothing, however, in treatment, is more important than position. If the fibrous capsule alone is affected, it is less indispensable, though then it is desirable not to move the limb further than comfort may require; but when the deeper tissues are affected, it cannot be dispensed with: in those cases, ankylosis is the only

probable cure, and extension should therefore be permanent and complete. When other means have failed, resection of the articular surfaces has been occasionally resorted to, and sometimes successfully, but these occasional instances of success should not induce us to undertake too readily such an operation. It is very dangerous in itself, and under the most fortunate circumstances the patient will have a loose feeble joint, which will be of little use, or, what is better, complete ankylosis. Thus the dangers of this operation, and the little use that can be made of the limb, even when the operation succeeds, should induce us seriously to consider whether, when recourse can be had to amputation, we should resort to resection.

ANKYLOSIS.

Ankylosis is a condition which consists in a more or less complete loss of motion of a joint; if it be complete, it is termed *true*, if it is incomplete it is called *false*. When ankylosis is *true*, the bones are united, so as to form a single piece, and motion is utterly destroyed; the synovial membrane, the diarthrodial cartilages, and the compact surface of the bone, have entirely disappeared; the spongy substance of the extremity of one bone is continuous with that of the other. When it is *false* the bones are not united, they enjoy a certain mobility; the soft parts alone are affected, and motion at the part may be restored. Probably, a better division may be made, by shewing, that motion in a joint may be suspended by changes occurring within the joint, or around it. The changes within the joint are caused by adhesions of the synovial membrane, or by the union of the bony surfaces, after the disappearance of the articular cartilages; those external to the joint are affections of ligaments, tendons, muscles, and the soft parts around. Vidal proposed to divide it into intra- and extra-capsular, and it seems to me a specific and unobjectionable method. If we adopt it, we have then two varieties of intra-capsular ankylosis; in the first, the bony tissues are mediately united, that is, by means of the inflamed synovial membrane; it sometimes occurs, as a consequence of contusions, sprains, dislocations, wounds, or any thing capable of setting up inflammatory action within the joint. In this variety, which might be termed *membranous intra-capsular ankylosis*, the joint may still retain some motion, and all hope of cure may not be lost. In the second variety the articular osseous extremities are in immediate and complete union; the cartilages are destroyed, and motion is completely lost; this might be termed *osseous intra-capsular ankylosis*. In this variety greater mischief has been sus-

tained by the joint; caries, necrosis, tubercular disease, or *white swelling*, has usually preceded it. We can, in this variety, saw, longitudinally, through the joint, without finding any line of demarcation to indicate where the articular surfaces formerly existed: this condition is incurable. When the disease is *extra capsular*, the joint may, more or less, completely retain its integrity; the bony extremities, the articular cartilages, and synovial membrane, may be, more or less, completely intact; the organs which interfere with motion are the ligaments, tendons, muscles, and cellular tissue.

One particular position, long sustained, may produce this condition; it is for this reason that the Fakirs of India are so often reduced to this state: their religion condemns them for long periods to an unchanging attitude, which at last, by disease, becomes a permanent condition. Paralysis, or any disease, which compels a long persistence in a particular position, may equally produce it; this is seen in many bed-ridden people. The ligaments, tendons, and muscles, become permanently contracted. But apposition of surfaces alone does not seem to be enough to procure intra-capsular ankylosis. Cruveilhier mentions a case where complete ankylosis of the right temporo-maxillary articulation, had condemned the left side of the face to total inaction for eighty-three years, but the synovial surface was free. Walther mentions a similar case. Kuhnholz saw, in a woman of 60, a partial union of the body of the lower jaw with the upper; it was congenital; yet, although immoveable through life, the temporo maxillary articulations were altogether free at her death.

All joints may be ankylosed, but the ginglymoid suffer most frequently; those between the diarthrodial and synarthrodial may be affected; as the vertebra and the coccyx. One joint or many may suffer; in the former case the cause may be local; in the latter it is usually general. It may affect every joint in the body. S. Cooper mentions a case of universal ankylosis. In the history of the Academy of Sciences for 1716, is the case of a child of twenty-three months. Larrey, of Toulouse, presented to the Faculty of Medicine of Paris, the skeleton of a fisherman, in which there is ankylosis of almost all the joints. An officer died at Metz, in 1802, aged 50, who, as a consequence of the fatigues of war, in a cold damp climate, had rheumatism, which successively determined ankylosis of all his joints. The skeleton of that patient forms a single piece, the temporo-maxillary articulations did not escape, and it was necessary to extract two incisor teeth to give him food. The occurrence of ankylosis at the articulation of the lower jaw is very uncommon. Colum-

bus mentions one case. Meckel had another. Besides those cases, there is one at Berlin, in a man of 50. Portal mentions a case where all the joints, except that, had suffered, the patient having kept his bed for fourteen years. At Berlin, there is a skeleton where every joint is ankylosed, except the lower jaw, the pubis, and clavicles; the patient lived 26 years in this miserable condition.

Difference of opinion still exists on the subject of complete ankylosis of the pubis. Watler believes it to be possible; Meckel, Van de Wymperse, Hildebrand, and Blumenbach, hold it to be very rare. Pineau and Louis doubt even its occasional existence. Soemmering and Hunter never saw it. A single example is not to be found in the Cabinet du Roi described by Daubenton. Sandifort (Observat. Anat. Path.) says he has observed it; but his description would rather lead to the conclusion that there was ossific matter deposited in the connecting cartilage, than that the cartilage had been removed, and bony union of one branch of the pubis to the other had taken place.

However incomplete may be the history of cases of ankylosis, they are sufficient to warrant us in presuming that the remote cause was rheumatism. The remark of Van de Wymperse (Dissert. de Ankylosi) of the much greater frequency of ankylosis in man than woman, also favours this conclusion.

Ankylosis, of itself, is not a dangerous condition; it is more or less inconvenient, according to the joint affected, and the position in which it has taken place. Thus it is as much more inconvenient as it affects a large joint with much latitude of motion; again, ankylosis of the lower jaw materially interferes with the digestive functions, by preventing mastication and insalivation, or even by preventing the introduction of food into the month.

Treatment.—The treatment of ankylosis varies; it is sometimes a fortunate termination of dangerous articular disease, and should then be favoured, as far as possible, by absolute rest, by mitigating the symptoms which accompany or complicate the principal disease, and by giving the most comfortable and desirable position to the part. Thus we would endeavour, if the lower jaw were to suffer, to have it somewhat depressed; the thigh and the leg would be best in a state of extension; the foot in a right angle with the leg, the toes in extension; the arm should be depressed and a little removed from the trunk, the forearm upon the arm should be in a state of semi-flexion, and between pronation and supination, the hand in a line with the forearm, and the fingers slightly flexed. In some cases we are obliged to modify

these positions, or even to let the patient place the limb in the situation most comfortable to himself.

The object of treatment in incomplete anchylosis is to restore to the limb the motion it has lost. In those diseases which may make a joint stiff when left long in one position, as in fracture; to prevent it we lessen inflammatory action of the soft parts, and impress upon the part as much motion as can be safely borne; and this is especially necessary in the ginglymoid joints, from their great facility in becoming anchylosed. When false or incomplete anchylosis exists, we must seek to restore the ligaments, tendons, and muscles, to their natural flexibility and extensibility; for this purpose "douches" of various kinds, vapour baths, and relaxing applications, have been employed, together with friction and shampooing, and in slight cases they are useful in relaxing the parts: motion must then be employed in the sense necessary to overcome the contraction: by this means the ligaments and tendons sometimes yield, and motion is restored. As we have formerly seen, the tendons, and even the ligaments, may now and then be cut, so as to accomplish the end more speedily, but it must be associated with mechanical extension or flexion according to the case. Of late, in cases of incomplete anchylosis, a person of the name of Louvrier has been employing force, suddenly applied, as a means of cure: that a sufficient force can be applied to rupture almost any bonds of union, the cases upon which he has operated are sufficient evidence; that such violence may produce incalculable mischief is again proved by the results of the same cases; that a few cases may do well is also shown; but this we knew before the advent of M. Louvrier. Meekren published the case of a man who had, no doubt, false anchylosis of the elbow, which resisted every mode of treatment: one day he had a fall upon that arm, and motion was restored.

The motion which we impress upon the limb should be cautiously used; if incautiously applied it will produce pain, and may occasion inflammation. Often, when motion is first impressed, in such cases, a crepitation is perceived, but it gradually disappears. The surgeon himself, or an intelligent assistant, should attend to the process of moving; it should not be left to the patient himself, because the fear of pain will prevent him from doing what is proper, and therefore it will be inefficacious.

To cure such cases much patience and perseverance are necessary; with them many reputed incurable cases may yield. A multitude of examples of this might be given. In the cure of cases of complete

anchylosis, our brethren in America have resorted to a bold and novel practice. In a case of anchylosis of the hip, Dr Barton, of Philadelphia, in 1827, restored motion, by making an artificial joint; he cut down upon the neck of the femur, sawed out a portion of it, and kept up motion at the part. This example has also found followers; but I trust none of you will follow it until you have taken all necessary means to assure yourself that such an operation is in any case justifiable.

LOOSE CARTILAGES.

Loose cartilages are not unfrequently found in joints, but they seem to manifest a greater predilection for ginglymoidal than orbicular articulations. They may be free and floating; they may be attached, or some may be found in each condition in a single joint. The plate in Cruveilhier (*Anat. Path.*) shews some pediculated, some without pedicle, just projecting into the joint, and some entirely free.

The joints in which they are most commonly found are the temporo-maxillary, where Haller saw 20, (*Prog. de indur. &c.*); the elbow, where Robert found 18 or 20; and the knee, where Malgaigne saw 60. The knee, however, is the situation where, in the living body, they most frequently come under our observation. Generally we hold, that the first example of the disease was that of Paré (1558); that of Pechlin, (1661,) seems to have been the second. Succeeding observers, such as Henkel, Simson, (*Edin. Essays*), Hewitt, (*Raimairus de fungo Articulorum*), Ford, (*Med. Observations and Enquiries*), Bromfield, Theden, Desault, and others, have described a large number.

In size these bodies vary very much; some are not larger than a barley corn, others, such as that of Paré, may be as large as an almond. Although the surface may occasionally be rough, it is usually smooth and polished: some exceed a cartilage in hardness, others can easily be broken down between the fingers and thumb; the centre is usually the most resistant part: desiccation reduces them almost to nothing. Some specimens so strongly resemble fragments of cartilage, that it is difficult to distinguish one from the other. They contain neither vessel nor laminæ; nor do they exhibit any appearance of texture.

How these bodies are formed is a matter about which there is much difference of opinion. The earliest idea upon the subject was, that they were produced by a precipitation from the synovia, like vesical calculi from the urine: this opinion induced Paré to call them stones. The next opinion was, that they were frag-

ments of cartilage accidentally detached. Certainly, in the knee examined by Monro, a depression on the articular surfaces seemed to point out the surfaces from which they had been exfoliated or detached. Professor Schreger of Erlangen (Beobacht, &c. Erlangen 1813,) believed they proceeded (by exfoliation) from the cartilages of the joint, or were fragments of the synovial membrane changed into cartilage, and afterwards detached; yet he assimilates them to inorganic concretions, like biliary and urinary calculi, because they increase like them by the juxta-position of successive layers, the elements of which are furnished by the synovia. What induces him to come to that conclusion is, the stratified structure which he thinks he has observed in those cartilages, as well as the absence of nutritive vessels, even when they adhere to the synovial membrane. The more probable explanation is that which supposes their formation external to the joint, and afterwards pushing the synovial membrane before them so as to procure a covering, and when far advanced into the joint, a pedicle. This opinion, promulgated by Hunter, (Transactions of a Society, &c., vol. i.) adopted by Sir Astley Cooper, and Beclard, is formally opposed to previous hypotheses. It explains the existence of a pedicle and their mode of attachment. Cruveilhier's plate shews the pedicle in different stages of its existence; in some ready to give way, and allow the cartilage to move freely in the joint; in others scarcely raising the synovial membrane. Sir B. Brodie believes them to be a consequence of a mass of fibrine or a clot of blood having been effused into a joint, either as a consequence of contusion or other cause, and that this fibrine ultimately acquires the characters we have mentioned. There is no question that fibrine may undergo certain transformations; it is possible that it may undergo those necessary to constitute a loose cartilage.

I believe it is possible that each of these explanations may be occasionally right, and that neither can be adopted so as to exclude all the rest; I conceive that they may sometimes be formed without, sometimes within the synovial capsule. I believe that the elements of such concretions may exist in the synovial fluid, or that they may sometimes be produced by a chipping off or exfoliation of cartilage; but I apprehend that in the greater number of cases they are a consequence of violence inflicted upon the joint; that violence may cause an effusion of blood, or it may set up slight inflammatory action within or without the synovial capsule, and this action may determine the secretion of fibrine; in this respect they are not unlike similiar

concretions in bursæ or the sheaths of tendons.

Symptoms.—It is not usually difficult to distinguish the symptoms of loose cartilages. So long as they remain in a cul-de-sac nothing reveals their existence; but when a false step or shock brings them between the articular surfaces, an extremely sudden acute pain, threatening syncope, is developed, and the patient usually falls to the ground. Commonly in a few minutes this pain gradually subsides, but sometimes it may continue for an hour or even more, after which the patient can get up and walk as if nothing had happened. This accident may be renewed more or less frequently; the sensibility is increased, and not so soon dissipated, as the accident becomes more frequent. In some persons the cartilage, at last, is so extremely moveable, that walking is almost impracticable. Still although these symptoms be sufficiently significant, we have no certainty until we have felt the cartilage itself. If we examine the joint carefully we generally discover the body slipping from under the finger like the pip of an apple, and occasioning some pain: the patient usually discovers the object himself. At the knee-joint it is at the inside that it is commonly met with.

Prognosis.—These bodies may remain for years in the sacs which contain them; but a shock having precipitated them from their resting place, and thrown them between the articular surfaces, then suffering follows; they may not return to their former nook, and the chances of their interfering with motion are then imminent. When they become sources of acute irritation, the joint itself may at last suffer, as in Knox's case, or acute or chronic inflammation may be excited.

Treatment.—The idea of extracting these bodies is one which naturally arises in the mind of the surgeon, but the consequences of opening the joint occur quite as naturally. Richerand says, of twelve cases in which he had performed the operation, four had died in consequence of it. Bell preferred amputation of the limb. These feelings and apprehensions have induced surgeons to look for some palliatory means of treating the disease; of these, compression is the only one which can be properly substituted for it. We endeavour to fix the body at a point external to the articular surfaces. Middleton believed that, when thus fixed, absorption or dissolution might occur; but we have no facts to prove the possibility of either. Middleton has successfully treated the disease by compression, (Raimarius de Fungi, p. 27—54); so has Gooch, (Cases in Surgery); Hey, (Practical Observations, p. 342), who used a laced elastic knee-cap; and Boyer.

When we use compression, we must first coax the cartilage into a cul-de-sac, above, or on the sides of the patella, if the knee be affected, and apply upon it the knee-cap, which will not then require to be much constricted. Unless this apparatus fail, we need not resort to absolute rest, or to the application of an apparatus for preventing motion, which will often fail. Raimarius' cases show this: Averill (Edin. Med. and Surg. Journal) mentions a case, in which Ballingall had used similar means without success.

When extraction has become necessary, it is easily performed; but one thing must particularly be borne in mind—synovial inflammation may follow; therefore all prudent means should be taken to prevent it. Richerand lost four patients; Hewit lost one; Sanson's was not out of danger for months; S. Cooper mentions two deaths; and it would not be difficult to make the catalogue very formidable. At the same time many surgeons have operated frequently without loss; and therefore we are justified in supposing, that in many of the fatal cases the circumstances under which the operation was performed were adverse, that it was carelessly done, or that after-treatment was neglected. The cases which I have seen, with a single exception, (and in that case there was bungling in getting out the cartilage,) have done well, and that very rapidly, without the development of any unfavourable symptom. It is, however, my duty to tell you, that it is an operation not exempt from danger, and that it should not therefore be lightly undertaken. You should not operate without well weighing the circumstances of the case, and telling the patient and his friends, that, though a comparatively painless operation, it is not wholly without risk. If the cartilage occasion only slight inconvenience, advise the patient to bear it; if it interferes much with the functions of the joint, try compression; if that fail, if the inconvenience be great, and irritation be kept up in the joint, you may, provided the cartilage be moveable, undertake the operation; but not until all irritation is dissipated, because I believe that to be a great element of failure. I say *moveable*, because if it be not, the violence done to the joint in the efforts to detach it may be attended with fatal consequences.

The operation being decided on, it may be performed with great facility—it is extremely simple. Most surgeons have very carefully endeavoured to exclude the air, and this they have sought to do by preventing parallelism between the external and the capsular incision. Some have advised that the integument should be drawn upwards; others, that it should be drawn laterally. What is of more importance is

to get the cartilage as far as possible from the articular surfaces, as superficial as possible; then to fix it between the finger and thumb, to transfix it with a needle, or to follow the plan of Averill, (Edin. Med. and Surg. Journal, vol. lx. p. 307), fix it with a metallic ring, which, by making the parts tense, prevents it slipping off under the pressure of the knife. This done, the incision should be fair and as prompt as possible. It should be made perpendicularly upon the cartilage, and its extent should be proportioned to the size of the foreign body. If it do not immediately escape through the opening, it should be seized with a hook, and the pedicle, if there be one, should be snipped with a scissors. The wound is immediately closed with strapping, and perfect rest maintained until the wound is cicatrised. Some persons, for greater security, cover the part with a white of egg bandage, and, if necessary, apply cold. Before the end of a week, or even ten days, the patient should not be allowed to rest on the limb.

Having considered the diseases affecting the system generally, or, at least, several organs or tissues at the same time—having considered successively the diseases of which each tissue in itself is susceptible, and having therefore completed two great divisions of our subject—we shall now proceed to consider the diseases of regions; but as a region, in the ordinary acceptance of the term, may sometimes represent a group of organs, sometimes a single one, we shall limit ourselves rather to the consideration of the organs which the several regions may contain. Our first chapter will furnish an example of the advantage of considering the organ, because a disease may affect at the same time several of its tissues. In the head the connection of the several parts constituting it is so intimate, that almost always the morbid agent affects, simultaneously, several tissues at the same time, and may influence all. Even if an injury be comparatively simple at the outset, it is rarely limited to the tissue first affected. To be convinced of this it is only necessary to observe the composition of the cranium, the integument, the fleshy or fibrous substratum, a flat bone between two fibrous membranes, and the connection between them is very intimate. Their intimacy is still further assured by a large number of blood-vessels and nerves. It must appear singular that the osseous arrangement for the protection of the brain should be such as is favourable in many cases for the extension of injury or disease. In blows upon the head, the bone often protects the brain at the part; but the very fact of its resistance favours concussion. These circumstances render the study of diseases of the cranium very

difficult, because most cases are complicated.

INJURIES OF THE HEAD.

Wounds.—Wounds of the head belong to questions probably the most important in surgery. The injury of the brain which occurs at the moment of the accident, or consecutively, gives them their great importance. It is necessary, therefore, that we should consider them under two points of view, according as the different coverings are affected, or as the brain itself has suffered.

These wounds are never so simple as those of other parts; the proximity of the brain, and the intimate vascular connection between the interior and the exterior, to a certain extent explain the gravity of these wounds. If made by a cutting instrument, they are usually less dangerous than when contused or lacerated: wounds made during surgical operations show this. A wound may be vertical or oblique; a slice may be completely detached, it may adhere by a pedicle. In either case the indication is to bring the parts together, with the view of union by first intention; but where a flap is almost detached, a point of suture may be necessary to assure contact. These are the wounds which usually bleed most freely. If there be much hæmorrhage, it is difficult to apply a ligature; the tissue is lax; the vessels are probably retracted. Stuffing the wound is dangerous, from the irritation which it will seldom fail to occasion. Pressure should not be made on the part itself, unless it can be judiciously applied with the dressing; if it be employed at all, the advantages are best obtained by placing it at a distance, in the course of the bleeding vessel. In some cases we restrain it, by making a complete, where there was only a partial, section of an artery; this is a common resource after opening the temporal artery, when the hæmorrhage is obstinate. In all cases the dressings should be simple, and incapable of creating irritation at the part.

When the instrument by which the wound is inflicted is a pointed one, the bleeding is usually trifling, but the wound is often painful, and the consequences serious; because the general experience is, that those wounds are, more commonly than incised wounds, followed by erysipelas. It has been usual to explain the increased pain, by assuming that nerves have been incompletely divided; but where is the wound in which some nervous filaments have not been incompletely divided? I believe this is not the only cause. It has been recommended that the puncture should be converted into an incision, as a remedy for the pain; but

though this may complete the section of some filaments, it must inevitably leave others incompletely divided. It is true there are on record many cases in which instant and complete relief has been afforded by this means, leading to the previous conclusion; but every surgeon has seen many cases in which it has utterly failed; and it seems to me quite as reasonable to refer the relief to the relaxation which the incisions afford to the part, as to the complete section of certain nervous filaments.

Erysipelas, however, is the dreaded complication of wounds of the scalp. Pott believed that if the wound did not implicate subcutaneous tissues, the erysipelatous affection might creep on, over the ears, the face, and the neck; that if the aponeuroses were implicated, the erysipelas would be limited to the cranium, would neither extend to the eyelids nor the ears; that its colour would be a deep red, whilst a yellowish tint would be the characteristic of the former. That this rule may frequently apply, is probably true; that it will often fail is quite as true, although the contrary has been affirmed by so great a surgeon as Percival Pott.

Nothing is better known, than that spontaneous erysipelas, even when confined to the face, is apt to produce cerebral symptoms; still more is it to be apprehended when it affects the cranium, and has been produced by a wound. Then we fear the advent of cerebral or meningeal inflammation; but aggravated cases of erysipelas of the head and face, accompanied by delirium, do often pass away, without leaving us any reason to suppose that the brain was affected, otherwise than by sympathy. If delirium and stupor may accompany erysipelas without indicating cerebral disease, how are we to assure ourselves, in any case, that cerebral disease is really present? Boyer supposed, that a mode of diagnosis, practically useful, though not infallible, could be chalked out. "The inflammation of the wound," says he, "is not marked before the third or fourth day. It is manifested by redness, pain, and swelling of the lips of the wound. The inflammation extends, and takes an erysipelatous character; frequently fever supervenes, the tongue has a yellowish coating, the head is heavy and painful, there may be stupor or delirium. These symptoms may induce a suspicion of meningitis; but we know that the symptoms may be referred to the wound, by the situation, the cause, the time when these symptoms are manifested, the acute pain at the injured part when we touch it, the inflammatory tumefaction which was evident before the cerebral functions had suffered."

It is certainly wise to endeavour to make these distinctions, though their practical value may not be very great, because the cerebral symptoms existing, we are bound to act with that energy which cerebral disease requires.

Contusions of the head often produce at the part a tumor, caused to some extent by an effusion of blood under the scalp. Its consistency depends very much on the quantity of blood which has been poured out at the part. With moderate care and practice it is hardly possible to fail in distinguishing these tumors; but every surgeon has had opportunities of seeing them mistaken for depression of the cranium, and, therefore, we may assume, that this is an error into which, in an early part of their career, most men have fallen. Certainly, after the candid confessions and cautions of Ruysch, Petit, and Pott, the error, in the present day, is more inexcusable. The reason of the mistake is this: these tumors present an extremely depressible centre, and a raised and resistant circumference. If, too, an artery passes directly under or beside them, the pulsation has been mistaken for that of the brain. But if we compress, with sufficient force, the centre of one of these tumors, we find it resting on an equal bony surface. If, with the tumor, there were an unequal base, with hard angular and sometimes moveable points, then we should be justified in pronouncing for fracture with depression; but as to pulsation of the brain, it cannot be perceived without exposing comparatively a considerable point of its surface.

These tumors of themselves are comparatively unimportant. In many cases they are left to themselves; but in most instances it is prudent to subject them to treatment, because in those situations absorption is difficult, and the mass of fibrine remaining there may become the nucleus for a troublesome degeneration. It was formerly the custom to compress them, but this is often painful: they are sometimes leeches; sometimes cut down upon, and evacuated; but, considering the occasional consequences of wounds of the scalp, the latter plan should not be employed until other means have failed, and the necessity for acting has become decided. When the tumor is large, and the quantity of blood effused very considerable, absorption can scarcely be hoped for; and, preceded by the contusion, it may irritate subjacent tissues, and as the brain is very near it may suffer.

A contusion, in appearance, may be so trifling as to produce neither concussion nor external tumefaction, and yet may be pregnant with the greatest mischief. A man receives on the head a blow

with a small stick; after an hour he ceases to regard it; at the end of eight, ten, or fourteen days, you are requested to see that man; you find him suffering from headache, rigors, nausea: you perhaps hear nothing of the blow unless you ask the question. You examine the head; you find a tender puffy point where the blow was received: this is the seat of mischief. The explanation is simple; the blow destroyed a blood vessel, and caused an extravasation of blood between the pericranium and the bone, which induced inflammatory action, ending in a purulent secretion; or it excited inflammation of the pericranium or the bone itself; in either case the result being the same, the separation of the pericranium from the bone, and the death of a certain extent of bone: that condition produces a corresponding separation of the dura mater from the internal surface of the cranium; the dura mater and other membranes may be irritated and inflamed by the presence of the pus, and the inflammation may be communicated to the brain itself. The course of treatment necessary in such a case is to cut down upon the puffy point for the purpose of evacuating any fluid which may be collected there, and if possible to dissipate the irritation at the part.

In violent contusion of the cranium, the vessels which connect the dura mater with the cranium may give way; blood may be effused between them, or inflammation and suppuration may follow, and the bone may be mortified in its entire thickness. In some cases the patient does not for some time experience any severe symptoms; a slight pain only is complained of. Many days after, the pain may extend to the whole head; physically and morally the patient is prostrated: there are nausea, vomiting, sleeplessness; the pulse is hard and frequent: some days after these symptoms are manifested, if the inflammation be not arrested, a tumor without much pain is manifested at the contused point; when it is opened we find that the periosteum is detached, and dark in colour; that ichorous pus is formed under it; that the bone itself is altered, at least in colour. Gradually the fever increases; the patient is agitated, and the pulse more frequent; soon, rigors, cold sweat, convulsions, or delirium, follow; the patient becomes comatose, and death is not far off. If there be an external wound, the nature of the pus changes, as those symptoms are developed; it becomes sanious; the edges of the wound are tumid, and the pericranium is detached. Examination after death shews the dura mater no longer adherent to the bone, and much changed by the action of the ichorous fluid collected between it and

the cranium; sometimes also we find a collection of pus between the dura and pia mater.

An energetic antiphlogistic treatment, venesection, leeching, and cold, may in some cases prevent the fatal effects of contusion of the cranium. When they fail, and the periosteum is detached, a circumscribed tumor formed, and symptoms of inflammation and compression are manifested, the use of the trepan is indicated, and should not be delayed.

A contusion may destroy continuity, producing what is termed a *contused wound*. In these cases we must attempt to procure union by first intention, as in an incised wound, but the chances of our accomplishing it are more remote, because the edges are often contused, so as to be unable to enter into adhesion; still the resources of nature are great, and, however great the injury, we can set no limit to her power of reparation. At some points adhesion will take place, at others it will not. These wounds are not unfrequently followed by suppuration; pus may be pent up, and we must lose no time in setting it free. With respect to all general principles of treating wounds, we have already set them forth at sufficient length when we treated of wounds generally. I then stated that sutures, as a means of bringing the lips of wounds of the scalp into apposition, were to be used with caution, because they not unfrequently irritate, and that much might be done with long straps.

A contused, incised, or lacerated wound may be accompanied by injury of the cranium itself; it may be, that it leaves only a slight trace—the *hedra* of older writers; it may implicate the entire thickness. In the greater number of cases the kind of injury is easily made out, because the soft parts have been entirely destroyed, and we can apply the finger or a probe directly upon the point, but the extent of mischief, how far the bone is contused, how deeply perforated, are not easily made out. These injuries are often complicated with fracture and depression, or concussion. It is astonishing, however, how much loss of substance may be sustained without fracture or concussion. In Larrey's Clinical Surgery of Armies this is very strikingly exemplified, especially in the Egyptian campaign, where the Mamelukes were encountered. Using the sword as they did as the principal offensive weapon, it was not to be wondered at, that sabre wounds of the head were very frequent; but it is astonishing how frequently the injury was limited to the external wound. The sword in those cases, says Petit, cuts the cranium as a knife cuts an apple, without concussion, and the cases often do well. In many cases, even when a slice of the cranium,

and even of the dura mater, or the brain itself, has been carried off, they have done well. There is a curious case in point, in Dupuytren (*Traité des Blessures, &c.*), of a citizen, who, in July 1830, believing himself to be followed by at least fifty concitoyens, wished to drive back a squadron; the soldiers sliced the scalp in all directions; one laid bare the dura mater: he walked to a neighbouring house, was dressed, and did well.

In all these cases a clear indication is, if the osseous injury be not very great, to heal the soft parts if possible by first intention; if it be, there is difference of opinion on this point. Some persons even then recommend immediate union, but the greater number are of opinion that it is wiser to leave a vent for the pus that may be formed, and to secure union from the bottom of the wound. When a piece of bone is fairly detached, but still adhering to the soft parts, some persons endeavour to save it, by reapplying it immediately, as Paré advised; others think it best to remove it, as advised by Beranger and Fallopius. Although I do not pretend to say that a slice of bone may not reunite, I do maintain, that nine times out of ten it will not; and if it do not, it will be a source of irritation; therefore as a rule I hold that the safest course is to extract it at once, and there would be then a better chance of immediate union of the soft parts.

When the wound is a puncture from a bayonet, a sword, or other similar weapon, a very severe blow is necessary to penetrate through the whole thickness of the cranial bones, and in such a case the chances of concussion or fracture are very great: except in particular points of the cranium, usually the instrument does not pass beyond the outer table. If the instrument break, and a portion of it remain in the wound, no prudent means of removing it should be neglected, because it will be an infallible source of dangerous irritation. A man in a quarrel was struck on the top of the head with a knife, the point broke off and remained in the wound; the surgeon who dressed the wound did not sufficiently examine it; the edges were brought together, and the wound healed. Many years passed without accident, except from time to time pain was felt in the cicatrix. After some years he applied for admission at the Hôtel-Dieu, and was received. In examining the cicatrix, Dupuytren felt that it was raised by some foreign body; he cut down upon it, discovered the point of the knife, and with the crown of a trepan removed it. The symptoms were not dissipated, and there was paralysis of the side of the body opposite to the wound. The dura mater was

incised; nothing escaped; the brain was carefully punctured, and out gushed a quantity of pus: all the bad symptoms, fever, coma, delirium, disappeared, and the man did well.

In these injuries the internal table often suffers to a much greater extent than the external, and this is often a cause of the unfortunate result of so many cases. I lately saw a man who presented on the external table a fair incision without any depression, whilst a portion of the internal table, more than two inches long and half an inch wide, was driven into the brain. In these cases, if no part of the instrument remain in the wound, and there be no symptom of compression, the proper course is, to endeavour to heal the wound by first intention. But as we often cannot ascertain the depth of the wound nor the extent of injury, it is necessary for many days to watch the patient very carefully, and to act with proper energy upon the occurrence of any cerebral symptoms.

Contusing bodies may contuse or fracture the bones of the cranium, but the soft parts must have proportionally suffered, and the contents of the cranium may not have escaped unharmed. It is not easy to ascertain how far the bones have been contused, but that very uncertainty shews how necessary it is to be on our guard against ulterior mischief, which may be very insidiously developed, and sometimes after considerable intervals. The frequency with which serious mischief has followed contusions of the cranium, raised the question of the prudence of using the trepan before any symptoms were developed. Unquestionably Desault was right in stating that when a contusing body has destroyed the pericranium, so as to uncover the bone, the chance of after accident is very imminent; but I doubt whether the best opinions of the present day would go so far as to say that in this case the trepan is as necessary as in fracture, or that, if we do not trepan, the dura mater will inflame, and mortal suppuration follow. I have already stated that a contusion may cause the separation of pericranium, even when there is destruction of the soft parts, and this state may require the use of the trepan; but where the soft parts are destroyed, and the cranium exposed, the mischief is often less serious, because, if pus forms, it is not pent up. I do not think, with Desault, that, in all such cases, the occurrence of untoward symptoms must be anticipated, by the application of the trepan. I believe most men would agree with him in opinion, that where a contusion has been very severe, it is prudent to incise the integuments, for the purpose of ascertaining the condition of the cranium, and that if the pericranium be detached, and the colour of the

bone be changed, the question of the trepan then very fairly arises.

The greater number of surgeons of the present day deny, whilst the majority of the older surgeons affirm, that depression of the external table of the skull may occur without fracture. That some of the cases of so-called depression were bloody tumors, with depressible centres, consequent upon contusion, that others may have been congenital, I can readily believe; but I have had evidence, other than that furnished by infants, to satisfy my mind that depression without fracture, as a consequence of contusion, is possible: at the same time I am free to admit, that Plattner's case may be taken as a fair representative of the class. A man fell from a window, was insensible, and remained for some time in a state of stupor; the head being shaved, a deep depression was observed, without injury to the corresponding integument: the patient recovering sensibility, and fearing some operation, cried out that the depression was not a consequence of his fall, but had existed from birth; he got well without any bad symptom. For this condition to be possible, the blow must have been inflicted over the frontal sinuses, or some point where there is a great thickness of diploë, otherwise the very brittle internal table must be fractured by any considerable depression of the external table.

REMARKS ON THE PATHOLOGY AND TREATMENT OF CROUP.

To the Editor of the Medical Gazette.

SIR,

THE object of my former communication was to shew the benefits accruing from a combination of opiates with antimonial emetics very early in croup. My convictions are strong as to the utility of the practice. I am, of course, fully aware of the benefit which every one knows to be derived from an antimonial emetic alone; but from the good effects produced by the anodyne, I am persuaded the combination will greatly enhance the success. I purpose, with your permission, laying before the profession a few notes of cases of croup, illustrating this point, and subjoining one or two others as gleanings in the pathological anatomy of the disease under consideration.

CASE I.—T. H., æt. 18 months, stout and healthy, was seized with very unequivocal symptoms of croup on 16th of Feb., 1837; tonsils red and swollen,

but no effusion or membrane on them; attack preceded by catarrhal symptoms of considerable severity. He was ill ten hours before I saw him; he had immediately a quarter of a grain of tart. emetic, a tea-spoonful of syrup of poppy, and a dessert-spoonful of water; this was repeated twice, at intervals of fifteen minutes, before profuse vomiting took place. During this period a leech was put upon each foot: these being active, dropped off in twenty-five minutes, and the child put into a hot bath, in which situation he vomited most freely, became pale, drowsy, and exhausted, after being fifteen minutes in the bath: he was previously fretful, and coughing and crying in a most distressing degree; all of which subsided, and he fell into a calm deep sleep. A dose of calomel in a little jelly was given before putting him to rest; he had a long quiet deep sleep, with little coughing and no crying; the calomel purged him. His voice though hoarse was free from croupy sound or nearly so. Two grains of calomel and three of Dover's powder were given every six hours, and appeared to mitigate his cough, as also did holding his head over a deep vessel, a jug, containing hot water. His gums were scarified; and the counter-irritation of equal parts of lin. ammon. and ol. terebinth. applied on a bit of surgeon's lint to the proper part of thorax seemed to accomplish a cure. He completely recovered, and continued stout, thriving, and healthy, till the 17th of April next year (1838), when he forms the subject of

CASE II.—T. H. was now two years and a half old; though healthy, has ever since the former attack of croup had a croupy sounding cough when vexed; and on taking cold he always seemed to his parents to be threatened with croup, which they combated by their own skill.

Ten days ago he took measles with considerable cough, which three days ago became croupy. Common antimonial emetics, baths, leeches to feet, purgatives, and a blister, during these three days were tried, but in vain; he is now decidedly affected with well marked croup; breathing quick and oppressed; pulse 140; skin hot; thirst; tongue white.

To abbreviate details, I would state that every effort was made to save the child by emetics with and without anodynes; bleeding, baths, and blistering; sulphate of copper was freely administered; mer-

curial inunction and mercurials by the mouth were steadily persevered in till the gums were decidedly affected.

On the 19th, the following is the notice of the physical signs of the thorax:—Inspiration more difficult and shorter than expiration; dulness on percussion on some points, but not universal; natural at upper and anterior parts; respiratory sound extinct on lower and posterior parts of left lung, though percussion is natural there.

22d.—A whitish coating over all inside of throat and fauces, and on tongue, which is spotted-like; barking sound of cough and rapid breathing; percussion of chest natural; vesicular respiratory sound gone on right side; bronchial breathing still heard.

26th.—Besides other remarks, crepitant rale to a considerable extent on right side, but percussion nearly natural over all chest; is sinking; several mouthfuls of a fluid like prune juice in colour, forcibly coughed up when I was present, devoid of all smell.

27th.—Convulsive fits and death.

He had no delirium throughout; senses acute till night of 26th. Never any blood or films coughed up or expectorated; there was a dirty white stuff on the tongue and fauces, about consistence of paste, but granular looking, day before death. He was not apparently distressed in his breathing at the last, nor were the lips livid to the degree of those dying of croup; he mostly swallowed instead of spitting out what came up from his air passages.

Section cadaveris.—11 A.M. 29th April: little change in expression of countenance, which was placid; a considerable quantity of fat under the skin every where, though not much in the internal organs; muscles of a colour approaching to slight purple; a considerable quantity of fluid blood in large veins—the jugular, the subclavian, and the thoracic branches thereof. The lungs filled the chest, were of a mottled light purple and buff colour at upper parts; the summit of upper lobe on right side had many bullæ of emphysema in it; there were many fine firm membranes, of a filamentous appearance when stretched, obviously of long standing, binding the lung to the pleura costalis, particularly the upper lobe; the lower lobe being glued to the pleura costalis by lymph, yellow, soft, and very easily broken, doubtless quite recent. The parts of the pleura costalis not ad-

hering had many points of redness and vascularity, and there were six or seven drachms of serous fluid in it; the lower and posterior part of the right lung's surface was mottled, or spotted deep red; felt firm and liver-like, heavy, and its sharp margin covered by a recent layer of lymph; the upper lobe was distinctly emphysematous, and there were several irregular small pouches or vesicles of air, the walls of which consisted of the pleura pulmonalis, the air cells having given way. The parenchyma of this portion was of a lake red, mingled with a reddish buff; crepitated when cut into, and swam buoyantly in water; the lower lobe was consolidated at many points of considerable size; sank in water, and was infiltrated with yellow diffuent puriform matter, easily torn and broken down; its section presented a somewhat mottled greyish appearance; it did not pit on pressure. The air tubes or bronchia still potent and obvious in the midst of it. *The left cavity of thorax*: pretty extensive adhesions of the pleura pulmonalis to the pleura costalis, by friable yellow lymph and a little serous fluid: an ounce and a half in cavity. The summit of left lung was crepitant, swam in water, and was tolerably free from disease, but the lower lobe was infiltrated with puriform matter, consolidated, and sank in water heavily; lost the crepitation on handling or cutting, and its substance was of a dark venous-red appearance. In both lungs there were portions in very various stages of phlogosis.

The coating observed previous to death on the tongue and fauces had disappeared, nor was any visible on the gullet, epiglottis, and the margins of the glottis. The epiglottis was thicker than natural, and the margins of glottis were red as red currant jelly, swollen to the thickness of half a common lead pencil all round the margin of the chink, forming, as it were, a collar or rounded edge, instead of the sharp margin of these parts in their natural state. The surface of this swollen margin was abraded at some small points, and on its surface were several small vesicles or blisters. It felt soft and fleshy; no fluid flowed on cutting into it. The lining membrane of the larynx was of a red currant-jelly-like colour, several vessels seen on it, and some dirty mucus with specks of the lining membrane intermixed, several patches of which, very thin and very pale, and not larger

than herring scales, were still firmly adherent to the mucous lining of the air-tubes. The redness and the small patches extended down the trachea and bronchi. None of the prune-juice looking stuff, which he coughed up before death, could be seen in the air-passages.

The heart was healthy; right cavities contained primrose yellow clots, about the full of an ounce measure, and much purple serum flowed away on cutting off the apex of the heart; they had long tails extending into the venæ cavæ and into the pulmonary artery, which, when drawn out, might by fancy be likened to worms. There was a little of the same coagula in the left side, but not one-third so much as in the right.

Serous membrane of *abdomen* quite natural throughout; liver paler than usual. Gall bladder very full, and of a dark green colour.

Mucous lining of alimentary canal had every evidence of a phlogosed condition in many parts. The stomach had much dark greenish fluid in it; spleen and pancreas sound; kidney, ureters, and bladder, healthy. We were not permitted to open the head.

CASE III.—R. B., æt. 2 years, a healthy child, but had a smart attack of diarrhœa for some days, which has left him weakened and languid. About eleven P.M. of 3rd of August he was observed suddenly to cough and breathe with a croupy sound, which the whole family knew too well from his sister's late fatal attack. *He has had no cough or other catarrhal symptoms*, and the first sound of a croupy kind was heard on his waking out of sleep and suddenly coughing and breathing with the brazen clanging sound.

I saw him at half-past eleven, P.M. when he had no other symptom than the barking croupy cough, and when peevish back-draughts of a hoarse croupy character. Every function in a healthy state; no fever; cheerful and lively and played in good spirits when in the hot bath, into which he was instantly put. He had a dessert spoonful of a strong solution of tartar emetic, and eight drops of the sol. mur. morph. in it. The emetic solution was repeated in fifteen minutes with four drops of the anodyne. He was kept forty minutes in the hot bath, and vomited freely several times. The croupy sound abated; he soon fell into a calm slumber.

Eleven A. M. of 4th August. — He had a very quiet night, and had only one or two croupy coughs. Had two doses of Dover's powder, $2\frac{1}{2}$ grains each. One or two patches of dirty lymph on posterior fauces, and a large one on left tonsil, which is red and swollen. A dose of castor oil has purged freely. No constitutional symptoms.

1 P. M. — Croupy symptoms have returned as well marked as ever; and at 1 P. M. after a consultation with Dr. James Watson, he had an emetic dose of the antimonial solution every hour: in the first dose I gave him six drops of the solution of mur. morph. Two grains of calomel every two hours were also given. He was kept in bed, and a counterirritant embrocation (ol. tereb. et lin. ammon.) applied to chest.

Vespere. — He has vomited freely; all patches off the throat; has slept a great deal all day, and free from cough and croupy symptoms. Dr. Watson, whose kind and efficient attentions he now had (for I was at St. Andrew's), continued the calomel; and on Wednesday evening I found him free from complaint, though very weak.

REMARKS. — This case may be viewed by some as differing from the type of real croup; it might be said that it came on in too sudden a manner, and wanted the precursory symptoms of catarrh or bronchitis, which usher in certainly a vast proportion of cases of cynanche trachealis. I should have thought so too, unless I had evidence from experience of the accession of real croup being as sudden and unexpected as in the case just related.

CASE IV. — A girl, 4 years of age, full and healthy, was somewhat exposed to a cold east wind; she was put to bed at 8 P. M., in high health and spirits, and was observed to be free from complaint as late as 11 P. M. that evening. About 3 A. M. of following morning she awoke suddenly, with sense of suffocation, intense pain in ear, croupy breathing, and other evident marks of great distress. I saw her about 4 A. M. of 4th March, with every symptom of croupy breathing and cough; much ear-ache; tonsils reddish and slightly swollen, but presented no other morbid appearance. She had an emetic of sulphate of copper, and the same medicine continued in smaller doses; leeches applied to throat, and warm bath; calomel was given in the forenoon, and repeated during the

day; with the calomel in the evening a dose of Dover's powder was given. Considerable relief ensued; the medicines were continued, and a blister was applied to top of sternum. On the 5th I was called out of town, and requested the parents, in case she was no better, to ask the advice of one of my professional friends. On the 7th I found her, after the steady use of the sulph. cupri, the calomel and Dover's powder, considerably freer from croup; cough and breathing less strepitous. On the 8th symptoms were aggravated, and a thick layer of dirty white lymph on whole of tonsils, uvula, and pillars of fauces, and extending down as far as the eye could reach; breathing croupy, loud, and laborious. A fearful attack of suffocation came on, followed by convulsions and coma, in which state she continued till evening of same day, and died. Leave could not be obtained to open the body.

I could adduce other cases in which croup of an inflammatory nature came on with equal suddenness, so that I cannot admit its sudden advent to be a sufficient mark that the case is not cynanche trachealis, or of an inflammatory character, but one of a spasmodic nature. Nor can I avoid relating the following case, to shew that *in some cases of inflammatory croup febrile symptoms are very late in making their appearance*, and that their absence should not throw us off our guard, so as to lead us to mistake the disease because there are no febrile symptoms present, an error into which the description of some authors might lead the unwary.

CASE V. — W. R. —, a boy six years of age, full habit, though labouring under whooping cough for twelve weeks, and sent here from Aberdeen for change of air.

30th October, 1834. — Three days ago his cough put on the croupy sound, and his breathing became *wheezy*, particularly at night; but he continued playful and took his food, though rather restless and disturbed by cough last night. This morning he took his porridge at breakfast, and came, to all appearance, free from complaint, into the room to have my advice. This is my note of the case: — "Distinct croupy breathing and croupy cough; appetite good; pulse natural; bowels moved by castor oil; tongue slightly white; skin cold and moist."

Notwithstanding the entire absence of constitutional or febrile symptoms, the decided character of the croupy sound induced me to point out to the friends of the boy my alarm and his risk, and to ask a consultation. Dr. Jas. Watson saw this patient along with me; our chief reliance was placed on antimony and mercurials; leeches and a blister were also had recourse to.

On 31st (the fifth day of disease), there is the following note: "A good night after free vomiting; but at 7 A.M. began to breathe with more difficulty, and I now (11 A.M.) find it very much more oppressed and more wheezing; pulse 90, soft; skin natural. No visible affection in fauces; he points to larynx, and says it is painful; sounds of respiration and on percussion quite natural."

Vespere.—After six leeches to the throat, which bled well, I find his breathing more loud, 26 times in a minute; inspiration and expiration equal in length; he is restless, but occasionally sleeps a little; considerable visible movement or heaving of chest; sound of chest on percussion quite natural; respiratory sound extinct in some parts, but wherever heard it is natural. Now and then there is a fit of coughing, which is like a bark, and very brazen and clanging, and has a back draught.

Nov. 1st.—Blister rose in five and a half hours; a very restless night, during which breathing difficult, and he "vomited" or coughed up a film, which, on inspection, had the consistence of lymph, one broad piece of a quarter of an inch broad, nearly one inch in length, and having several tails or branches attached to it, obviously from the air tubes, though they were not entire or tubular themselves. About 9 A.M. to-day his feet became cold, his breathing slower and slower, countenance livid and cadaverous, and he sunk without a convulsion or struggle at half-past 10 A.M. He was quite acute and sensible till within two hours of his death. He felt relieved after vomiting the film.

On inspecting the trachea we found it inflamed, and in part covered with a layer of lymph of various breadths, and its continuity broken at two or more points; there was no lymph in left bronchus or in larger branches near it, probably the site from whence the film coughed up had been separated. The film or layer of lymph penetrated, as far as we could

trace it, into the tubes in the parenchyma. There was a considerable quantity of fluid (serum) in the substance of the lung, but no inflammation in it, or in pleura; some portions of the lung emphysematous.

I cannot doubt, after having seen such cases as these recited above, that croup or tracheitis may come on to all appearance in a most sudden and unexpected manner, and, until a very advanced period of its progress, may be unattended with febrile symptoms. I would most respectfully suggest, that the following sentence from the writings of an eminent author should have been qualified, lest (as I fear it will) so unguarded a statement lead into error. "From spasm of the glottis, or purely spasmodic croup and hysterical affections simulating it, inflammatory croup may be distinguished by the presence of febrile symptoms, the less sudden and more permanent character of its attack, and other points of its history." Against a statement so likely to mislead the unwary I beg to raise my testimony. With your permission I shall transmit one case more of this fatal disease, with a few remarks.—I am, sir,

Your obedient servant,

ALEX. J. HANNAY, M.D.

Andersonian University,
17th July, 1840.

ON THE "REFLEX FUNCTION."

To the Editor of the Medical Gazette.

SIR,

In the July number of the British and Foreign Medical Review, I have just read a notice of Dr. F. Nasse's observations on Dr. Marshall Hall's doctrine of the non-participation of sensation in the (so-called) reflex motions. Dr. Nasse's arguments against the doctrine appear to me to be very much the same with those which I offered to the public, in a series of papers on the subject, in the second volume of your journal for 1838-9, page 74, and with some previously published by Dr. Volkmann, none of which have as yet been satisfactorily answered. The question is not whether reflex motions from mere impression, and without any intervention of sensation, occur at all, for it has been long known that they do, as in the contraction after death of the iris on the

admission of the light, or of the lids when the eyelashes are touched. But are we, on the strength of such few reflex movements following impressions, where the connection between the incident and reflex nerves is direct, to deny the influence of sensation in the thousand complex movements in which it intervenes, and which no known anatomical connection can account for—to leave the relation of sensation to such movements a wonder and a mystery; and finally, to supplant its agency by a new theory of the dependence of combined movements on a reflex power, to which, however specious, objections exist as startling and apparently insuperable as ever interfered with the reception of any new doctrine.

The theory of combined muscular actions excited by impressions on the extremities of nerves without the intervention of sensation, necessarily supposes definite and direct connections between the excitator and the reflex nerves in all cases. Yet Professor Alison has shewn fully, that no anatomical discovery, no conjectural connection of nerves in their course or at their roots, can account for the muscular actions which arise in obedience to certain irritations applied and sensations experienced; these actions accompanying or succeeding one another in great variety, not according to the nerves or parts irritated, but according to the sensations excited. Why does not Dr. M. Hall's theory offer some explanation on this head? Why is it that irritation of the fifth pair in the nose excites sneezing, while irritation of the same nerve in the cheek excites full inspiration only; and other violent irritations of the same nerve, and same branches of it, excite no respiratory action whatever. Why the nerves of the abdominal muscles act simultaneously in the actions of vomiting and straining, but alternately in the action of coughing, sneezing, laughing, weeping, &c.; or why the nerves of the diaphragm act alone in the case of full inspiration, whether from irritation of the fifth pair in the face, or of the par vagum in the lungs; or why the nerves of the abdominal muscles associate themselves and act simultaneously with those of the muscles of the face in the actions of sneezing, laughing, weeping; but not in those of full expiration, or coughing, or tenesmus, in which they themselves act with equal force; or why the laryngeal branch of the par vagum, which

moves the arytenoid muscles, acts in concert with the nerves of the abdominal muscles, and closes the glottis in the actions of vomiting and tenesmus, but escapes such combinations in the actions of laughing, coughing, or sneezing?

It is not deniable that many facts and arguments of a specious nature, favour Dr. Marshall Hall's theory of the reflex function; but this was always the case with Sir Charles Bell's system of respiratory nerves, which, supported as it was by his many beautiful illustrations of the connection between incident and reflex nerves, yet failed in establishing itself permanently or generally with physiologists. One objection to a theory, however harmonious or imposing the general facts or arguments supporting it, if that objection be inexplicable, forms as great a bar to its reception as if there were a thousand; and it is fruitless adding proof upon proof in corroboration of its truth, while few or no efforts are made to set aside the difficulties which it includes. Sir Isaac Newton laid aside his wonderful theory of gravitation for many years, supported as it was by innumerable facts, when one simple statement respecting the dimensions of the earth, which was at variance with it, but which afterwards proved to be incorrect, was offered in some paper read at the Royal Society.

With regard to the now disputed proposition, that certain combined muscular movements, or muscular expressions, or cries, are evidences of animal suffering, as mankind has admitted them to be for ages, and as the brute creation has instinctively acknowledged, it is hard to say what satisfactory evidence can now be offered in support of it.

When we refer to those complex movements observed in respiration, coughing, laughing, &c., as instances of beautiful and harmonious combinations of muscular action by a single sensation, the influence of the sensation is denied, the movements being, it is said, reflex, and the result of purely physical impressions on the nerves. When the still more extraordinary movements observed in decapitated animals, either evincing the ordinary actions expressive of pain, or adapted to resistance or escape, are pointed to, it is said adaptation of motions to an end means nothing, the whole organized fabric being made up of a number of such adaptations. When it is shown

that the motions often continue after the impulsive force is removed, and the impressions of all physical stimuli have died away, it is inferred to be merely a consequence of new parts of the surface coming in contact with the table on which the animal moved, and so occasioning, momentarily, new impressions, and therefore new reflex movements. One only description of action—spontaneous action—resulting from internal sensations, not from external impression, is admitted by Dr. Marshall Hall, as characteristic of the sentient system in contra-distinction to the excito-motor. He says, unhesitatingly, "these latter are never spontaneous; they are always excited;" yet when proofs are brought forward of actions indisputably spontaneous taking place after decapitation, or after dividing an animal into segments, their consideration is almost wholly passed by, as if even spontaneity of action is also to be explained by the reflex system.

Not to embarrass the subject now with the many objections put forward by Volkmann and Nasse, I shall simply ask those who are advocates of Dr. Marshall Hall's excito-motor system, to repeat my experiments on the earthworm, taken recently from the earth, and, if it be possible, explain how the extraordinary spontaneous movements in the hinder segments, already described in my papers, could occur without the agency of sensation. In those papers it will be seen that by spontaneous, I do not mean voluntary, movements, but movements arising out of internal continuous feelings, and wholly independent of impressions produced by external stimuli, which, of necessity, cease when the stimuli are withdrawn, and cannot recur unless they are reapplied.

I remain, sir,

Your very obedient servant,

WILLIAM GRIFFIN, M.D.

Limerick, 74, George Street,
July 23, 1840.

NOTE,

BY DR. POWER, ON MR. H. CARMICHAEL'S
INVESTIGATIONS REGARDING
THE PLACENTA.

[*For the Medical Gazette.*]

THE position which the after-birth occupies in the womb in the different

stages of gestation, has lately been undergoing a very interesting, and we may say satisfactory, inquiry, at the Coombe Lying-in Hospital, Dublin, by Mr. Hugh Carmichael.

The extensive opportunities which that institution in every respect affords, renders it peculiarly favourable for the investigation of a subject of so abstruse and difficult a nature; and it is but justice to Mr. Carmichael to say, that in his hands this appears to have been fully accomplished, and a point of science, heretofore veiled in mystery, developed and explained in a way that is both intelligible and satisfactory.

We regret our space precludes the possibility of our giving other than a very slight sketch of this explanation, and the mode adopted in his inquiry. We must for this purpose refer to Mr. Hugh Carmichael's paper on the subject, which appeared in the "Dublin Journal of Medical Science" for January, 1839, and the perusal of which will amply repay the reader.

The opinion respecting the situation of the after-birth in the womb has heretofore, as is well known, been, that, with some few exceptions, inasmuch as its first formation takes place in the vicinity of the fundus, at the uterine extremities of the fallopian tubes, in that position it continued throughout gestation. Mr. H. Carmichael has shown, as well by reasoning on the matter as by demonstrative proof, that this opinion is erroneous, and that, although its position may at its formation be as above stated, yet, by the time labour is about to come on, it has so changed that position that it is then low down on the posterior wall of the womb, generally either to the right or left side, according as the fallopian tube lies through which the ovum entered the uterus.

The first of these points, which relates to its original formation at the fundus, Mr. C. does not think it necessary to dwell on; it is admitted generally. To the position of it when labour is near, and the changes in this respect it appears to be undergoing during gestation, his attention has been chiefly directed, and as it appears to us with complete success.

The mode adopted for this purpose consists in an examination of the secundines after their delivery, the membranes of which, he shows, bear such marks as will enable us to ascertain where each

part of them lay when within the womb, and thus assign to the placenta, which is always attached to them, its uterine position likewise.

Mr. H. Carmichael remarks, in his interesting essay, that it has been observed by several writers on midwifery, that the distance the placenta lies from the fundus or from the mouth of the womb may be ascertained by simply observing the secundines after their delivery. The child, it is known, is enveloped in the membranes within the uterus, in a shut bag, similar in formation to the peritoneum, or any other of the serous class; and in order to its birth, the head, or whatever part presents, must first perforate this bag where it corresponds to the mouth of the womb. The membranes, with the placenta attached, are afterwards delivered uninjured or broken elsewhere, and the distance the placenta is from the perforation at once demonstrates where its distance from the mouth of the womb was when within the latter.

Mr. Carmichael, however, has gone further in his examination of these parts than his predecessors. All former inquirers merely sought to learn from them the altitude of the placenta in the womb, and even this we may say none made the subject of conclusive inquiry, as is evident from the opinion of the present time being, that the fundus is its usual position at all stages of gestation. Our author, however, has shown that by inspecting them in the manner pointed out by him—first, that the placenta is, in ninety-six times out of the hundred, in the vicinity of the aperture made in them by the head previous to its birth; and next, that the longest part of the membranes give evidence of having lined the most distended or concave part of the womb; the shortest, one comparatively of a straight superficies.

The inference he obviously deduces from these facts are two-fold. The one, that the fundus is not the situation of the placenta at the close of utero-gestation, but that it is somewhere near the os uteri; and the other, that that somewhere is on the posterior surface.

Mr. Carmichael then goes into a very ingenious disquisition as to how the womb enlarges as the child grows. He contends that this cannot be in the way generally supposed; the fundus rising

up and maintaining its position unaltered all through, because in that case, he says, the placenta, which is first formed on that part of the womb, would continue there, and the inspection of the secundines, as above, would discover it implanted on them exactly opposite their aperture or opening. He then declares his opinion on this point to be, that to account for this apparent sinking of the placenta on the posterior part of the womb, the anterior wall of the organ must chiefly supply the increasing superficies, while the back part of the womb, and what was the fundus on the formation of the placenta, only increases in a proportion sufficient to accommodate the placenta. If the fact be that the placenta is found at the close of utero-gestation low in the womb, as Mr. C. states, this appears a very rational conclusion, because its first formation being at the uterine opening of the fallopian tubes, it would be difficult otherwise to account for the change of position; and some explanation of how this takes place may be derived from the mechanical effect produced on the front of the womb by the weight of the increasing child, pressing against that part of the organ, and thereby loosening out its texture, and which could not occur in the same way in any other part of it.

Mr. Carmichael then submits, that if this be the mode the womb enlarges, the contractions must take place in a corresponding retrograde direction; so that if uterine expansion goes on, on the anterior wall chiefly, its diminution or expulsive efforts at labour must be there likewise; and on this supposition he explains several matters connected with the process of gestation and parturition, which, it must be admitted, were heretofore very unsatisfactorily accounted for. We cannot, however, enter into any detail of these matters, but shall only say the subject is highly deserving of attention, and hope he will follow up the investigation, and fully avail himself of the extensive field for observation which is happily placed at his disposal.

The opinions put forward by Mr. Hugh Carmichael have, in subsequent numbers of the Dublin Journal, been impugned, and their stability questioned. Mr. C., however, complains of the manner in which this examination was conducted, and shows how some

of his statements were not fairly represented. We cannot suppose this would arise from other than misconception. The view Mr. Carmichael has taken of the subject, and the manner he has handled it, are highly interesting, and we would say, as far as appearances go, convincing. In the last number of the above journal he has in part answered a reply to his paper from the Dublin Lying-in Hospital, and the remainder is to appear in the next succeeding number;—he ought in that to apply himself to the consideration of a statistical table of 100 cases, which the reply in question contains, and which certainly, as it stands, makes very much against him;—he has, however, stated his intention to do such, and we shall anxiously await its appearance.

THE LARGE PROPORTION
OF
INDIGENT OR IMPROVIDENT
FAMILIES

IN THE POPULATION OF THE TOWNSHIP OF
MANCHESTER, SHEWN FROM THE REGIS-
TERS OF THE LYING-IN HOSPITAL.

BY JOHN ROBERTON, ESQ.

Late Senior Surgeon in Ordinary to that
Institution.

[For the London Medical Gazette.]

MANY attempts have been made at different times to exhibit the physical and moral condition of the people of this township, by pursuing various lines of statistical inquiry; as, concerning the state of education, the condition of the dwellings, the amount of poor's rate, the number of persons receiving relief, the quantities of certain kinds of food consumed, and the like. My present object is, by a somewhat different line, to exhibit the population as unfortunate in consisting too exclusively of the working classes—of persons low in the social scale, both in respect to the means of living, and, what is of far more consequence, in respect to forethought.

In the year 1796, the Manchester Lying-in Hospital was opened for the reception and delivery of poor pregnant married women; also, as a charity for the delivery of the same class at their own homes. Relief in these two ways was afforded up to the year 1814, when the admission of in-patients ceased, and

thenceforward the establishment was a Lying-in Charity alone. Its operations extended to the poor of the whole town of Manchester, excepting Pendleton, including the townships of Salford, Manchester, Hulme, Chorlton-upon-Medlock, and Ardwick. In 1815 (the year after the reception of in-patients ceased), the number of women delivered at their own homes was 1433. In the year 1825 the number had more than doubled, being 3120. From that period the increase was so great, that in the years 1830, 1831, and 1832, the number delivered averaged 4428 per annum.

In extracting certain particulars from the registers of the Charity, I purposely confine myself to the three years above mentioned, because the census of the population, taken in 1831, affords an accurate enumeration, for those years, of the inhabitants of Manchester, whose poor married women had the benefit of the Charity; in the next place, because the population of the townships has probably undergone little increase, and certainly no material improvement as to condition, since that period; and chiefly, in the last place, because the Committee of the Charity, alarmed at the increasing tide of applicants, began, late in 1832, or the year following, to reject all patients in a first pregnancy; and gradually, by various new regulations, to lessen and limit the number of admissions.

By the census of 1831, Manchester (by which I mean the afore-mentioned five townships) contained a population of 218,529. Now, in the year ending May 1830 as many as 4397 patients were delivered by the Charity; in 1831, 4444; and in 1832, 4445; being, as I have said, 4428 deliveries on the average per annum.

Such was the number of births attended by the Charity. What proportion did it bear to the entire number of births in the whole population? The number of births which occurred in the whole population cannot be accurately ascertained, owing to the want then, and indeed the same may be said at the present moment, of a perfect system of registration; for even now the returns of births cannot be considered as complete. But a near approach to correctness may be got by reference to the proportion of births to the population in

certain foreign towns, where registers are probably to be relied on; and it is guided by such instances that I infer that the legitimate births in Manchester are as one, annually, to every thirty inhabitants*. Assuming this as the probable proportion, the number of births for the whole population would be 7244, consequently the proportion attended by the Charity must have amounted to more than three-fifths of the whole: or, to express the same in different words, out of a population of 218,529 persons no fewer than 132,840 had yearly all the legitimate births that occurred among them, attended by the Lying-in Charity.

In reflecting on these startling results a question naturally suggests itself, did recently married women—those, I mean, in a first or a second pregnancy, find admission? The following table supplies an answer:—

	Total of Women delivered.	Of which there were in a first Pregnancy		In a second Pregnancy
1830 ...	4397 ...	375	610	
1831 ...	4411 ...	310	609	
1832 ...	4445 ...	141	529	

Thus it appears the average annual number of patients delivered by the Charity being 4428, there were included in this number, 276 married women (upwards of 6 per cent.) pregnant for the first time, and 580 (upwards of thirteen per cent.) pregnant for the second time, making together nearly one-fifth of the total number delivered.

The trade or occupation of the patients' husbands: concerning this particular I have made what I could out of the register, for one year, extracting the names of the trades of all set down: the number of names extracted is 2089, but under this head the register is very incomplete.

Apprentice, 1.	Cleaner, 1.	Journeyman, 2.	Skinner, 3.
Batter, 7.	Cooper, 2.	Joiner, 12.	Scavenger, 4.
Book-keeper, 1.	Clothes seller, 2.	Labourer, 437.	Shoe-binder, 1.
Bookbinder, 1.	Card-grinder, 3.	Lamplighter, 1.	Soldier, 15.
Box-maker, 1.	Cutler, 3.	Lodge-keeper, 1.	Stainer, 1.
Brazier, 2.	Currier, 1.	Moulder, 5.	Sailor, 1.
Blacksmith, 9.	Comb maker, 1.	Millwright, 1.	Stone mason, 7.
Basket-maker, 4.	Chandler, 1.	Mechanic, 3.	Sawyer, 10.
Butcher, 2.	Dyer, 91.	Maker-up, 3.	Sizer, 4.
Boatman, 12.	Draper, 1.	Miller, 3.	Stripper, 15.
Brush-maker, 4.	Dresser, 2.	Nailer, 1.	Setter, 1.
Brewer, 3.	Doubler, 1.	Needle-maker, 1.	Servant, 2.
Baker, 6.	Ender, 1.	Overlooker, 1.	Stone-breaker, 3.
Bat-maker, 1.	Engineer, 1.	Ostler, 2.	Schoolmaster, 2.
Brick-maker, 6.	Engraver, 1.	Porter, 53.	Saddler, 4.
Band-box-maker, 1.	Foundry-man, 1.	Packer, 5.	Sweep, 5.
Blacking maker, 2.	Frame-maker, 4.	Plasterer, 5.	Slubber, 4.
Bricklayer, 15.	Fustian-shearer and cutter, 71.	Pinheader, 1.	Striker, 5.
Binder, 2.	File-cutter, 3.	Piecer, 23.	Silk-winder, 8.
Barber, 1.	Fringe-maker, 1.	Pereher, 1.	Spinner, 103.
Boatbuilder, 1.	Factory-worker, 20.	Painter, 29.	Spindle-maker, 2.
Boiler-maker, 1.	Grinder, 6.	Pipe-maker, 1.	Tailor, 45.
Cotton-picker, 7.	Gasman, 2.	Pot-seller, 1.	Tenter, 1.
Clockmaker, 2.	Groom, 9.	Printer, 16.	Throster, 1.
Collier, 2.	Grocer, 2.	Plumber, 4.	Turner, 4.
Carter, 32.	Glassblower, 3.	Reeler, 13.	Umbrella-maker, 1.
Carder, 28.	Gardener, 2.	Rope-maker, 8.	Weaver, 518.
Chemist, 2.	Gilder, 1.	Reed-maker, 2.	Wire cutter, 1.
Chestmaker, 5.	Hawker, 8.	Smith, 4.	Winder, 47.
Carpenter, 28.	Hatter, 2.	Sinker-maker, 1.	Warehousemen, 4.
Calenderers, 11.	Hat dyer, 11.	Silk weaver, 4.	Wood-turner, 1.
Corkeutter, 1.	Huckster, 2.	Slater, 4.	Watchmen, 15.
Clogger, 2.	Hairdresser, 1.	Stretcher, 7.	Warper, 4.
Coachmaker, 3.	Jobber, 23.	Shoemaker, 89.	Wheelwright, 2.
Chair-maker, 5.		Stillener, 1.	Whitesmith, 3.
Coachmen, 5.			

* I have said *legitimate* births, as it is with these only I am concerned, none but married women being admissible as patients of the Cha-

rity. But it was ascertained a number of years ago, in 1827, that the number of illegitimate to the legitimate births in the township of Manchester

From this table, I select the occupations whose number is 20 and upwards, and arrange them in order:—

Weavers, 518.	Tailors, 45.
Labourers, 437.	Carters, 32.
Spinners, 103.	Painters, 29.
Dyers, 91.	Carders, 28.
Shoemakers, 89.	Carpenters, 28.
Fustian shearers and cutters, 71.	Jobbers, 23.
Porters, 53.	Piecers, 23.
Winders, 47.	Factory-workers, 20.

Hitherto it has been the number of women delivered by the Charity, as compared with the entire population included in the before-mentioned townships, to which reference has been made. But it is time to remark that the patients are furnished in very different and unequal proportions by these townships; the township of Manchester supplying nearly six times as many as any one of the others. The following table presents the number of lying-in women attended by the Charity in the different townships in the years 1830-31-32:—

	1830.	1831.	1832.
Manchester...	3417	3710	3681
Salford	683	505	487
Charlton-row	195	126	69
Ardwick	19	29	35
Hulme	47	28	48
Omissions as to residence	36	46	124
	4397	4444	4445

The table which follows shews the population of each of the five townships in 1831, and the annual number of poor married women delivered in each on the average of the years 1830-31-32:—

Township of	Population.	Delivered by charity.
Manchester...	142026	3602
Salford	40786	558
Hulme	9624	41
Charlton upon		
Medlock	20569	130
Ardwick	5524	27
Omissions as to residence and in Cheetham.	27	—

The population of the township of Manchester in 1831 being 142,026, the total number of legitimate births therein must have been (on the principle before

assumed) 4734. But 3602 of this number were attended by the Charity, shewing that a proportion of its inhabitants, amounting to 108,060, must have been so *poor* or so *degraded* as to stoop to receive this kind of charitable assistance. To vary the manner of stating this surprising fact, out of a population of 142026 persons, having annually 4734 legitimate births, only 33,966 persons, with 1132 births, remained independent of the Lying-in Charity's aid.

The township of Manchester embraces the older portion of Manchester; it also contains a great proportion of the mills, machine-shops, and foundries, all the warehouses, and the principal lines of shops. The inhabited portion of the township from Knott Mill to Miles Platting, is, in length about two miles, and from Ducie Bridge to Ancoats Bridge in breadth upwards of one mile. In it very few of the more respectable inhabitants of the borough reside, and these few chiefly in the professions. Nearly all the manufacturers, merchants, and warehousemen, and the more affluent shopkeepers, have, during the last fifteen years, removed to the surrounding townships: even the clergy, and the ministers of the different religious bodies, with few exceptions, are withdrawing to a purer atmosphere: consequently, the resident population consists chiefly of operatives, and of the families of the publicans and smaller shopkeepers by whom they are supplied with the articles of living. Intermingled with the crowd of operative poor, and residing amongst them, there is only a very small number, in some populous parts of the township, perhaps none, who, by education, superior intelligence, and respectable station, are fitted to exhibit an improving example, or to perform those various acts of kindness and benevolence so often and so greatly needed in a dense population. As an illustration of this, I may mention what I have often heard from professional men connected with our medical charities, that they always found that their exertions in attending on the poor in the township of Manchester, howsoever meritorious, remained unnoticed by, because unknown to, the respectable portion of the general community; that it was extremely rare to find any of their patients who were visited and looked after by members of the wealthier families; that however

was probably as one-twelfth; consequently both together will give a proportion of births to the population as 1 to 27. Whether this proportion of births to the population be a little too high, or the reverse, can, of course, in no material way affect the value of any calculations in this paper.

skilfully they might conduct the treatment of a case, howsoever remarkable the cure they performed, it was all one; there was little or no chance of its getting known amongst those families, of an upper class, to which the medical officer of a charity naturally looks for the reward of his gratuitous and self-denying exertions.

That the Lying-in Charity, at the period referred to, was abused and imposed on there can be no doubt. Some few of the patients (contrary to the rules) were unmarried, and others were in too good circumstances to need its aid; but the vast majority were in a state of poverty. Having been many years much engaged in visiting the abodes of the patients, I am obliged to declare that, judging from appearances, and from what I could gather in other ways, their families were very poor, generally destitute of every comfort and convenience, and often even of necessary articles. Few of them, comparatively speaking, rented an entire cottage; a considerable proportion lived in cellars; and those living above ground were, in many instances, lodgers; a single family, however numerous they might be, commonly occupying but one apartment. I have rarely, if ever, observed any of them possessed of a single article of good cottage furniture, as a chest of oak or mahogany drawers, or an eight-day-clock. The furniture was generally of the rudest kind, consisting of one or two clumsy bedsteads, a deal table, two or three deal chairs, and (though this is not always to be observed) a paltry cupboard containing a few articles of common earthenware. At the time of lying-in, the midwife had often, out of her own pocket, to furnish money to procure candles, and meal to make a basin of gruel with. My impression is that it was rare indeed to find any of the patients in circumstances above what would be thought suitable in the applicants to a public charity. Two or three brief inferences drawn from the foregoing tables will conclude what I have to say.

1st. The *fact* of a pregnant married woman applying for the aid of a lying-in charity, is evidence of itself, generally speaking, of either indigence or habits of improvidence.

2nd. The large annual number of applicants on the list of the Manchester Lying-in Charity, in a *first* and *second*

pregnancy, shews with how little forethought the married state must have been entered. In reference to those in a *first* pregnancy, as far as my experience, as one of the surgeons of the Charity, extended, the parties were always found living in lodgings.

3rd. The table displaying the occupations of the patients' husbands, proves that a considerable proportion was of the *skilled* class of workmen.

4th. The circumstances of the population consisting in so unmixed and exclusive a degree of the working classes, is to be regarded as unfavourable to the progress of sound intelligence, morals, and happiness; for since it is unquestionable, that "evil communications corrupt good manners," such a community must *necessarily* be exposed to every kind of corrupting and debasing example and influence; while, from the vastness of the field presented, the means of correction and improvement have hitherto been found to be in a lamentable degree inoperative.

5th. It is often asserted, that because wheaten bread, butcher's meat, and certain articles of luxury, are consumed in much larger quantities, and partaken of by a much greater number of people than was the case half a century ago, the population must be much better fed now than formerly: but in this assertion an important particular is overlooked; for though it be true that the absolute quantity of wheaten bread, butcher's meat, &c., consumed in Britain is immensely greater than it was fifty years ago, the relative quantity may not be equally increased, *i. e.* the quantity in relation to the increased number of inhabitants. The population occupying the soil of the island in the year 1801, was upwards of ten millions; in 1831, there were found nearly six millions more. Hence, it is obvious, there may be great absolute increase of wealth and the means of luxury, and yet the very same or a smaller per centage of the population partaking of them. Indeed, it is easy to conceive that the country may go on, for a time, increasing its wealth, while indigence is the lot of an increasing per centage of its population.

6th. The manufacturing system of this country, grouped as it is in great towns and villages, is an experiment of only fifty years' duration; whose results, as to whether they will be ultimately favourable or detrimental to human hap-

pinness, cannot, as yet, be confidently determined.

7th. It is probable that rapidity and cheapness, in the transit of goods and passengers from one place to another, arising from the construction of railways, will tend to prevent the continued growth of the operative population of Manchester, and other great manufacturing towns, by leading to the erection of manufactories, and the putting out of various kinds of work in the villages near and remote of the surrounding counties.

TWO CASES

OF

ACUTE INFLAMMATION FOLLOWING THE REMOVAL OF FOREIGN BODIES FROM THE ŒSOPHAGUS,

CONTRASTING THEIR AFTER TREATMENT
AND RESULTS.

By GILES BORRETT, M.R.C.S.

[For the Medical Gazette.]

IT has fallen to my lot to witness many cases of choking from food and portions of bone sticking in the œsophagus. I have been often called upon to remove needles, pins, and other sharp bodies from the larynx, which I have succeeded in extracting by means of forceps with shoemakers' wax at their points.

The following cases serve clearly to mark the treatment required after the removal of the foreign body, when inflammation is set up by the mechanical injury done to the soft parts. In the one, inflammation of the œsophagus and adjacent textures brought the life of my patient into imminent danger, and in the other it proved fatal.

On Wednesday, 4th of September, 1839, Mr. Walter Macgrigor ran to our surgery in consequence of a piece of bone sticking in his throat while eating a hasty meal of a mutton chop, about 4 o'clock in the afternoon. My partner, Mr. S. Ferrier, on hearing from him the occurrence, immediately prepared and passed a probang (having an ivory ball at one end), to dislodge and carry the bone down into the stomach, which at the time was thought to have been accomplished. At 8 o'clock the same evening I was called to Mr. Macgrigor, who was complaining of great pain from the bone pricking him, which he

felt persuaded was still lodged in his œsophagus.

I then took a probang with a sponge end, new, soft, and large, and having oiled it, I passed it gently and gradually down the œsophagus, giving it a slight rotatory motion opposite the seat of irritation, hoping the bone would be caught in the loose texture of the sponge, and carried into the stomach; this he seemed convinced had been effected. I advised him to take only barley water and thin gruel.

On Thursday, 5th, he walked out; it was a cold day and he supposed that he caught cold, for on the Friday I met him in the town, when he complained to me of great soreness of his throat. I ordered him a gargle of emuls. amygd. dul., potass. nitrat., et liq. opii sedat.; to swallow a table spoonful frequently.

Saturday, 7th, he was feverish, and I requested him to keep quiet at home, and apply twelve leeches to his throat, and prescribed aperient and antimonial medicines. The next day, Sunday, 8th, I found him more ill; the leeches were repeated, and I begged him to send for me if the pain was not relieved. At 4 o'clock I was called from church to him; I now felt great anxiety at the alarming increase of his symptoms. He was suffering from pain and tenderness of the throat behind the pomum Adami, with frequent spitting, flushed face, eyes suffused, with a full and hard pulse, afraid to swallow, or even make the attempt. I immediately prepared to bleed him, which both he and his friend and companion opposed; I however insisted upon it, assuring them that he was certainly in great danger, and that, in my opinion, bleeding alone would save him. I placed him upright in bed, and bled him from a large orifice until he fainted, in which state he remained some time; indeed the faintness did not pass off for some hours: he took nothing throughout the night. The following morning I had the great satisfaction to find that the pain and other urgent symptoms had been at once arrested by the blood-letting (thirty-six ounces); he could now swallow a little milk and water. From that time his recovery was decided. He was well enough to leave Yarmouth in about ten days, with Sir James and Lady Macgrigor.

After the bleeding of Sunday, 3th, I first learned that our patient was a son

of Sir James Macgrigor. I requested that his friends should be immediately informed of his present alarming state; they arrived here on Tuesday morning early. I directed Sir James's attention to the remarkable appearance of the blood, which I had ordered to be preserved, by which he was enabled to judge of the state he had been in. The coagulation of the first-drawn blood was buffed, cupped, and with a crisped edge; that in the second basin was firm, hard, and slightly buffed.

I shall now contrast the preceding case with that of a young man, aged 25, living near Bury St. Edmund's; the unfortunate occurrence happened at night, June 30th, 1837, and terminated fatally on the 12th of July, as stated by a medical gentleman under whose care he first came. I quote from a letter he was so obliging as to write me on the case, in which I was much interested. "It appears that the young man was spending the evening at a dress-maker's, to whom he was paying his addresses, that he was laughing and talking with the young women, and showing them how he could place a darning needle between his teeth, so as to set his mouth open. While he was doing this, one of the young women came behind him, and either touched him or pulled the chair, when the needle suddenly snapped, and it was supposed that one or both pieces went down his throat: this was about 10 o'clock at night. I was immediately sent for; but on examination of the throat by a most imperfect light, I could not discover the needle or any part of it; it was supposed that the other part flew from his mouth at the moment of the accident, yet it could not be found in the room. The young man still thought that something was in his throat, and requested me to pass something down. I did not much approve of this suggestion, but in the anxiety of the moment I consented; I then oiled a small probang, and passed it cautiously into the œsophagus, and after requesting my patient to state at which part of the throat the foreign body appeared to rest upon, I drew the probang upwards and against that part, in order to withdraw it with the instrument; still nothing came away, although the patient felt immediately relieved, and almost fancied that the needle was removed. The symptoms soon returned, when, at his urgent request, I again passed the probang. As it did not dis-

lodge the needle, I was resolved to do no more till I had the advantage of daylight to explore the throat, which, being in summer, would be about four o'clock in the morning. In the meantime I ordered twelve leeches to the throat, and gave a dose of castor oil; I then left him, telling his friends that I should see him again about four o'clock; but just as I set out from my house at that time, I received a message that it would be unnecessary for me to go, as the family had called in their usual medical attendant. The young man remained under the hands of his medical man nearly the whole of the succeeding day, during which time, I understand, various attempts were made to extract the needle without success."

The sequel of this story is from a letter of a medical friend at Bury, one of the Hospital surgeons; he says—"the man came to the hospital the day after the accident, an emetic having been previously given him. The needle was extracted the day of the admission, with a pair of forceps with cobbler's wax at the end. The man died three weeks afterwards of inflammation, which extended all over the pharynx down the œsophagus. I saw the parts, and they were almost in a state of gangrene." I fear I cannot give you any further particulars, as the surgeon took no notes of the case.

Great Yarmouth, July 28th, 1840.

STRYCHNINE IN NEURALGIA.

To the Editor of the Medical Gazette.

SIR,

IN the administration of active remedies, it has been, I conceive, too much the custom gradually to augment the dose to the utmost limit of tolerance. This mode of procedure is more calculated to exhibit the poisonous than to elicit the medicinal effect of medicines. It is a mode of trying the powers of resistance on the part of the patient, instead of proving the efficacy of the remedy.

The question in every case is, not how large a dose the patient can take with impunity, but, by how small a dose his disease can be cured; for it will not, I think, be denied, that every medicinal agent which is potent for good, is equally potent for evil, when unduly, as well as when untimely administered.

This is a medical canon of universa

application. The paramount duty of the prescribers, therefore, is carefully to note the operation of the remedy upon the disease, and if the disease be yielding to the influence of the remedy, although it may be slowly, instead of augmenting the dose to the utmost limit of safety, to suspend the remedy, from time to time, in order to ascertain what progress has been made towards the cure.

This rule applies to the administration of all energetic medicinal agents—to mercury in the cure of syphilis; to tartarized antimony in pneumonia; to calomel and opium in pleurisy; to acetate of lead and opium in hæmorrhage; to quinine in intermittent fevers; to colchicum in gout and rheumatism; to conium in carcinoma; to digitalis in dropsy; to iodine in bronchocele; to opium in tetanus and other spasmodic diseases; to nitrate of silver in epilepsy; to strychnia in paralysis. In each of these cases, experience has shewn that results far more satisfactory have been obtained from these active agents in medicinal than in poisonous doses. Inattention to this simple rule has doubtless been frequently the cause of their failure.

With these few prefatory remarks, I proceed to the immediate subject of this paper.

The attention of the profession has been for nearly thirty years directed to the *nux vomica*, in the form of its alcoholic extract, as a remedy in paralysis; and for nearly twenty years to its alkaloid, strychnia, for the same purpose. To Dr. J. L. Bardsley we are indebted for several valuable cases, in which the efficacy of strychnia in paralysis was fairly tested.* It is to the utility of strychnia in another class of diseases—the various forms of *neuralgia*—to which I desire to invite attention. Mine was first directed to the employment of strychnia in a case of this description, from conceiving that neuralgia might be occasioned by a diseased condition of the nerves of sensation, similar to that which occasions one form of paralysis in the nerves of motion, viz., an injected state of the capillary vessels of the investing membranes of the nerves. That the loss of voluntary power in the one case, and the acute pain in the other, proceed from one and the same pathological condition—an alteration in the relative

state, or a deviation from the normal relation, which ought to subsist between the capillary vessels and the nervous fibrils.

It is probable this injected state of the capillaries may be owing to the altered qualities of the circulating fluids, which occasion the loss of tone in those minute vessels; and hence their admission of the red particles of blood. The first case in which I tried the strychnia was in that of a maid-servant, who suffered from neuralgia of the infra-orbital branch of the fifth pair. The agony was dreadful. After a variety of means had been employed without any alleviation, strychnia, in the dose of a twelfth of a grain, mixed with sugar, was prescribed. After the third dose relief was obtained. The pain entirely ceased before a grain had been taken. In a few days the pain returned in a slighter degree; the medicine was resumed with the same good effect, and there has been no relapse.

The second case was of another maid-servant. The affected nerve was the infra-orbital branch of the fifth pair, the pain extending to the joint of the lower jaw, the motion of which, in eating, speaking, &c., brought on the paroxysms. After a few doses of the twelfth of a grain of strychnia, the pain ceased, and has not returned.

The third case was of sciatica in a labouring man. One grain of strychnia, divided into twelve doses, sufficed for the cure. The pain returned after several weeks. The cure a second time was effected by the same remedy, and he remains free from pain.

The fourth case was a complication of neuralgia, and loss of power in the right hand and arm, in a female teacher in an infant school. On attempting to write, paroxysms of severe pain, and loss of control over the muscles, compelled her to desist.

After taking the twelfth of a grain of strychnia three times a day, for three days, a great increase of pain in the arm and hand supervened, with violent agitation affecting the whole side. Relinquishing the medicine for a few days, the pain and agitation subsided, and she felt the arm much stronger and less painful. The medicine was resumed again, and relinquished on a recurrence of the same symptoms in a slighter degree. A third course of the medicine effected a cure. The improvement in

* Hospital Facts and Observations.

the state of the general health was no less striking in this case, than in the hand and arm. To use her own expression, "She had never taken any medicine from which she had derived so much benefit as from those pills."

The fifth was a case of sciatica in an elderly woman. The pain had existed for several months, and at times it was excruciating; it commenced with lumbago. Tenderness on pressure being felt in the sacral nerves, a few leeches were applied, and blue pill at night, followed by castor oil in the morning, was prescribed. By these means the tenderness at the lower part of the back was removed, but without any alleviation of the pain along the course of the sciatic nerve. Strychnia, in the twelfth of a grain dose, was given; three grains of the medicine, taken with occasional intervals of a few days, effected the cure, with a very decided amendment in the state of her health.

The sixth case was severe neuralgia of the left arm, accompanied with cerebral symptoms, fits of vertigo, and loss of recollection. The patient had formerly suffered from epileptic attacks, and had obtained immunity from epilepsy by the use of strychnia, in poisonous doses. The dreadful agitation she had experienced under the influence of this medicine rendered her unwilling to have recourse to it again. After a few doses of alterative and aperient medicine, she commenced with the small dose of strychnia. The same symptoms, only in a very moderate degree, followed the use of the remedy—unsteadiness in walking, and irregular twitching in the muscles, with aggravation of pain in the arm. The strychnia being omitted, the pain subsided, and so on several times, each time the pain being less, till it has almost entirely ceased. The removal of the cerebral symptoms preceded the diminution of the pain in the arm, and an amended state of her general health has become apparent under the influence of the strychnia, which she is still taking.

These six cases are insufficient to establish the efficacy of the strychnia in neuralgia; but the result has shown the power of the remedy over painful, no less than over paralytic, affections of the nerves; and it has been so far satisfactory as to entitle the strychnia, in minute doses, to a more extensive trial in this most distressing class of diseases.

As in cases of paralysis strychnia has only been found of use where there was no organic lesion of the cerebro-spinal centres, so, in cases of neuralgia, no hope of benefit from strychnia is to be entertained, where there is any mechanical cause of irritation affecting the nerve at its origin or along its course. The difficulty of ascertaining the existence of such a mechanical cause oftentimes is confessedly very great. The only dietetic restrictions are careful abstinence from any thing sour,—vinegar, hard beer, cyder, acescent wines, unripe and acid fruits, common salt in large quantity, and saline medicines.

The *modus operandi* of strychnia, besides its direct influence upon the nervous system, seems to be similar to that of all bitter tonics; increasing the appetite for food; promoting digestion; and as a consequence occasioning constipation. But this is perhaps not to be regarded as a morbid condition, but as the effect of a more perfect digestion, and the absorption of a larger proportion of nutriment into the system.

It may be owing to the introduction of a larger quantity of perfectly assimilated chyle into the blood, that harmony is restored between the circulating fluids and the nervous system, and hence the benefit of the *diète blanche* in hysterical and other nervous disorders.—I am, sir,

Your obedient servant,

J. PIDDUCK.

Great Russell Street, July 24, 1840.

ACCOUNT OF A PREPARATION
EXHIBITING
AN ADHESION OF ONE OF THE
AORTIC VALVES TO THE
AORTA,

AND AN OCCLUSION OF THE LEFT CORONARY ARTERY.

By P. N. KINGSTON, M.D.

Physician to the St. George's and St. James's Dispensary*.

To the Editor of the Medical Gazette.

SIR,

THOUGH I perceive that a short notice of this preparation has already appeared in your journal, you may, perhaps, deem a more complete history of the case worthy of publication. The follow-

* Read at the Pathological Meeting of the Royal Medico-Chirurgical Society, on April 21st, 1840.

ing is the account which I read to the society, with some corrections suggested by a subsequent dissection of the part.

I have the honour to be, sir,

Your obedient servant,

P. K. KINGSTON.

7, Charles Street, Berkeley Square,
22d July, 1840.

The preparation which I have the honour to lay before the society was obtained by Mr. Charles Walsh and myself at a post-mortem examination on Friday last. It exhibits lesions of which no cases have yet been recorded. There is, in the first place, a perfectly close adhesion of one of the aortic valves, through its whole extent, to the surface of the aorta. It is bound down both by tough bands intervening between the valve and the artery, and also by a membrane, which passes straight over the valve's free edge, and covers the adjacent part of the ventricle and aorta. It is a thin, tough, reddish membrane, with loose shreds appended to its surface. It adheres with firmness, but is easily dissected from the serous tunic below. The valve in question is very slightly thickened at its edges; the other two are rather more so. Where the adhesion has taken place, the aorta is thickened to a quarter of an inch, and of a texture principally fibro-cartilaginous. The rest of its upper part is irregularly thickened from atheromatous, fibro-cartilaginous, and osseous degeneration; the serous tunic is in some places denuded, leaving a rough atheromatous surface, and is in other places torn and undermined. Its orifice and channel are of moderate calibre.

The second lesion to which I referred is an occlusion of the orifice of the left coronary artery, which lies in front of the adherent valve. This is effected by the false membrane above described, which covers and adheres to it. The artery in its passage through the aorta is somewhat thickened and fibro-cartilaginous, flattened and much contracted, with a longitudinal wrinkling of its inner surface. A little beyond, it regains a tolerable size. The right coronary artery is rather small, but healthy.

The heart's cavities were all greatly dilated; those of the left side much the most so. The tricuspid orifice had a circumference of five inches, while its valve was somewhat shortened. The

parietes of the left ventricle were attenuated nearly in proportion to their dilatation; those of the right ventricle were somewhat hypertrophous.

There were extensive bronchitis, pulmonary apoplexy, rather recent adhesion of the left lung to the pericardium, granular liver, softening and deep reddening throughout the mucous membrane of the stomach.

The subject of these lesions, Sarah Guest, was a widow, aged 53, who had rather indulged in spirituous liquors. Her complaint commenced five years ago, as the catamenia became scanty and irregular, were generally worse just before the menstrual discharges, and greatly increased three years afterwards on the entire cessation of the menstrual function. There were cardiac palpitation, pain extending from the heart to the scapulae, dyspnoea, and faintness, which often occurred in sudden and severe paroxysms, either during exercise, when she could hardly save herself from falling, or during sleep, when she was startled up in great terror, and obliged to continue erect for a considerable time. There was also great weight at the stomach after food, frequently combined with crampish pain and vomiting. In all her seizures she took hot stimulating drinks, which excited flatulent eructations, followed by relief.

Six months before her death, her husband having met with an accident which killed him in a fortnight, she suffered extreme anxiety, and, on the last night of his life, she fell into a state of syncope, which continued some hours, and threatened to be fatal. From that time her former complaints increased greatly, and became attended with much cough, excitability, depression of spirits, and debility. Some months afterwards she was my patient for six weeks at the St. George's and St. James's Dispensary, and then a patient of Mr. Walsh, with whom I saw her several times in consultation. There was great tremor of hands; tongue white; pulse, while in bed, about 100, but much faster and sometimes unequal after the exertion of walking; not irregular nor decidedly deficient in firmness or fulness; none of that visible pulsation of the carotids and subclavians supposed to be pathognomonic of aortic regurgitation; a hoarse murmur at the lower cardiac region, owing to the regurgitation at the tri-

cuspid orifice; and a strong blowing murmur at the region of the semilunar valves, owing to the regurgitation through the aortic orifice, one-third of which was permanently patent. To the latter cause may likewise be referred a peculiar vibratory pulsation, which alternated with the heart's impulse between the sternal extremities of the third and fourth left cartilages. The heart's pulsation was seen over a large surface; its impulse was not considerable.

While at the Dispensary, she obtained great relief for six weeks from tonics, antispasmodics, and carminatives; but she then relapsed, and hydropericardium and anasarca supervened. She was confined to bed a month, and sank gradually.

Our diagnosis, as respects the heart, had been, "Defect of the valves of the left side, enlargement of the heart, principally by dilatation, and hydropericardium," which probably was afterwards absorbed.

OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

As much attention is just now bestowed on the subject of Dieffenbach's operation for strabismus, I trust you will permit me to offer a remark upon it.

All those who have described the operation mention a sharp hook as a necessary instrument for fixing the eyeball; indeed, some consider that several hooks are required. Besides the objection of wounding the sclerotic tunic, if it can be avoided, the use of the hook is attended with a very considerable degree of pain and alarm to the patient. I believe it to be a perfectly unnecessary instrument, and that the operation may in all cases be performed without it.

I have thus performed the operation three times. One of the patients, a boy in St. James's Workhouse, was but five years of age, and therefore incapable of assisting the operator by any voluntary effort to fix the eyeball.

The following is the mode in which the operations were conducted:—

The sound eye being covered with a bandage, my friend, Mr. Farquhar, of Albemarle Street, raised the upper eyelid with a speculum; I then raised the

conjunctiva slightly with a forceps, and made a vertical incision in it with a pair of scissors, midway between the cornea and the inner canthus; I then passed a probe-pointed hook, furnished with a cutting concave edge, under the internal rectus muscle; but as too much resistance was made by the muscle to the hook-knife, a few of the superficial fibres were divided with the scissors; the former instrument serving as a director until it cut its way out.

I venture to express a confident opinion that the sharp hook will shortly be entirely abandoned in this operation.

I am, sir,

Your obedient servant,

J. G. FRENCH.

St. James's Infirmary,
July 27, 1840.

CHRONIC PERIPNEUMONIA.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following remarks appear to you worthy of public perusal, their early insertion in your valuable journal will oblige, sir,

Your obedient servant,

J. A. HINGESTON.

London, July 3, 1840.

Every surgeon knows a form of inflammation of the eye in which the conjunctiva is as red as a soldier's coat, matted, and dry. The whole of the conjunctiva is of the same character, and even the layer of it which overspreads the transparent cornea becomes dim, and red vessels, or a fasciculus of vessels, may be seen shooting across the cornea. The red colour has, however, a bluish tinge, and the skin of the palpebræ externally is pallid and slightly œdematous. There is no doubt that this is inflammation. But it does not necessarily lead to the usual products of inflammation, at least not to the process of destruction resulting from acute conjunctivitis. The reason of the milder issue of this inflammatory condition would seem to be, 1st, in venous fulness, rather than arterial action; and 2dly, in a general condition of the system in which there is evidently diminished nervous power—the power of the brain being lowered. Under such circumstances, the pathologist well knows that the disorganizing

process is more tardily put into play; that the venous turgescence is a stagnation of the circulating fluid rather than a too rapid transmission of the blood through those small arterial capillaries, which John Hunter designated "the workers;" and that the diminished nervous energy would suspend or delay for a time the procedure of morbid formations. "Slowness of action," says Hunter, "is inimical to integrity of structure;" and here destruction would inevitably ensue, were the issue of the case committed finally to its own operation. Slow, but permanent, disorganization would be the result.

Instances are not wanting in other parts of the body to exemplify the above position: *e. g.* varicocele, in which the functions of the organ are at last impaired, and the testis wasted; and spasmodic asthma, in which the lungs are overcharged with venous blood as well as the rest of the body. In each of these cases the same amount of arterial error would lead inevitably to a speedy disorganization.

In the treatment of the above form of conjunctivitis one may defy the surgeon to cure it by the usual antiphlogistic remedies. Bleeding from the arm, antimonials, salines, mercury to ptyalism, do, as is well known, disappoint those who rely upon the same prompt efficacy as that which is so sure to favour the active treatment of acute conjunctivitis. In the acute form, free venesection, purgatives, calomel, and abstinence, will arrest the progress of the disease at once; but not thus in the chronic or congested form. In this case the digestive organs are debilitated in exact proportion to the debility of the cerebro-spinal system, and the bold treatment will only precipitate the patient into a state of depression, from which he must be first raised before he can be cured or the eye saved. It is the want of brain power which would seem to prevent the vessels of the conjunctiva from returning to the tonic contraction of health; or, is it a diminished power of the ganglionic nerves, the nerves of nutrition and involution, originating in a defective condition or a previous abuse of the gastro-hepatic system? Under either view, the restoration and regulation of nervous power, be that power primarily resident in the cerebral or ganglionic nerves, is the chief point of practice; and then, while this power is

being recovered, the local inflammation may be treated by the appropriate antiphlogistic remedies locally.

I have been thus distinct and minute in tracing out this form of chronic inflammation of the conjunctiva, because every one may see it, and those who have seen it will not for one moment deny its existence. This advantage attends ophthalmic medicine, that we see almost every thing we are called upon to treat, and moreover that we see our treatment.

There is the same form of chronic pneumonia, running the same course, lingering in the same manner, yielding to the same treatment, and probably ending in the same slow process of disorganization. These cases are not generally understood, and are therefore not rightly treated. We never do any thing rightly when we do not understand the matter subject to our senses.

A patient presents himself, weak, coughing, hoarse, and unfit for his usual occupation. The countenance is that of illness—dejected, with a sunken eye, sharpened features, a pale lip, and a faint flush on the cheek. The features are dark; the skin is dry and hot; the pulse small, sharp, and quick; the tongue white, dry, and rough; the breath fetid; the appetite deficient; and the bowels wrong. The nights are restless, occupied in coughing, dreaming, and shifting about in bed, and interrupted first by fever, and then by perspiration towards the dawn. The number of respirations is increased; the breathing is hurried on going up stairs; and there is a stitch in the side on taking a deep inspiration.

Upon a superficial view this is a case of consumption. A formidable opinion is pronounced, and the patient is sentenced and delivered over to await his end in the country or among his friends. But upon a minute consideration of the symptoms we shall arrive at a different judgment.

The features of a consumptive patient are not dark, except towards the very close; for, in general, the countenance is painted with a deceptive hue of health. The expression is not dejected; for, in general, a bitter smile rests upon the lips of a victim doomed to consumption. The tongue is not white, dry, and rough, except towards the close, when aphthæ appear; for the consumptive tongue is generally clean and moist. Neither is the derange-

ment of the gastro-hepatic system so marked when a tuberculous excavation actually exists; for a consumptive patient will often eat well even to the close. There is, therefore, a discrepancy in the outward symptoms.

But then, on examining the cavity of the thorax. First of all, there is a healthy hollow sound on percussion of each clavicle; and, on listening to the chest, there is, over the whole of one lung, complete evidence of its being pervious to the air, with only some sibilous sound denoting bronchitis, and some mucous wheezing. But, on examining the opposite lung, though the same characters present themselves, yet we at last arrive at a point of dull respiration—no respiration, ægophony, and dull percussion. Here lies the seat of the malady; here are peripneumonia and pleuritis; and, though the patient may have been ill and declining for weeks and months, yet here is the seat of illness, and here the mischief weighing down the rest of the body. On questioning the patient, he will answer that the stitch is on *this* side—that he cannot lie on *this* side—that he often has pain *here* on breathing deeply, or on going upstairs.

Furthermore, on retracing the history of the case, evidence will be gathered of the health having been out of order previous to the cough coming on, and of there having been some accidental exposure to cold, which seemed to bring on the cough during a state of progressive debility. Other signs may by chance confirm us in the right view of the case, *v. c.* the complexion not being consumptive; the relatives not being so; the previous health not having been interrupted by occasional coughs; the whole illness dating from a particular epoch: but no evidence can supersede that of auscultation and percussion.

There is no doubt that active peripneumonia could not continue long without hepatization, the disorganizing process being commenced; and, indeed, acute peripneumonia is too startling and too loud an illness to be easily overlooked by any one. But here is the evidence of peripneumonia *de facto* existing for some length of time: it is therefore not acute peripneumonia. What state of inflammation is it then which exists thus long? Does the chronic inflammation of the conjunctiva yield a solution of the problem? *viz.* venous fulness rather than arterial action, and marked debility

of the nervous power, with gastro-hepatic derangement? To my mind, this is the true solution of the problem. These cases, misunderstood, wrongly treated, and left to themselves, must, there can be no doubt, slowly proceed to disorganization and, eventually, to death. The issue confirms the evil diagnosis given under a mistaken view of the malady. The very event arrives according to the very ignorance which predicted and insured it. It is thus that our errors often appear to ourselves the confirmations of our wisdom. If it be true, what Burke said is the attribute of a great statesman, "That he ought greatly to fear himself," it is especially true of the upright physician.

Now these cases of chronic pleuro-peripneumonia are not curable by the usual round of antiphlogistic remedies. The bold depleting measures would quickly destroy the powers of life, already enfeebled. Our object is to reduce the local inflammation, and to sustain the strength. A moderate venesection from the arm, mild aperients, antimonials, the milder oxides of mercury, local loss of blood, vesication, and moderate ptyalism, slowly, carefully, and resolutely persisted in, with a milk and farinaceous diet, will be certain of effecting a cure. Days or weeks may be required; but it will be gratifying to hear the healthy sounds of the lung return, and very interesting to remark how the gradual departure of the morbid sounds establishes the correctness of the view taken previous to putting in practice the treatment. The return of the healthy sounds in the lung will be consentaneous with the mercurial action on the gums; and as soon as the gums are sore, and the pneumonia has yielded, a copious pituitous and mucopurulent excretion will arise, causing an incessant cough, and entirely preventing sleep. In this stage of the illness opium will be beneficial; infusion of bark with a mineral acid instead of mercurials, and an improved diet. Sulphate of zinc may be required to check the phlegm arising from the chronic bronchitis; and, lastly, what is often prescribed erroneously at the first, meat diet and fresh air.

Time will be requisite to accomplish this cure. But a patient who has been at the first looked upon by every one as labouring under a fatal disease (and a fatal disease it would be), will, if the

case be strictly investigated, rightly understood, and carefully treated, recover as good health as ever he had in his life. The principle of treatment lies in detecting the inflammation, and in applying moderately and resolutely antiphlogistic remedies (mercury and blood-letting), according to the vigour of the body. It is like a riddle; when once made out the case is a very simple one.

I am not certain that others will regard this subject with the same interest as myself. It would appear that many cases of imputed consumption are nothing else than chronic peripneumonia; and it may be well to discriminate carefully between two things wonderfully similar, but by no means identical. At one glance we may see the result of erroneous notions and practice. Mercury and the loss of blood would destroy a consumptive patient; but they are the only means of safety in a case of chronic inflammation of the lung.

My own mind was awakened chiefly to this malady by watching cases of chronic conjunctivitis, and transferring the slowness of their cure, and also the completeness of their cure, to cases which I had been certain were some form of inflamed lungs—not catarrh, but peripneumony.

We must not forget, in the treatment of inflammation, that the veins perform as important a part as the arteries. Chronic inflammation is especially characterised by venous congestion. There is a good and an evil in the venous circulation predominating over the arterial—namely, that the case is lingering, on the one hand, but less disorganizing on the other. Also, in these cases, tonics are borne throughout the course of their duration without increasing inflammation, which is not the case in acute inflammations, where tonics only add fuel to fire. Physiology easily explains this seeming paradox; for the total powers of life sink under the circulation of carbonized blood: *v. c.* asphyxia. It is probable that many cases of paralysis, usually called asthenic, and curable by tonics and a generous diet, are the result of venous *not* arterial fulness; and that the different forms of hepatic derangement, which yield to bark and iron, have their origin in the same pathological condition of the liver. Ague, low fever, debility from grief, anxiety, and study, are each

of them marked by venous torpidity of the brain, in the whole or in some of their stages, and equally sink under or are injured by the use of the lancet, but improved by a sustaining treatment.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

On the Nature and Structural Characteristics of Cancer, and of those Morbid Growths which may be confounded with it. By JOHN MUELLER, M.D., &c. Translated, with Notes, by CHARLES WEST, M.D., &c. Part I. 8vo. pp. 182.

THIS work contains a part of the results of the observations which Professor Müller has continued to make since 1836, when he published some remarks on tumors, in a paper read before the Berlin Academy of Sciences, of which an abstract was given in our number for June 24, 1837. Since that time the author has not only been steadily pursuing the subject in Berlin, by the examination of numerous specimens, both recent and prepared, of morbid growths, but has also inspected the museums of this country and of several of the universities of Germany, and has collected at them such observations that he believes he can now present a classification of tumors, founded on constant differences in their structure and composition, which may be recognized with certainty. The reputation of Müller is a sufficient guarantee that his work is well done; but we shall probably afford the best evidence of this by giving a brief abstract of its most important parts, which we shall do, as far as possible, in the words of the excellent translation.

Its first pages are occupied with some general observations on the minute structure of morbid growths. After pointing out the confirmation which their examination affords of the truth of what we must presume our readers to be acquainted with, namely, Schleiden's and Schwann's remarkable discoveries of the development of all tissues from nucleated cells, the laws of which are found to be strictly observed in the formation of all tumors, the author proceeds “to a more minute examination of the chemical composition

and microscopic structure of morbid growths."

Their chemical composition, as far as it can be at present ascertained, differs comparatively little from that of the ordinary constituents of the body. The proximate animal principles existing in morbid growths, are either some kind of fat, or gelatine, or albumen; other materials are present in only small quantities in them. They may, therefore, be usefully, though not very definitely, divided into three classes, according as one or other of these principles exists alone, or is very predominant.

Fatty tumors always consist of an animal organized basis of cells or cysts secreting fat, and of the fat itself. There are several varieties of them, which may be determined by examination of the physical and chemical characters of the fat; the chief among them are the lipoma or common adipose tumor, and cholesteatoma or laminated fatty tumor. In those growths of which fat is not the chief constituent, it generally exists only in the form of oil-globules, or of granules, or as minute crystals.

The second class are almost entirely reducible to gelatine, by boiling them from 10 to 20 hours, or more. Among them are arranged the cellulo-fibrous tumor, enchondroma or cartilaginous tumor, and the osteoid tumor; all of which have characters by which, when once known, they may be easily recognized.

Albuminous structures either yield no gelatine after many hours' boiling, or only so small a quantity as may proceed from the cellular or other tissue accidentally mixed with or present in them. Their external appearance is so striking that, when once seen, they are easily identified. They never have a compact tendinous texture; sometimes they are tender and gelatiniform, at others fibrous, at others cellular, glandular, or fibrous; generally they are friable and easily torn; they include collagenoma, scrofulous tumors, albuminous sarcoma, albuminous osteo-sarcoma, and *all varieties of real carcinoma*.

The microscopic elements of morbid growths are (in addition to capillary vessels), fibres, granules, cells both with and without nuclei, caudate or spindle-shaped bodies, and vessels. Blood-vessels exist in almost all; with the exception of cholesteatoma, fine injections (though by no means well suited to dis-

play the minute texture of morbid growths), exhibit blood-vessels in the substance of every one. These vessels, however, with the exception of those in aneurism by anastomosis, have no remarkable arrangement. [A fact which may be of some interest to those who were engaged in the warm controversy on varicose capillaries, with which our pages were not long since occupied.]

Fibres form a grand constituent both of albuminous and of gelatinous growths. The cellulo-fibrous and tendino-fibrous tumors, among the former, are almost entirely composed of fibres, more or less resembling those of cellular tissue; and among the latter, in the albumino-fibrous tumor and the carcinoma fasciculatum, very transparent fibres form the most striking characteristic.

Granules, *i. e.*, spheroidal or elliptical bodies, which do not present any internal cavity when viewed under the microscope, exist in vast numbers in some albuminous tumors, being either contained in the germinal cells, or arranged about the fibres.

But the cell is by far the most frequent element of morbid growths. Cells alone sometimes form nearly the whole tissue, as in cholesteatoma, cancer alveolare, cellular sarcoma and osteo-sarcoma, which are composed of cells cohering by their walls, while fibres of cellular tissue serve only to form the connecting membranes of their lobuli. In other cases the cells do not adhere, but are deposited close together in great numbers in the meshes of a fibrous texture, as in several forms of carcinoma, in which they form the real *seminium morbi*. In some cases the cells have nuclei either in the substance of their walls or within their cavities; in the former case the nucleus is that from which each cell has been developed; in the latter the nuclei are the germs of new cellules. In other cases, however, as in cholesteatoma, the cells have no nuclei. Some cellular structures yield gelatine, as the enchondromatous tumour, which is the pathological parallel of normal cartilage; others are albuminous, as the cellular sarcoma, which is the parallel of the chorda dorsalis and of the decidua. Some cells do not contain young cellules, as those in laminated cholesteatoma; in other cases the cells are encased one within the other, as in many of the cells in carcinoma alveolare, and in enchondroma, and

some of the formative globules in carcinoma simplex and articulare. The average size of the cells is 0.00054 of an English inch; but they are often not larger than 0.00015 to 0.00021.

Caudate bodies are another frequent element of morbid growths; they are elliptical pouches or cells, terminating at one or both extremities in a fine caudiform fibril of uncertain length; they sometimes contain granules, and occasionally a nucleus, with one or more nuclei. This structure is exactly the same as that which Schwann observed in primitive cellular tissue, and in other tissues which undergo the transformation from cellular to fibrous structure. Most fibres in the animal body are formed by the elongation of cells; but in the morbid structures which consist of caudate corpuscles, it would appear as though the development of the fibres were arrested in the half-cellular state in which they exist in the embryo. The fibrils proceeding from one or both ends of the corpuscles have generally a diameter equal to one-fourth or one-fifth of that of the body; sometimes they are bifurcated, and sometimes a third fibril springs from the side of the corpuscle.

The caudate bodies are elements of several carcinomatous growths, as well as of perfectly innocent albuminous tumors; but the author has never met with them in those that are chiefly gelatinous, though it is probable (since they are merely fibres in an early stage of development) that they may exist in them at certain periods.

Differences in the structure of the microscopic forms of morbid growths depend on the way in which their development proceeds. The process is an exact repetition of the changes which are observed in the development of the several normal tissues. In enchondroma, or cartilaginous tumor, a development of new cellules upon nuclei formed in the cavity of the old cells, and again of still younger cells within the former, is observed in all respects similar to the endogenous development of cells in healthy cartilage. In like manner, in albumino-cellular sarcoma, and in the osteo- and gelatiniform sarcoma, many of the parent cells are sure to contain young cellules with parietal nuclei; and in carcinoma alveolare the same mode of development is yet more evidently seen. The large cells which, in this form of cancer, are visible to the

naked eye, contain in their cavities a second generation, and so forth, till we arrive at the smallest cells of all, in which are nuclei of a darkish yellow tint, generally somewhat elongated, and presenting a minutely granular structure, which either lie free in the cavity of the cell, or have in some parts already evolved a germinal cell around them. Corresponding differences are also observed in the mode of development of the caudate bodies, in the different forms of morbid growths.

From all these preceding observations, it is evident that the division of morbid growths which has hitherto been made, into homologous and heterologous productions, is incorrect; for the most innocent growths do not differ in their minute elements, nor in their origin, from carcinoma. Still the author is convinced that pathognomonic marks of carcinomatous growths, which it is of such great importance to practical medicine to find out, may be ascertained; for they possess certain peculiar anatomical characters, which are distinguishable either with the naked eye, or by the aid of a common magnifying glass. It is to this portion of his subject, namely, his investigations into the minute structure of carcinomatous growths, that he next proceeds.

He terms those growths cancerous which destroy the natural structure of all tissues, which are constitutional from their very commencement, or become so in the natural process of their development, and which, when once they have infected the constitution, if extirpated, invariably return, and conduct the parties who are affected by them to inevitable destruction. The several forms of these growths, though in their extremes widely different from each other, are shewn to have an intimate relation, not only by all possessing the above characters in common, but by the gradations by which they pass into one another being often imperceptible, and by the circumstance that, after extirpation, one form may take the place of another.

The most invariable character of cancer is the loss of the proper tissue of the part affected by it; its elementary forms are developed between, and displace the natural tissues of the part, giving rise to, but not being themselves dependent upon, their degeneration. The tissues in the neighbourhood usually become

soon connected with the growth; hence carcinoma is less moveable than other tumors, and hence the retraction of the nipple when the cancer of the mammary gland is seated close beneath it. Other signs of considerable importance are the enlargement of adjacent glands, and the coincident existence of other similar growths.

Taking these as the general characters of cancerous tumors, the author divides them into six varieties, viz. Carcinoma simplex or schirrus, *C. reticulare*, *C. alveolare*, *C. melanodes*, *C. medullare*, and *C. fasciculatum*.

1. *Carcinoma simplex* is the variety which is described in the works of most of the earlier writers, and which is usually spoken of as the common cancer of the breast and other parts. The diseased masses of this kind are generally (according to the description which the author has drawn up from the examination of a great number of recently extirpated carcinomatous breasts) irregular in form, not lobulated, hard, and resisting the knife, and presenting when divided a greyish appearance, which has but very little similarity to cartilage. Whitish bands are not invariably present. Here and there they occasionally shew whitish filaments, some of which are hollow, and contain a colourless, whitish, or yellowish matter, and which probably result from the thickening of the walls of the lactiferous tubes and lymphatics. The mass is composed of two substances, the one fibrous, the other grey and granular. The former is best seen on scraping away the grey matter, for which it serves as a sort of basis, from the surface of a section. It is then shewn to be composed of a very irregular net-work of firm bundles of fibres. The grey matter consists of microscopic formative globules placed among the fibres, and but slightly adherent to each other; they are transparent hollow cellules, from 0.00048 to 0.00130 of an English inch in diameter, insoluble in acetic acid and in water at any temperature, and containing either only a few granules, or one larger body, which looks like a nucleus, or like a smaller cell. In addition to these, oil-globules are also always seen in considerable numbers diffused through scirrhous growths.

2. *Carcinoma reticulare* is found in many parts of the body, and is even more common in the female breast

than *C. simplex*, from which, on a section, it is distinguished by the white reticulated figures intersecting the grey mass, which are perfectly evident to the naked eye. It is oftener of large size than *C. simplex* is, and has a tendency to a lobulated form. It is sometimes nearly as hard as the preceding, but is at others softer, more nearly resembling medullary cancer, and among a large number of specimens its consistence is found to be very variable. Its mass is composed of globules imbedded in a reticulated fibrous tissue; the former are formative globules or cells, similar to those of *C. simplex*. The white, or yellowish white, reticulated figures, which are always more or less distinct in this form, are peculiar to it; they are irregularly reticulated; sometimes they present a branched arrangement; at other times they appear in spots. They are peculiar formations, not dilated vessels with thickened parietes, but produced by the deposition of grains of white matter, composed of opaque agglomerated granules, in the grey mass. These white bodies accumulate as the disease advances, and by the time that the mass begins to be disorganized they form a great part of its texture. They often lie in large masses imbedded in the surrounding tissue, or invest with a cream-like lining the interior of cavities which have formed in the diseased growth.

3. *C. alveolare*. — This is the form commonly described under the name of gelatiniform or areolar cancer, and which is found by far most frequently in the stomach. In the part of the stomach affected with this disease there is usually great thickening; the basis of the structure is composed of interlacing white fibres and laminae, whose interspaces are occupied by cells, varying in size from a grain of sand to that of a very large pea, some closed, others communicating, and all containing a very viscous, clear, perfectly transparent jelly. In the early stages the cells can be seen only with the microscope; in the later the disease, which commences in the muscular coat, makes its way both to the mucous and the peritoneal surfaces. The smaller cells, when examined with the microscope, are found to contain encased within them many still smaller, which, in their turn, include others. Many cells contain only nuclei, which lie free within their cavity. The

walls of the largest cells are distinctly fibrous, and the fibres run from one cell to another.

The history of the development of this form of carcinoma corresponds exactly to that of the primitive formation of cartilage, and of the *chorda dorsalis*. The young cells are produced from nuclei developed within the parent cell, and in time filling its cavity; then coming in contact they form one compound cell, whose exterior at length may burst and discharge its contents. The fibres forming the walls of the largest cells constitute a nidus, within which younger generations of cells are developed. The main distinction between this and the two preceding forms of cancer seems to be, that in this the cells continue to grow, and their walls become adherent to each other, while in the preceding such a progressive development and mutual adhesion do not take place.

4. *C. melanodes*.—Melanosis is merely a variety of cancerous degeneration. Microscopic examination detects two forms of it. In both the basis is formed of a fibrous net-work, in the meshes of which the melanoid matter is deposited. The latter is formed of separate cells of various forms, or of caudate bodies filled with yellowish or blackish granules. They are real pigment-cells, and the globules of pigment are seen both within and around them; the latter are probably such as have escaped from cells, and these frequently present a rapid molecular motion, like the pigment-globules of the pigmentum nigrum of the eye.

5. *C. medullare, fungus hæmatodes, &c.*—The component parts of this growth are a medullary mass, composed of globules or other corpuscles, and a tissue made up of delicate fibres, in the meshes of which they are placed. Its colour is properly white, or greyish white; and the various other hues that it presents depend on the blood-vessels which it contains, and which are usually very numerous, and on the blood which is often effused into its substance. The author describes three varieties of this form, distinguished by being formed either, first, for the most part of roundish formative globules; or, second, of an exceedingly soft cerebriform base, composed of pale elliptical bodies without caudate appendages; or, third, of a mass containing caudate or spindle-

shaped corpuscles, which are often so arranged as to give it a fibrous appearance.

6. *C. fasciculatum seu hyalinum* is a variety which is commonly included in the preceding, with which, however, it corresponds only in softness. It is chiefly composed of fibres which, in some cases, have a tufted arrangement, running in a divergent course from a common centre, so that the mass may be rent into radiating bundles, but which in others are irregularly interlaced, and form lobules with membranous septa. Such growths are extremely vascular, and their vessels follow the arrangement of the fibres; occasionally they are transparent, like jelly, whence the name first given of *hyalinum*. The fibres of which they are composed are extremely pale and transparent; their surface is beset here and there with granules; they have the same diameter as those of cellular tissue, but are in no other respect similar to them.

[To be continued.]

The Maternal Management of Children in Health and Disease. By THOMAS BULL, M.D. London, 1840.

It is observed by Robert Hall, in his Discourse on War, as a peculiar aggravation of that calamity, that, according to the remark of the most ancient of poets, "In peace, children bury their parents; in war, parents bury their children." Would that it were so, and that it was only when the fierce passions of man were let loose, and the sword unsheathed to inflict violent death, that this unnatural state of things occurred. But if war destroy its thousands, ignorance hews down its tens of thousands; and the registration lists disclose the melancholy fact, that in the midst of the profoundest peace we are suffering one of the direst calamities of war—that of parents burying their children!

The report from the town of Liverpool alone shows that this is no exaggerated statement, since, in the year 1838, "48·34 per cent. of the entire deaths, or nearly one-half, occurred under five years of age." That this fearful mortality need not happen is proved by the striking contrast exhibited in the Lying-in Hospital of Dublin, where, during the four years ending in 1784, out of 7650 children, there died in a badly-ventilated house 2494 children;

while in a similar period, under more favourable circumstances, there died, of a like number of children, only 279. A similar diminution of the rate of mortality was witnessed in Manchester, under the wise regulations of Drs. Percival and Ferriar. It becomes a most important object to make known to the community at large the principles on which this amelioration depends; and this is done in Dr. Combe's work, and that now under notice. This last, however, occupies a place peculiarly its own, and dwells less on the means by which disease is prevented, though this is clearly but succinctly done, than on the signs by which each malady to which infancy or youth is commonly subject may be recognised at its first onset, with directions how to act *in giving effect to the directions of the medical attendant*, whom it supposes to be immediately sent for. It may be looked upon either as a sequel to the author's previous work, "*Hints to Mothers*," or as an independent treatise. It is composed with the same attention to method which characterised the former, and is written in the same simple and intelligible style. Of such a work it is impossible to give an abstract or analysis, but it is one which it will be as beneficial for the practitioner to find in the hands of a parent whose children he attends, as for the children whose mother studies and applies its precepts. By the enlightened parent he will be aided and usefully seconded; by the ignorant and prejudiced he will be thwarted and disappointed. The best thanks of the profession, as well as of all intelligent mothers, or those who are in the place of mothers, are due to Dr. Bull for his very excellent little book.

Advice to Mothers on the Management of their Offspring. BY PYE HENRY CHAVASSE, M.R.C.S. London and Birmingham, 1839. Small 8vo. pp. xvij. and 148.

THIS little work is written in question and answer—a method which stands in the way of any continuous flow of thought or reasoning, but which will be grateful to those readers who like to have knowledge presented to them in the most practical shape, and would rather obey precepts than discuss principles. The fault of this book is excess

of caution. Thus a child is to eat no vegetable but potatoes, "except it be occasionally a few asparagus heads." (p. 77.)

From the place in which it occurs, this restriction appears to be intended for very young children; but why should they not eat carrots, turnips, cauliflower, &c. &c.? At page 123, in answer to the question "what is the best dinner for a youth?" we find, among other things, that greens and trash should not be given. Now, no one will defend trash; but why should we prohibit greens?

Our author approves of dancing, but does not approve of balls, and makes a distinction which is reasonable enough, between an evening dance and a midnight ball; but he goes an extravagant length on the subject. "A delicate female leaves the heated ball-room, decked out in her airy finery, to breathe the damp and cold air of night. She goes to bed: for the first few hours she is "too much excited to sleep," &c.; and he asks, "Can it then be wondered at, if the laws of nature and of common sense be so set at defiance, that one-fourth, and that fourth comprising the most interesting part of the community, that one-fourth of the deaths that occur in Great Britain arise from consumption; that more than fifty thousand die annually of this disease alone?" (p. 120-1).

But surely, the majority of the fifty thousand must be persons who have very little to do with heated ball rooms, airy finery, gallopades, or ices! Of course, we do not deny that fashionable hours and exposed scapulæ may be among the causes of disease; but we protest against their being put down as prime agents of national mortality.

Nor do we agree with our author in setting down the "hurly-burly and excitement of fashionable life" among the causes of chlorosis. However, he is quite in the right when he gives skipping, dancing, and running, among the preventives, with abundance of good air, and warm loose clothing adapted to the season.

On the whole, Mr. Chavasse's book is a useful one; and the very excess of his prudence will render it a desirable guide for those whose task it is to rear children of extreme delicacy. The cautions to be observed in the case of a child who has been attacked by hæmoptysis, or who is much predisposed to

sore-throat, are sensible, though we should prefer Italy to the South of France as a residence in the former case.

Other observations are equally judicious, and more extensively applicable; as those on sleep and sleeping-rooms at p. 132-4; against the domestic use of calomel, p. 56 and 143; and the five counts of the indictment against stays, at p. 118-9.

MEDICAL GAZETTE.

Friday, August 7, 1840.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

MEDICAL EDUCATION IN FRANCE.

ANOTHER measure which has resulted from the recent agitation for medical reform in France—an agitation which does not seem likely to be calmed by these piece-meal alterations of the system, however palatable this or any other small morsel may be—is the appointment of a number of courses of lectures on certain special portions of the medical sciences, which are to be delivered gratuitously by the associates (*agrégés*) of the faculties, and which are intended to serve as complements of the more extended ordinary courses delivered by the several Professors. The associates of each faculty of medicine are to be allowed, on the recommendation of the dean, and with the authority of the minister of public instruction, to deliver such courses in, or in the immediate neighbourhood of, the schools: the permission will be granted for a year, and may then be renewed, and the success which the associates obtain will form part of the grounds upon which their merits will be decided in the *concours* for the professorship.

Among several subjects of interest which the announcement of this measure suggests, not the least important is the indication which it affords that the teach-

ing of medicine in France, which has been so often pointed to, as the model that should be followed in this country, is deemed incomplete and unsatisfactory, by nearly all the parties concerned in it. There is not one of the French medical journals that does not speak of this piece of reform, slight though it be, as gratifying, not merely for its own sake, but because it affords a good omen that the time for a complete reorganization of the whole scheme is not far distant. The most violent opponents of existing institutions in this kingdom are scarcely more anxious for alteration than are nearly all the writers in France. Surely, then, it is not wise that the tendency of all propositions for the improvement of medical education amongst us should be to approximate it more closely to the system of the French!

For the measure itself, its main object seems to be to give authority and opportunities of attending gratuitously those numerous courses of lectures on parts of medicine, of which, in every medical season in Paris, the professors so thickly abound. Although the regular courses of lectures delivered by the professors of the schools are not shorter than those regularly given in this country, it is conceived to be impossible for any one to include in a single, or in some cases even in three or four courses, the whole of the subjects that come within his scope. In England the course of lectures on medicine, or on surgery, for example, which is continued from October to April, professes (and in most cases, we believe, with truth) to comprise all the subjects included in these departments of science; and such a course, in the hands of a capable teacher, may undoubtedly be made to fulfil all the purposes of which such lectures are capable, viz.: to convey, in an acceptable manner, to the mind of the student, and where it is possible, to illustrate, the knowledge of

a complete general system of medicine or surgery, such as he may carry in his mind to the bed-side. How perfectly this may be accomplished, the pages of many of our past volumes will amply testify.

In France the case is very different: a sessional course of lectures is not expected to include more of the subject professed than the time or the taste of the professor permits; and thus those that pretend to be full courses are generally special courses on some part of his subject to which the teacher has of late paid particular attention, or in which, from any circumstance, he feels unusual interest. In short, the French courses are, in many cases, rather an exhibition of the professor than of the subject which he professes to teach, but which he makes the means of displaying his own special learning. There are courses of lectures announced every year in the programmes of the faculties which are hardly quite finished in three or four years, if they ever are; though they ought to be gone through, and in England are gone through, at least once in the single winter session.

Now there is nothing in the nature of the subjects of the several courses, in which it is usual for the whole of medical science to be taught, that need give rise to an error like this. Doubtless, to teach every part of medicine perfectly, and to say all that in the present day is known upon each, would occupy very many hours, and more time might thus be given to a single class of diseases than, with us, is usually devoted to the whole practice of medicine. The size of many of our own monographs is sufficient proof that the subject of each might be the subject of a full course of lectures; and the translations which we have occasionally given of some of the better class of the French lectures, shew that they partake very much of the monographic character.

But we hold that the object of lectures addressed to pupils is not to teach medicine in this manner, but to impart to them the rudiments of the science generally, and to give them the means of working out the detail in actual practice or in clinical study, or to follow out any branch that may most attract them, in accordance with their own, not their lecturer's, views. It is, indeed, quite impossible for one who is not acquainted with the general elements of science, to appreciate, much less to appropriate, lectures on the more abstruse parts of any one department in it: we conceive that this must be plain and evident to every one; and in this constant system of special instruction, we believe, lies one of the main evils of French teaching, and which the present change will tend to perpetuate rather than to remedy. We cannot too often repeat that the large majority of students come to schools and universities, to be made, not philosophers, but practitioners; and the best scheme of medical education is that which will effect this object, and pretend to nothing more. To such a consummation we are glad to believe that medical education is rapidly approaching in this country; and we do earnestly hope that special courses of lectures, though we readily grant that they never can be superfluous, will ever be regarded as works of supererogation.

It is presumed that the subjects taught by the associates will be such as the diseases of the eyes, of the skin, of the mind, of children, of the uterus, of the organs of respiration, and so on; in short, it will rest with the Dean of the Faculty to appoint any subjects which he is led to believe will be omitted or slurred over in the ordinary full courses. Such a plan may be the only mode in which, the original error of the ordinary courses being allowed to continue, the students could be in any degree recompensed; but its evils must be immediately

evident to all. The best case that can now happen will be, that by attending a far greater number of lectures than is at all necessary, the student will be able to hear a number of special courses, in which, if he is fortunate, the whole of the subjects of one English course may be included: the professor, in this case, will treat of his own hobbies, and the associates will be set to work out those which do not happen to be favourites with him. This will be the best that can occur; but in many more cases, the professor, having no particular predilections, but many antipathies, will leave the latter to the associates; and happy will it be if, by a fortunate difference of tastes, they are not abhorred by one as much as by the other. But, perhaps, that which might seem to some the happiest arrangement will prove to the unlucky students the most disastrous. Conceive the professor by choice, and the associates by compulsion, to have all to treat of the subjects of their chief admiration; can any one conceive any thing more fatiguing, or less likely to lead to solid good, than the perpetual laudations by each of his own Diana? Surely, of all the absurdities ever committed, even in medicine, the greatest have originated in the anxiety of monographists to elevate the subject of their several themes into the places of the highest importance, and to prove that there was no field over which it had not sway, and in which it was not prime mover for mischief or for good. Yet these are the errors which the French, like every other system of special instruction, cannot fail to foster, and which we are the more surprised to see them encouraging, when we remember the sensible and spirited remonstrance which was addressed not long since to the government by all the leading surgeons of Paris, on the occasion of the appointment of M. Leroy d'Etiolles to an office in the Central Bureau, for the

special treatment of diseases of the urinary organs.

We cannot, therefore, find any ground to praise this endeavour to remedy an error which might have been very shortly and easily cured by insisting on the professorial courses being made to include the elements of the whole of their several subjects. That, we are well assured, would have been no doubtful remedy; and if, by showing that those who have the working of it are by no means well pleased with the much-lauded scheme of education in France, and that the remedy which they have devised is likely to perpetuate or increase the evil, we can succeed in moderating a little the admiration which some among us entertain towards every thing which is foreign, we shall be glad.

There is, however, one part of the French scheme (but which is not newly introduced in the present alteration), that it would be fortunate for us if we could imitate—we mean the education of the lecturers themselves. In France, by the plan of having associates of the Faculties, each professor, before he reaches his chair, is a practised, and therefore, as far as his language and his manner are concerned, a good lecturer; so that we cannot remember to have heard, during a residence of some time in Paris, a single lecture which, whatever were its scientific or its practical merits, was not fluently and well delivered. Granting fully as much as is fair to the habitual vivacity and the natural *savoir parler* of the French, there can still be no doubt that much of this great advantage results from their system of gradual elevation to the lectureships. It is surely a matter of no mean importance to have the instruction by lectures, which in itself has much that is forbidding, rendered attractive by fluency of speech and ease of deportment; to have the lecturer possess at least a seeming familiarity with his

subject, and to avoid the awkwardness which too often in this country distracts attention, if it does not excite ridicule, and the hesitation from want of confidence, which so exactly resembles that from want of knowledge. We fear, however, the evil will never be remedied so long as we have no preparatory education for teachers as well as pupils, or so long as gentlemen, however talented, are called to perform the full duties of professors as soon as they have become renowned for their writings, or, from any circumstances whatever, have become attached to the medical staff of an hospital.

MEDICAL REFORM IN IRELAND.

To the Editor of the Medical Gazette.

SIR,

EVERY true friend of surgery in Ireland, every well-wisher of our national institutions, must be gratified by the perusal of the judicious and well-merited observations which you have thought it your duty to make in rejoinder to the Dublin Medical Press, relative to your criticism of Mr. Carmichael's medico-political exposé, at the late annual meeting of the Medical Association of Ireland.

Mr. Carmichael stands forth as Mr. Attorney-General; his indictment runs, "that all licensing corporations have prostituted themselves from the high national purposes for which they were founded, and have constituted themselves into what he calls a Dutch auction, for the basest of all objects—the attainment of filthy lucre. He offers proof,—he tenders evidence,—*ex uno disce omnes* the Dublin College,—he calls for condemnation, death, and destruction, and upon the ruins of all to rear up one immaculate tripartite Utopia, which is to exhibit to the admiration of mankind that which the very nature and essence of mankind has forbidden to exist—perfection!

Such reasoning may suit the peculiar logic of Mr. Carmichael's mind—such mode of legislation may be adapted to the florid enthusiasm of those who wish to figure in the page of history as the

authors of some new system, or the not unwise speculations of those who live upon the hope of being one of these days made the instruments of carrying that system into practice; but, sir, if we are to have the intervention of a sober, rational jury, such proceedings are not calculated to sway them. The sound and reflecting portion of society will not argue *a particulari ad universale*—will not indulge hasty and imperfect legislation, however pleasing either may be to inordinate vanity, or aspiring selfishness.

Here you have justly and wisely interposed, and have not only shewn the false reasoning that led Mr. Carmichael to his sweeping anathema, but more than this, the unfounded nature of the facts upon which he relied, and have demonstrated the improved examination in four or five of our most important corporations, from whence, it is fair to conclude, that there has been an average improvement in those examinations in all, in compliance with public opinion freely and in no doubtful terms expressed.

But, sir, Mr. Attorney Carmichael is not alone in this state prosecution; he is sustained by other counsel learned in the law—the editors, proprietors, and contributors to the Dublin Medical Press, who support his indictment, but only by ringing changes to "the self-same tune and words," from all of which, one thing is established beyond contradiction—that the Dublin College has deteriorated its examination and curriculum, has introduced the underselling system, and, alas, that I must say it, "stands alone in its (infamous) glory."

Here it is important to know who are those prosecuting parties who thus offer themselves as Queen's counsel and sergeants at law? I know not how far the editorial we may sustain their incognito at your side of the water, but here they are openly avowed—Messrs. Jacob, Mannsell, Porter, Williams, Hart, &c. &c.; there is no secret, nor, indeed, attempt at secret, in the matter at all. These, and their associates, are almost one and all professors in the school attached to the College of Surgeons in this city; but the strange part of the business is, that these same individuals are the very persons who introduced, advocated, and established the diminished curriculum, the milk-and-water examinations, and the underselling

price of the piece of parchment; and the reason of their so doing was obvious enough. It has always been the misfortune of the Dublin College, strange as it may appear, to be governed entirely by its School: when this was filled with men of large practice, like Messrs. Dease, Todd, Colles, &c., the profession, and the members at large, suffered little from their sovereignty, because *their* interest and the interest of the profession were identical to a certain extent; but the influence of such men has long passed away: the School, with its greatly lengthened staff of lectures, has lapsed into the hands of other parties, scarcely any of whom enjoy any extensive practice: in other words, the self-interest of the present generation of school men is opposed to that of the profession, and manifestly lies in facilitating, in every possible way, the *entré* into the profession: hence the diminished curriculum, the lax examinations, the cheap license, the black-ball by-law, that excludes from the membership and keeps the corporation in its present position, where a certain part are tolerably certain of a majority. The plea, and the cry in justification of these steps, which are recent innovations, always has been, "the College is in danger" from diminished funds; but really, there has never been any danger from such a cause, whereas, from these shameful innovations, the College income has considerably abated.

But the object of this communication is not to expose the inconsistencies of these men, or to hold up what might be justly called their selfish tergiversations to public odium; suffice it now to say, they are sensible of the evil of their ways: in their public discussions they have acknowledged and condemned the rottenness of that vicious system, which, in the name of reform and yielding to public opinion, has been based on the ruin of the wiser and better one that their immediate predecessors established. Will they retrace their steps—will they restore the strictness of examination that did then shed some lustre upon our College—will they recur to a more stringent and extensive curriculum—will they depart from the debasing underselling system, and fix once more upon their license a price that shall ensure respectability? They *can* do all this, as they have undone it all before: *will* they do it? or, like the cat in the

adage, will they let "I would wait upon I could," and so prefer vapid and empty clap-trap declamation about reform and amended legislation, to the undoubted and self-evident pointings of, at once, a wise policy and common integrity? This will be a real reform, and will tend to establish their honesty in the advocacy of it, which under present circumstances is considered rather problematical: if they do this, they will find abundant support among those whom it has pleased them to denominate anti-reformers and Tories.

I have charged not only the underselling system and the diminished curriculum, but also the relaxed and almost merely formal examinations upon the School party. The former is a mere matter of fact, which cannot be denied; both *counts* contained in it were brought forward and established by Mr. Jacob, who is the most prominent of the School party, as well as one of the editors and proprietors of "the Press." But it may seem hard, without any proof, to lay at the doors of the same individual the heavy imputation of empty formal examination. The justification of this, however, will be self-evident, when I remind you that the School *party* act as one man, and that they have in their own persons almost always the majority in the Court of Censors, a list of which I subjoin:—

President.—Mr. Adams, (an annual officer), who has no voice unless equal voting require a casting vote.

Senior or Surgical side of the Court.

Hart.—Professor of Anatomy in the College School.

Palmer.—A friend of the school party, elected by them.

Taggart.

Junior or Anatomical side of the Court.

Benson.—Professor of Physic in the College School.

Hutton.

Hargrave.—Professor of Anatomy in the College School.

Four of the court, with the president, constitute a quorum.

By inserting the preceding remarks, which are not written with an invidious object, but simply with a view to improvement, you will do a public good, and greatly gratify

A REAL REFORMER, AND CONSTANT
READER AND SUBSCRIBER.

MEETING OF THE PROVINCIAL MEDICAL ASSOCIATION.

THE meeting for the present year (being the eighth anniversary) took place at the Audit House, Southampton, the week before last; and the proceedings which took place are most fully detailed in the *Hampshire Independent*. The number present is estimated at one hundred, and the business passed off in the most satisfactory manner.

Dr. Jeffreys, of Liverpool, took the chair in the first instance, as the Preses of last year, but resigned it after some observations, in which he alluded to the various objects which the Association had in view, and the satisfactory manner in which their affairs generally proceeded. He was followed by

Dr. Steed, the president for the present season, who dwelt a good deal upon local affairs; after which, he proceeded to speak of various inconveniences and abuses which exist in the profession, alluding particularly to the present system of farming the poor, &c.

After some business of form, such as presenting addresses to the Queen, &c.,

Dr. Hastings read the report of the Council, in which particular reference was made to the essay of Mr. Ceely, in illustration of the identity of small-pox and cow-pox; large extracts from which were given in our two previous numbers. A very heavy expense was incurred in procuring the coloured engravings which accompany it; not less, it appears, than £700, leaving a balance of only £225.5s. in hand, out of the income of the present year. The report goes on to speak of the circumstances connected with the Vaccination Bill recently passed. Medical reform was next alluded to, and the growing importance attached to it was insisted upon—a little gentle admonition being directed to Mr. Warburton for his laziness and apathy.

Various votes of thanks were then passed. After which

Dr. Forbes mentioned that the £50 offered by Dr. Thackeray, as a prize, had been awarded to Mr. Wm. Davison, Lecturer on *Materia Medica*, Glasgow, for the best essay on the causes of the continuance of fever in England.

Dr. Webster then read the report of the poor law medical relief committee. It was moved and carried that it be printed. An opinion was expressed in

favour of the clauses which Mr. Talford intends to bring forward when the poor law amendment bill is under discussion.

It was next proposed by Dr. Dodd, and carried unanimously, that a circular letter be addressed to the schools, urging the expediency of requiring certificates of vaccination from all pupils previously to their admission.

The next proceeding consisted in reading the report on medical reform, which was done by Dr. Barlow. The Committee stated that the petitions formerly agreed upon had been presented to Parliament, and remarked that the number of such appeals had of late greatly increased, showing the increasing desire for reform which existed. Allusion was made to the fact that medical reform would necessarily interfere with existing Institutions, from which quarters opposition was naturally to be expected. It was hinted that a National Medical College might be framed by the amalgamation of the several bodies now extant, and that a constituency might be organised out of those who had been members during a certain period. Reference was made to the fact of Mr. Warburton having given notice of a bill, and it was urged that, until the nature of the measure to be proposed by him was known, the interference of the Association would be useless. It was, therefore, thought advisable that the Council should be authorized to act on emergency for the members generally, in case of any thing occurring to require their interference before the next annual meeting.

Thanks to the Committee was moved by Mr. Carmichael, and carried.

Dr. Webster, of Dulwich, thought they ought to go rather further than had been done in the report. All the other associations, he argued, had acknowledged the representative system; and not less than 130 petitions, with 4321 signatures, had been presented to Parliament. He expressed some misgivings as to Mr. Warburton's intentions, and advised the Council to ascertain what these really were. He then moved that steps be taken to obtain medical reform, on the principle of uniformity in qualification, and a representative system of government. This resolution was agreed to, and concluded the business of the morning.

In the evening Dr. Dodd read a re-

trospective address on the progress of surgery, for which the thanks of the meeting was voted to the author.

A report on quackery was next presented by Dr. Cowan, the committee being instructed to continue their services till the meeting next year at York, on which occasion Dr. Goldie is to preside.

The retrospective address on medicine was from the pen of Dr. Scott, of Liverpool, in which he pointed out, among other things, the advantages of the Association, and referred triumphantly to the "Transactions." A vote of thanks followed this communication, after which Dr. Barlow presented the report of the benevolent fund, by which it appears that many applications had been unavoidably denied relief from want of funds. A debt of £40, due at last anniversary, had not been paid; and it was therefore resolved to grant no more assistance till the above sum was liquidated, and a balance in hand of £100. It is calculated that the small sum of five shillings from each member would answer the purposes in view; and Dr. Cowan intimated his intention to bring forward a motion rendering this subscription compulsory on the members.

Several professional papers were then read, which we hope to see published in the Transactions, after which various votes of thanks were passed, and the meeting adjourned.

The dinner, which took place the same evening, was numerously attended, and passed off with spirit.

SOME PATHOLOGICAL EXAMINATIONS OF THE ORGANS OF HEARING AND SPEECH IN THE DEAF AND DUMB.

By DR. VINCENZ BOCHDALEK,

Professor of Pathological Anatomy at Prague.

THE object which the author professes to have in view is not to consider what has been hitherto effected in this branch of pathology, but to present the results of the anatomical examinations of the apparatus of hearing and speech in six deaf and dumb persons, which he made with all possible pains and caution.

The first case was that of a deaf and dumb boy, born in 1818. According to the statement of his parents he was not deaf from birth, but became so in his first

or second year. In the second half of the first year of his life he had severe convulsions; he was then for a whole year very ill, extremely weak and emaciated, and affected at the same time with a purulent discharge from the right ear. The loss of hearing was first observed after his recovery from the preceding symptoms.

On September 7, 1830, the child was received into the Deaf and Dumb Institution, where for two years he enjoyed tolerably good health, with the exception of some slight diseases, from which he easily recovered. In the summer of 1833 he was attacked by quartan intermittent fever, from which he did not recover till the middle of September. In November an inflammation of the intestines set in: the boy was taken to the hospital, where he ultimately died of phthisis, in February 1834.

I was permitted, says the author, to examine the head; but with all the precaution and care that I exercised in dissecting the brain, the auditory apparatus, and the organs of speech, I was unable to discover the cause of complete deafness and dumbness; for neither in the soft nor in the hard parts of those organs, or the adjacent regions, could I detect any thing uncommon or different from the normal form; and I was therefore obliged to assume that this child's loss of hearing was most probably dependent on an interruption of the nervous energy of the auditory organs, which (like many other nervous diseases) could not be recognised by any material alteration.

Whether the child were born deaf or not, it is quite impossible to determine; for though their statements could not be gained by anatomical facts, one can place but little confidence in the assurances of the parents. However, there is no ground for the denial of the supposition of *acquired* deafness, which will be made more probable by the following cases, in most of which a congenital and more or less distinct peculiarity of the soft parts, or of both, was discovered.

The second case was that of a deaf and dumb girl, born in 1815. In the opinion of her parents she had lost her hearing at the end of her second year, in consequence of a severe disease, which continued till near the end of her fourth year, and was accompanied by such frequent and severe convulsions that her limbs were often completely distorted. It was after her recovery from these that her parents first found that their child was deaf; or, at least, they believed that before this disease she had heard very well, and had begun to talk. In October 1839 she was received into the institution; but her health was still very poor, her gait was dragging,

her right elbow was immoveable, and she could not stretch out her arm. In 1834, her disease increasing, she was taken into the general hospital, where she died, in October, of exhausting diarrhœa, consequent on extensive ulceration of the intestines.

The brain, the auditory nerves, and the organs of speech, presented no remarkable anomaly. The external ear, and the parts adjacent to the tympanum, were on both sides normal. The *membrana tympani* was of its normal thickness, but on its outer surface more depressed than usual, and very tightly stretched. The outer surface of the right *membrana tympani* was more depressed than that of the left. The ossicula were of their usual size and form, but much more tightly connected both with each other and with the adjacent parts. In particular, the stapes in each ear stuck very firmly in the foramen ovale, and could be got out of it entire only with great care. The muscles of the ossicula were not remarkably altered on either side. The cavity of the tympanum was on each side in every respect normal, as were also the mucous membrane lining its walls and its nerves. The mastoid cells were proportioned to the age of the individual. The osseous part of the eustachian tube, at the end of it adjacent to the tympanum, was narrower than in the normal state, especially in the right ear; so much so, indeed, that it required some care to pass an elastic sound of scarcely one-third of a Vienna line in diameter through it. The labyrinth, up to the semicircular canals, whose walls were disproportionately thick, very compact and ivory-like, and formed at the expense of their narrowed interior, was normal. The membrane of the fenestra rotunda on each side was thickened and leather-like. The pyramidal processes of the vestibules appeared to be both wanting. The meatus internus, with the auditory nerve and its branches, presented no observable alteration on either side.

From this examination it results, 1st, That the complete deafness was produced by more than one important cause; for the unnaturally tense *membrana tympani*, which, according to Savart's experiments, vibrates less than it does in the flaccid condition, was not so adapted with the too slightly moveable ossicula as to propagate the sonorous vibrations that entered the meatus externus to the labyrinth; and, at the same time, the stapes was fixed almost immovably in the fenestra ovalis, so that it was hindered from agitating the water of the labyrinth, and, through its medium, of stimulating the auditory nerve. 2nd, That with such a remarkable narrowing of the eustachian tube, the atmospheric air from the fauces, if not entirely excluded,

was prevented from entering in sufficient quantity for hearing. 3rd, That with the enormous thickness of the walls, and the consequent very confined cavities of the semicircular canals, the elasticity which is necessary for the perception of sound, if not entirely destroyed, was certainly very much diminished; and, lastly, That by the leather-like membrane of the fenestra rotunda, the propagation of its oscillatory movements to the water of the cochlea, and to the auditory nerves, was rendered difficult.

The condition of the osseous part of the eustachian tube, and of the semicircular canals, render it most probable, notwithstanding the opinion of the parents, that this child was born deaf.

The third examination was made on a deaf and dumb boy, born in 1815. In his parents' opinion he had been able to hear up to his third year, and had even begun to speak; but in that year a severe illness attacked him, after which the loss of hearing was noticed. Various means were employed for its removal, but without effect. He was received into the Institute in the summer, and died of consumption in the winter of 1831.

On examining the organs of hearing and speech, I could find no other defect than that in the former all the three semicircular canals on both sides terminated with blind extremities without communicating with the vestibule—a malformation which might well suffice to preclude the power of hearing. It is probable, also, that this defect was congenital, and therefore that the deafness existed before the illness in the third year; for the exact symmetry of the misshapen canals, and the mode in which they terminated (by gradually narrowed extremities as they approached the vestibule), as well as the material by which they were closed, which was exactly similar to that of the rest of their walls, could scarcely have been the result of any process of disease occurring after the parts were formed.

The fourth examination was of a boy, born deaf in 1826, and received into the institution in 1835. His mother was so frightened during her pregnancy with him at the sight of another blind child, that she fainted, and from that time forward was in dread of having her child also born blind. It was certainly not born blind, but its left eye was closed, and its neighbourhood was coloured blue; and it was not till after a long time that he could open it. It was so weak, too, that it could scarcely utter a sound. A short time after birth it was observed to be completely deaf, and to a certain extent weak on the whole of its left side. In the first year of its life the child had a severe

discharge of pus from its left ear, and soon after from its right ear also, which returned in its third year after hooping-cough, in its seventh year after the nettle-rash, and in its ninth year after scarlet fever. When received into the institution the child was weak, but of ordinary size for his age, and possessed of the average mental powers of those similarly deprived of hearing. He had slight scrofulous affections during his residence there, and died of phthisis in April 1835.

The left concha was quite natural; that of the right ear somewhat deeper; the external cartilaginous and osseous external meatus on both sides in every respect normally formed, but with a moderate quantity of a yellow-grey, mucous, granular matter. The squamous and mastoid portions of the temporal bones were well formed, only the cells of the latter were unusually large, considering the age of the child, so that on the right side they even occupied the situation in which, in the normal state, the posterior or internal semicircular canal is placed. In the anterior part of each *membrana tympani* there was a hole; the diameters of that in the right were two and a half and nearly two lines; of that in the left two and one and a half lines. Both holes were of a nearly oval form, and were bounded by the smooth, sharp, and even edges of the remainder of the tympanum, which was, moreover, in both ears, thickened and completely opaque, being, in the right, formed of two easily separable laminae of cartilage, and in the left, completely ossified, except at the above-mentioned hole, and in the strip which is occupied by the handle of the malleus. The mucous membrane of the cavity of the tympanum was in like manner thickened, more spongy and looser than usual, and covered with a tough yellowish mucus. Among the ossicula, the base and the posterior crus of the right stapes were absent, but its head was much larger than in its natural state; the *os orbiculare*, on the other hand, was absent, and appeared to be replaced by the hypertrophied head of the stapes. These bones were also almost immovably connected together. The base of the left stapes was so firmly fixed in the *fenestra ovalis*, that even with all possible care it could not be extracted without injuring it; the position of the right stapes was, moreover, so distorted, that its remains, with the anterior crus, seemed sunk deep into the *fenestra ovalis*, while the rudiment of the posterior crus projected out of the same *fenestra* into the cavity of the tympanum. The *eustachian tube* and the muscles of the ossicula presented nothing peculiar.

The vestibule was less spacious than

natural; there were no orifices of the semicircular canals; in their place there were formed in the right ear, in which the canals were completely absent, shallow fossæ, and in the places of the canals themselves, the mastoid cells extended into the situation which they should have occupied. In the left ear the same disposition was, in general, presented, only in its confined vestibule there were not even the fossæ corresponding to the orifices of the semicircular canals, but two unequally long and narrow tubules closed at both ends, and connected with one another just at the situation which corresponds to the common union of the upper and posterior canals. One of these was three, the other two, lines long, and both were rather smaller than the healthy canals: neither of them was connected with the vestibule: the lining of the latter was thickened.

The cochlea was normal on both sides; only on the left the opening from the vestibule into its scala was closed with a thickened membrane. The meatus internus, especially on the left side, was of less than half its usual diameter. The auditory nerve of the same side appeared only as large as a fine thread, while that on the right side was scarcely half as large as in the normal condition. The substance of the former was almost transparent, and presented no genuine nervous matter. The right auditory nerve gave nearly a third of its filaments to the facial in the meatus.

The upper and posterior surface of the pyramid of the petrous bone was far more smooth than usual, so that one might at once have concluded on the complete absence, or the abnormal position, of the semicircular canals. That portion of the groove for the transverse sinus which descends at the root of the posterior surface of the base of the petrous bone was extraordinarily broad and deep on both sides, and appeared to have offered an obstacle to the development of the posterior semicircular canal.

The apparatus of the voice and the speech, which I examined with equal care in all their relations, presented nothing remarkable. From the condition of the auditory organs it results:—First, that the child was born deaf, a conclusion which is established by the deficiency of the semicircular canals, the confined vestibule, and the condition of the mother during pregnancy. Second, that besides these sufficient causes of deafness, chronic inflammation occurred at different periods after birth, in the interior of the ears, which probably terminated in ill-conditioned suppuration, by which the *membrana tympani* was destroyed; and that by long-continued and repeated inflammations the *membrana* was thickened and rendered cartilaginous

and osseous, the lining of the cavities of the tympanum and vestibule were made dense, and the ossicula auditus were ankylosed. And, thirdly, that the weakness and minuteness of the auditory nerves might perhaps be regarded as an origin of the congenital deafness, or, more probably, as the result of the atrophy consequent on their inactivity and paralysis.

The 5th case was that of a girl of ten years old, who was born deaf in 1827. Her parents were healthy, but her father's brother was deaf from birth. She enjoyed excellent health all her life, till she caught scarlet fever, and died in January 1838.

The right external ear down to the tympanum was quite natural. On the left side, in the lower wall of the bony portion of the external meatus, and somewhat more than a line from the tympanum, there was a roundish aperture as large as a vetch, surrounded by sharp and smooth edges, and, in my opinion, the result of an original arrest of development. It was closed by a thick tough periosteum, which rendered the lower wall of the meatus complete. The left membrana tympani was thickened, leathery, and opaque; the right was normal. The cavity of the tympanum was very much flattened from without inwards, so that the most prominent part of the membrana was scarcely one-fifth of a line from the promontory, though in the natural state they are usually from three-fourths of a line to a line apart. This anomaly was especially observable in the left ear, in which also the promontory was much less conical, but broader at its base than usual. The fenestra ovalis on each side was well formed; the F. rotunda on the contrary was a narrow fissure directed obliquely from above downwards, and which was moreover almost completely closed by the very swollen, thick, mucous membrane of the cavity of the tympanum. The ossicula and their muscles exhibited no anomaly. The mastoid cells, and their communication with the tympanum, were very spacious; the eustachian tube and the nerves of the tympanum normal. The mucous membrane of the tympanum, except that part which covers the membrana, was at least four times as thick as usual, spongy and loose, though tough. The vestibule, semicircular canals, cochlea, and two aqueducts, and the internal meatus, were on either side quite natural. The origins of the auditory nerves appeared rather small; the nerve on the right side especially seemed small, for it gave a very large fasciculus of fibres to the facial, instead of a fine fibril. On the left side this was not the case; the texture of the nerves presented nothing anomalous.

The organs of speech were in every respect healthy.

In this case the cause of the deafness was evidently in the walls of the tympanum; the effects of the changes in which, in preventing the necessary propagation of the vibrations, must be sufficiently evident; and as the history of the child shows that she had never suffered from any disease of the ears after birth, it is most probable that all the various peculiarities which they exhibited existed at the time when she was born.

The sixth examination was made on the body of a young man, who was born in 1814. His parents said that he could hear till he was three years old, when he was attacked by some nervous disorder that lasted for four or five weeks, and left him deaf. Since that time he had no disease, not even those common in childhood; and he had never suffered from discharge from the ears. His parents and sister had all good health. Having usually enjoyed excellent health, he died of phthisis in 1838.

Both external ears, as far as the membrana tympani, were healthy; the cavities of the tympana were also normal. The malleus and incus were in their natural state, but the base of the right stapes was closely united by bone to the margin of the fenestra ovalis, and immovably set in it. The fenestra itself had an irregular jagged edge, and its longest diameter was at least one-third shorter than usual. On the left side this was not the case. The muscles seemed healthy, except the right stapedius, which was remarkably atrophied. The eustachian tubes, and the mucous membranes, and nerves of the tympana, exhibited nothing unnatural.

Both vestibules were so small that neither of them would have held a vetch. The lining membrane of the left vestibule was so thickened that it nearly filled its cavity; its posterior wall presented a roundish fossa as large as a millet-seed, like an indication of the orifice of one of the semicircular canals. The opening of the vestibule into the scala vestibuli was in each ear completely closed by bony matter. Of the aquæductus vestibuli I could find no trace. Instead of the upper or anterior semicircular canal there were in the right ear only two cellules of a longish round form, and as large as millet-seeds, and covered by a fine membrane, which were separated by a vertical bony septum. On the left side there was not a trace of the corresponding semicircular canal. The posterior or inner canal was entirely deficient on both sides, its place being occupied by a spongy osseous substance, whose cells communicated with those of the mastoid process. The external or horizontal canal was probably wider than usual; but its whole cavity was filled from one end to the other by much

firmer, more compact, and more clear-coloured bone than its walls were composed of, so that, instead of a thinly walled brittle tube, there was a more than usually dense arch of bone.

The cochlea had its usual external form; but its cavity, like that of the last mentioned semicircular canal, was completely filled with a similar osseous matter, and so united with the malleolus and the lamina spiralis, that they could not be distinguished one from another. The aquæductus cochleæ was similarly obliterated.

The internal meatus was very spacious; the origin and course of the auditory nerves of both sides were as usual, but they were much smaller than natural, and both gave a large fasciculus of fibres to the communicans faciei in the meatus. The nervous cochlea was very small, and, at the perforated plate at the bottom of the meatus, suddenly changed its aspect into an atrophied very small mass, presenting only the appearance of cellular filaments, which coalesced with the periotem of the meatus. The vestibular nerve was larger than the cochlear, but still remarkably smaller than usual.

The whole of the organs of speech were perfectly natural.

The deafness in this case was amply accounted for; but the history given by the parents of the child renders it, in some measure, doubtful, what portion of, if not all, the changes found after death, were the result of original malformation. If their account that the child could hear till he was three years old be true, it would favour the view of those physiologists who maintain that the semicircular canals are a less essential part of the organ of hearing than the vestibule, and still less so than the cochlea, of which we find the analogue in many of even the invertebrata; at least, it would prove that, under certain circumstances, a single semicircular canal may be sufficient for hearing.

The author concludes from these cases, and some other considerations, that the proximate cause of dumbness is the simplest in the world; it is clearly, in most, if not in all cases, induced by deafness. The healthy hearing, and in part the observing of the movements of the mouth of the person speaking, are the most indispensable conditions for the gradual development of the power of speech, just as hearing is generally the only correct means of estimating speech; and where this sense is completely deficient, no speech could possibly be learnt, though the organs of speech were ever so sound and well formed. It may, indeed, be objected that an organ long unemployed gradually loses the power of performing its functions, and falls into a kind of paralysis. But this

law seems to have but little application with reference to the organs of speech in the deaf and dumb; for the tongue is a part which even the dumb person knows how to exercise, and it is only for the one purpose of articulate speech that his tongue is less employed than other persons. The inarticulate sounds that the dumb frequently utter are commonly palatine and lingual. In no case have I succeeded, with all the care I could adopt, and even by comparing them with the organs of speech of healthy persons, in detecting any essential difference in those of the deaf and dumb.

The opinion of those physicians who look for the cause of deafness and dumbness, especially those which are congenital, in a paralysis, or some disease like amaurosis of the auditory nerves, or the corresponding part of the brain, and who support their opinion by saying that organic alterations are rarely to be met with, I cannot, after my few observations, coincide with; for in six cases I was unable to find any material alteration in only one; and other physicians and anatomists, as Itard, Ackermann, Haughton, Müller, Cock, and many more, have also met with organic malformations of the auditory apparatus in similar cases.—*Medicinische Jahrbücher des k. k. österreichischen Staates*, Bd. 30, St. 1, 2.

ROYAL COLLEGE OF SURGEONS IN LONDON.

MR. VINCENT was recently elected President, and Mr. Guthrie and Mr. White, Vice-Presidents, for the ensuing year.

COLLEGIAL TRIENNIAL PRIZE OF FIFTY GUINEAS.

The Subject for this Prize is,

The Structure and Functions of the Lungs.

Candidates to be members of the College, not of the Council.

The dissertations to be in English, and to be distinguished by a motto or device, accompanied by a sealed paper, containing the name and residence of the author, and having, on the outside, a motto or device corresponding with that on the dissertation.

The dissertations to be addressed to the Secretary, and delivered at the College before Christmas Day 1842.

The manuscript Prize Essay, with every accompanying drawing and preparation, will become the property of the College: the other dissertations, and their corresponding sealed papers, will be returned upon authenticated application within the period of three years; after which period the papers containing the names of the

respective authors will be burned, unopened, and the manuscripts will become the property of the College.

EDMUND BELFOUR, Sec.

July 15th, 1840

JACKSONIAN PRIZE OF TWENTY GUINEAS.

The Prize Subject for the year 1841 is,
Injuries of the Thorax, and Operations on its Parietes.

Candidates to be members of the College, not of the Council.

The dissertations to be in English; and the number and importance of *original facts* will be considered principal points of excellence. Recited cases to be placed in an Appendix.

Each Dissertation to be distinguished by a motto or device, and accompanied by a sealed paper, containing the name and address of the author, and having, on the outside, a motto or device corresponding with that on the dissertation.

The dissertations to be addressed to the Secretary, and delivered at the College before Christmas Day 1841.

The manuscript Prize Dissertation, and every accompanying drawing and preparation, will become the property of the College.

Those dissertations which shall not be approved, with their accompanying drawings and preparations, and correspondent sealed papers, will be returned upon authenticated application within the period of three years; and those manuscripts which shall remain three years unclaimed, and every accompanying drawing and preparation, will become the property of the College; at which period their accompanying papers, containing the names of the respective Authors, will be burned, unopened.

There are two prize subjects for the present year, 1840, viz.

Nævi and other Erectile Tumors, their Structure and Treatment; and Hemorrhage, spontaneous and accidental,—the Nature and Treatment,

The dissertations upon which must be delivered at the College before Christmas Day next.

EDMUND BELFOUR, Sec.

July 15th, 1840.

LIST OF GENTLEMEN ADMITTED MEMBERS,

Friday, July 21, 1840.

W. S. Lucas.—C. H. Garstin.—J. Dutton.—R. Galvin.—J. E. Bath.—A. O. Leete.—H. F. Butt.—R. Botton.—J. T. Dunn.—J. Moline.

Monday, July 27, 1840.

C. S. Bompas.—T. G. Bush.—G. H. Makins.—G. S. Mitchell.—W. F. Shorbridge.—J. H. Evans.—J. G. Henry.—J. H. Wrentmore.—P. L'Anglois.—R. G. F. Smith.—J. N. Tresidder.—M. Murphy.—E. R. Houlden.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, July 23.

R. Pyper, Tullamore.—J. A. Stace, Southampton, Haants.—J. Taylor, Wargrave, Berks.—W. Clapp, Exeter.—S. Hobson, Northampton.—C. Godson, Heckington, Lincolnshire.—J. Moss, Macclesfield.—J. C. Bucknill.

Wednesday, July 29.

T. B. Hopkins, Chatham, Kent.—F. J. Lowes.—R. H. Wood, Glenshill, Salop.—C. H. Dobson, Northallerton.—C. B. Sewell, Linton, Cambridge-shire.—J. Brindley, Leek, Staffordshire.—H. Bursey, Brighton.—J. Spicer, Lambourn, Berks.—D. B. Whipple, Plymouth, Devon.—J. H. Jackman, Temple Blond, Somerset.—H. M. Blaker, Brighton.

NOTE FROM MR. OWEN.

To the Editor of the Medical Gazette.

SIR,

HAVING seen in your last (44th) number a letter headed "Mr. Owen and his Reviewer," I beg to say that it is not my intention to reply to that letter; and that, so far as I am concerned, the controversy to which it relates is at an end. I have asserted nothing in my published observations upon this subject which I do not know to be true; but I owe it to myself to express my regret, that the irritation produced by the charges so pertinaciously advanced against me, should have led me, in some passages, into the employment of language which my calmer judgment disapproves.—I remain, sir,

Your obedient servant,

RICHARD OWEN.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

INJURIES OF THE HEAD, continued.—*Fracture of the Cranium: Simple, Compound, and Counter-fracture.*—**SEPARATION OF THE SUTURES.**—*WOUNDS of the BRAIN or its Membranes.*—**CONCUSSION and COMPRESSSION.**—*Their Nature and their Treatment.*

FRACTURES.

ANY of the injuries we have spoken of may be accompanied by fracture of the skull: the fracture may happen at the point where the blow has been received, or at a distance: the former is termed direct, the latter indirect, or, as it is aptly named by the French, fracture by *contre-coup*: it may be with or without depression. A fracture by a contusing body is usually a more serious injury than when it is produced by a pointed instrument.

A fracture may implicate the external table alone, or may affect both; in the former case the region of the frontal sinuses is usually the affected point; in the latter, any region of the skull may have suffered.

Where the bones, though fractured, have not changed their situation, so as to compress the brain, it is termed *simple*, but, however simple, there is generally sufficient injury to render the chance of inflammation and compression probable. It is not always easy to detect the fracture; indeed, few things are more obscure than its diagnosis; sensible signs alone are sufficient to assure us of its existence. It may be a

simple fissure, and may be confounded with the natural or Wormian sutures; but every one ought to be so familiar with the situation of those sutures as to render that mistake improbable. Still, in the *Mélanges de Chirurgie*, of Saucerotte, is the case of a priest, who, tripping up, fell on his back and injured the occiput. The integuments were incised, the occipital bone exposed, and it presented a transverse division. The trepan was about to be applied, when one of the surgeons opposed it, saying that there was a large Wormian bone, by which the idea of fracture was conveyed. The patient got well, and bequeathed his skull to Nouvelle. The cranium afterwards figured in the collection of Saucerotte: the Wormian bone occupied the place of the superior angle of the occiput; it was nearly two inches square. Such a mistake would have been comparatively unimportant to a surgeon who, for a simple fracture, did not conceive the trepan necessary, and I believe the greater number of surgeons hold that opinion, but under other circumstances it might be a fatal mistake.

A compound or multiple fracture is always produced by direct violence; it may extend through a part, or the whole of the injured bone, or even beyond it; it may be radiated or linear: in these cases the violence has often exhausted itself at the point, and the chances of concussion are lessened. But a compound fracture which is not radiated may have more or less tortuous branches, which extend far and implicate many bones. In this variety there is usually concussion, or contusion of the cerebral pulp, with extravasation of blood.

Supposing the cranium not to be exposed, what symptoms would justify us in supposing that fracture exists? We should consider the nature of the instrument, the force of the blow, the sensations experienced at the moment, and the strength

of the skull at the injured point. If the instrument were very hard, the blow violent, and inflicted upon a weak point of the cranium; if the patient, more or less insensible, automatically raised the hand to the injured part; the presumption would be, it is said, in favour of fracture; still those symptoms may exist without it, and fracture may exist without any of these concomitants.

Although fracture may then exist, if the integument be entire, without any marked symptom to reveal it, I incline to the opinion that the circumstances just stated would justify our making an incision to ascertain the exact condition of the part. There is another symptom upon which some surgeons place great reliance, when symptoms of compression are present after a violent blow on the head—I mean the state of the pericranium: if it be detached they believe there is fracture, and in many cases unquestionably they would be right; but then, it must not be forgotten that the pericranium may be detached without fracture, and may be adherent with.

In each of these cases the necessity for the trepan is not made out: in the first, because the injury is not serious enough; in the second, because it is too serious. In fact, in the first, if the soft parts are not divided, the spiculæ be not moveable, and there is no symptom of compression, we should abstain from it. In the second, we should abstain, because to evacuate the extravasated blood many crans of a trepan may be insufficient. It could, in either case, exercise no salutary influence upon the concussion, and may increase the chances of inflammation. In either case a moveable spicula could generally be removed without it.

If the bones of the cranium were at all points equally solid and resistant, if foreign violence acted only on small points, direct fractures might alone be expected. But as some points of the cranium are less resistant than others, the force which was insufficient to fracture the point upon which it was directly applied may produce a fracture at a distant point: this is the fracture by *contre-coup* or *counter-fracture*; these injuries are also termed *contra-fractura*, or *contra-fissura*. These fractures are explained by the unequal resistance of the parietes of the cranium at different points of its extent. To make the explanation intelligible, we will suppose a blow to be applied on the os frontis, with a force which may be represented by the number 20: at this point the os frontis is thick, and opposes a resistance equal to twenty-five; the bone, therefore, does not give way at that point; but the impression is communicated to the orbital portion of this bone, which is thin and fragile, and its resistance

may be expressed by the number 12; it yields to a power, enfeebled by transmission it is true, but still strong enough to produce fracture. Experience supports the reasoning: many fractures of the orbit have been observed as consequences of blows directed upon the forehead, the coronal portion of the bone being intact. But the impression may be communicated to an adjoining bone; the os frontis may be struck, the parietal is fractured; it may extend to a greater distance, to a point diametrically opposite to that on which the blow has been received: a blow on the forehead may fracture the occiput; a blow on the vertex may fracture the base.

These cases present difficulties in diagnosis; sensible signs of the accident are wanting: we are, therefore, obliged to rely upon rational ones, which are very unsatisfactory. Much reliance used to be placed upon a circumstance which, in my opinion, is utterly valueless. It was assumed by Lanfranc, that the patient, at the moment of the injury, would hear a noise, similar to that of a pot at the moment of fracture: it is very improbable that, at such a time, the patient would distinguish any such thing; and if he had, at the moment we require the information, he is insensible. Again, it was necessary to look for a tumid point; this was supposed to be the seat of counter-fracture: where are we to look for it, if the fracture occupy the base of the skull? Again, it was proposed to place between the teeth a piece of string, or a straw, and the head was to be shaken, by small tugs upon the straw: the point where, under these circumstances, the patient complained of pain, was believed to be the seat of fracture. This plan has long been very properly abandoned as valueless. Again, the occurrence of pain at the seat of fracture, when the patient cants, speaks, or when we press at different points, is not entitled to confidence, for simple contusion may occasion it. The œdema, tumefaction, or separation of the pericranium, is no certain evidence of fracture; an injury to the soft parts may produce it. Neither do we accord our belief in the old doctrine, that if the head be shaved, and covered with a poultice, the point corresponding to the fracture will be more humid than any other; nor that vomiting, vertigo, faintness, paralysis, or convulsions, are any sufficient evidence of the existence of fracture. It is believed that fractures of the base usually produce bleeding at the nose or the ears; but simple concussion may produce these signs. The occurrence of amaurosis of one or both eyes, paralysis of the face, a serous fluid flowing from the ears, some days after the accident, are circumstances of grave suspicion, the latter two symptoms leading to the supposition that the petrous portion

of the temporal bone has suffered; but they are merely circumstances of suspicion. The eye, when there is denudation, or the finger, where the integuments are intact, alone furnishes conclusive evidence of the existence of fracture. To acquire more certain data when the bone is not uncovered, should incisions be made, and the bone exposed? On what point should the incision be made? why unnecessarily resort to any operation which may singularly retard the cure? Symptoms which clearly indicate urgent signs of compression alone justify our resorting to incision; and even then the signs of effusion from which compression results are so illusory that the indication is rarely precise.

A counter-fracture may affect the inner table alone, and the symptoms may be those of compression; such a case occurred to S. Cooper at Brussels, and there are others besides those of Paré and Bilguer on record. When the fragment is displaced, it may prick the membranes of the brain and occasion symptoms of irritation; but then, how many causes of irritation of the brain are there besides a spicula of bone? With isolated fracture of the internal table I believe there is always displacement of the fragment. As a general rule, when fracture exists without giving rise to compression, concussion, or inflammation, we have no right, surgically, to interfere; our course then is to watch, to diet, and to pursue the evacuant system of treatment.

There may be *separation of the sutures*; it is an accident which can scarcely happen to an old man or even an adult, but it now and then happens to a child. I recollect a child of three years, over whose forehead a waggon wheel passed and produced this state; the antero-posterior diameter of the cranium could be greatly lessened, by passing the posterior portion within the anterior: the case did well. There are several cases on record. One would naturally expect, in such a case, great concussion and extravasation; though in the case I allude to there was no evidence of the latter symptom, though the concussion was severe.

INJURIES TO THE BRAIN.

A wound may directly implicate the brain itself, or its coverings. Wounds of the brain have not all the gravity which was formerly believed to attach to them. The examples of incision, made to evacuate pus or other fluid, are by no means rare; and it has not been remarked that the symptoms have been aggravated by the operation, but, on the contrary, it has sometimes exercised a very salutary influence upon them. It is not the solution of continuity, or even the loss of substance, which constitutes the gravity of these dis-

cases; but concussion, compression, or consecutive mischief. The most remarkable examples of this kind are furnished by incised wounds; among them is the famous case of the dragoon, mentioned by Lamotte. The sabre cut through the right parietal bone to the extent of two inches, and the left to the extent of three or four inches, just above the ear. This wound, which included not only the membranes of the brain, the longitudinal sinus, and even the brain itself, and which was followed by syncope from the great loss of blood, was cured in two months and a half. Many similar and scarcely less marvellous cases are on record in works on military surgery.

Puncturing instruments, and even spiculae of bone, may wound the brain or its membranes; the great object is to extract the puncturing instrument if it remain in the wound. If the portion of the instrument left in the cranium be insufficient to allow of our laying hold of it, a crown of a trepan may be necessary for its extraction. It has been customary to range among fractured wounds of the brain and its meninges the lance-wound received by a celebrated person, Francis of Lorraine, Duke of Guise, before Boulogne. The arm, according to Boyer, entered below the eye, and was directed obliquely so as to come out on the other side between the neck and the ear. If the arm had entered above the eye the brain must have been wounded, but as it entered below, it passed through the face and not the brain; the cure of the wound is therefore the less extraordinary.

Contusing bodies wounding the brain are usually projectiles impelled by gunpowder. They sometimes carry off considerable masses of the brain, or the ball may remain in its substance. If we carefully examine these cases a singular result is developed. They are comparatively less frequently mortal than similar wounds in which the brain has not directly suffered. Extravasated fluids find a ready escape, and the chances of compression or consecutive inflammation are lessened. It is very extraordinary to read the accounts of enormous wounds of the head, with mortification of portions of the brain, get well after the elimination of the sloughs, and the development of granulations on the surface of the brain itself.

In such cases the dressing cannot be too simple, and we cannot be too much on the alert. Before the wound is dressed a very careful examination must be made to ascertain that no foreign body remains in the wound. If, however, the body be imbedded in the cerebral pulp, we should not usually proceed far in attempting to pursue it, or we may materially increase the mischief; and many cases are recorded

where foreign bodies had remained long in the substance of the brain without occasioning great suffering. Bartholin mentions a case where a man had the point of a sword in his brain for fourteen years. Zacutus Lusitanus mentions the case of a woman who died of fever: between the meninges and the cranium the blade of a knife was found, with which she had been wounded eight years before. Many similar facts are recorded, which sufficiently show, that to abstain from too much meddling, in search of foreign bodies in the brain, is wise; but they do not sanction us in leaving them there when they might be easily removed.

CONCUSSION OF THE BRAIN.

A violent blow upon the head, accompanied or not with a wound of the integuments, may excite an oscillation or vibration of the parietes of the cavity of the cranium. The motion so impressed, and the change of form consequent upon it, expose the brain to a series of slight contusions, which may bring about a longer or shorter suspension, or a more or less complete aberration of its functions. This species of injury is known by the term *concussion*; its effects are, the symptoms of the lesion. The extent of the concussion bears a certain proportion to the force of the blow, and the degree of the resistance. With an equal force two blows may have a very different result, in consequence of the difference in the resistance; where the resistance is least, the vibration is least, and the concussion least. A very common experiment makes this evident: Take in the hands a board, strike one end of it with the broad extremity of a hammer. If the texture of the board resist, the vibration will be very sensibly felt; but strike it with the pointed end of a hammer, the texture gives way, and the vibration will be scarcely perceptible. The brain exactly filling the cranium, we readily comprehend that if the latter suddenly changes shape, the former must be as suddenly contused or compressed. This is what passes at the moment of a blow; at the injured point the cranium is, for the moment, flattened, whilst in the opposite direction it is enlarged. These changes of form are extremely rapid, and the oscillations continue for some time. If the oscillations be very great, if the concussion be extreme, death may happen at once. Concussion, then, may, in the last analysis, be defined a compression, but an *instantaneous and general one*.

Concussion of the brain may be a consequence of direct or indirect injury, a blow on the head, or on a distant part: thus, in a fall upon the feet from a height, concussion may happen, though the force is much

broken by the intervention of many joints, before it is communicated to the brain.

Up to the present moment we have vainly sought to distinguish the anatomical lesions of concussion. Two facts seem to prove that, when extreme, the encephalic mass is lessened in bulk; but these facts are insufficient to frame any law on the subject. One of these facts was observed by Littre, the other by Sabatier. The first was the case of a young prisoner, who sought to destroy himself, but had not the means of doing it; to accomplish his object, however, he ran from one end of his cell to the other, and precipitated himself, head foremost, against the wall. The concussion was so violent that he never rose. At the examination after death, Littre found the brain lessened in bulk, and a space existing between it and the bones of the cranium. "I have seen," says Sabatier, the same thing in a person who died suddenly from the effects of a blow on the head."

Some years ago Gama attempted, with much ingenuity, to explain the phenomena of concussion. Concussion, says he, whether direct or indirect, acts upon the brain, by impressing upon it movements which follow certain lines which had not previously been determined, but which he conceives he has demonstrated by an experiment. He took a glass globe, in which he put a certain number of pieces of straw, chaff, or bristles; this globe was then filled with isinglass jelly, which, when cold, took as near as may be the consistency of the human brain. The globe was then closed, and upon it blows were inflicted, either with the hand or an instrument, so as to produce as strong a vibration as was consistent with the integrity of the vessel. The blows produced an oscillation through the whole mass of jelly, and as much more decided as the blows were harder; but the motions were not uniform, as was evident by the vibrations of the straws. Moderate percussion was always very sensible at a point between the glass and the jelly, but the effect did not extend far into the substance. If the percussion were more violent, the mass was momentarily detached from the side of the vessel at the point struck, and a similar effect was observed at the opposite point; the whole mass seemed for a moment to be compressed on all sides, and to occupy less space. This kind of double impulsion directs the shock towards the centre of the mass in two opposite directions. The particles which obeyed the two impulses, that is to say, which were directed inwards from those two opposite points, afterwards vibrated in opposite directions, and continued to move irregularly for some time. The vibrations of the globe itself could not be distinguished under any percussion, neither by the eye

nor by the hand. If you repeat the experiment, you will find that Gama's statement is as near as may be correct: he believes it to be an exact representation of what passes in the head under direct percussion, which produces concussion. If it be so, we see that the first effect of the blow is propagated from without inwards; that it acts on one or two points according to the violence of the shock.

Symptoms.—What is desirable for us to know is, what are the phenomena of concussion when not immediately mortal? In a first degree it is characterized by swimming sensations in the head, noise in the ears, dropping of the eyelid, and sudden incapacity of the lower limbs, so that the patient staggers or falls to the ground; from this condition he may soon recover, but lassitude may continue for two or three days; there may be wandering pain, loss of appetite, inability to exertion of any kind, but after a certain time this is gradually dissipated: this state is usually known as stunning.

In a *second degree* there is sudden loss of consciousness, so complete, that the patient recollects nothing of his accident when he comes to himself; he falls to the ground; the muscular system no longer acts; if a leg be raised it immediately falls down again; there may be spasmodic or convulsive action of the stomach, the rectum, and the bladder, causing, involuntarily, vomiting, evacuation of *feces* or urine. The respiration and circulation however continue, and life is preserved. At the moment of concussion, palpitations are often experienced; the respiration, at first altered and irregular, becomes regular, and so soft that it is often scarcely perceptible: this is a very characteristic sign. The eyelids are almost always closed; if we separate them, the eye is bright, but the pupil does not contract, even before a bright light; the sensibility is obtuse, but not extinguished; if we pinch a part, by a kind of automatic movement it is removed. In a few words, then, the characteristic signs are these: the patient lies in the way he is placed, he seems in a deep peaceful sleep; the thoracic parietes scarcely move; the surface of the body is pale, and for a certain time cold; the eyelids are paralysed; the pupil is insensible. The patient swallows, but deglutition does not happen, unless fluids be introduced far back; otherwise they remain in the month. Motion of the heart is scarcely perceptible; the pulse is so weak and soft as to be extinguished by the slightest pressure, but it is regular; digestion does not go on, neither do the excretions. If you pinch the patient he does not seem to perceive a first or even a second, and it must be severe to induce him to move the part; rarely does he direct his hand to the spot. These things are very marked at first, but gradually lessen;

the pinched part is sooner removed; the pulse is stronger and more frequent; the pupil is fatigued by light, even when the eyelids are closed, and the patient will sometimes interpose his hand between the eye and the light; speech returns; the wants are satisfied; he asks for food, and falls asleep, sometimes for many hours; after a time the intellectual faculties reappear, but he is incapable of sustained attention; he often begins a sentence and does not end it. After four, five, or six days, the faculties may be restored, but the consequences frequently continue for some time after; such as feebleness, incapacity to read, or to continue a conversation, or to think; the sexual functions sometimes seem debilitated for many weeks, and give the patient much disquiet. In a *third degree* almost all patients die promptly; they fall down insensibly, and all intellectual and voluntary functions are totally destroyed; there are often convulsive movements and involuntary evacuations; the pulse is very irregular; respiration is gradually extinguished, and after a few seconds life ceases.

Examined after death, we do not find, in the brain, any trace of extravasation, compression, or disorganization. If in patients who had died of apoplexy we open the cranium, we see that the cranium is completely filled; in concussion, on the contrary, the brain appears diminished, occupies less space, and contains less blood. Whether we examine with the eye alone or with a lens, we perceive no trace of separation, destruction, or confusion.

Treatment.—In cases of concussion of the brain, our first care should be to produce re-action, to rouse the dormant vitality of the contused and enfeebled organ; our second, to take all prudent means to prevent the development of inflammatory action; our third, to combat it when it is declared. To accomplish the first indications, warmth is applied to the surface of the body; warm diluent fluids may be given internally; but in some cases it is necessary to go farther, to exhibit diffusible stimuli, and to apply counter-irritants; mustard plasters or blisters to the legs or feet, the back of the neck, or even the previously shaved scalp. In a single case, which resisted all these means, I succeeded in rousing the patient by placing the feet in water of the temperature of 180. I have had no experience of the value of tartar emetic at this stage, and my impressions are unfavourable, although it has been strongly recommended. It is believed to act as a stimulant, which may, sympathetically, exercise a salutary action on the brain; and not as an evacuant, which would only increase the prostration; still less as an emetic, the

effects of which might naturally be expected to favour cerebral congestion. I repeat, I have had no opportunity of testing this remedy, and, theoretically, I am opposed to it. When reaction comes on, another set of agents must be brought into play. When sense returns, and the pulse is raised, if it become hard and quick, if the temperature of the body be much raised, congestion, and even inflammation of the brain, are to be apprehended: we must then bleed, but with the caution which the enfeebled state of an important organ would suggest. Bleeding is not, in many cases, so evidently useful as was once thought; the prostration and stupor may contra-indicate it. Indeed, until the stupor is partly or completely dissipated by coming reaction, we do not usually bleed. Then the suffused countenance, the injected conjunctiva, the full and hard pulse, point out the necessity. Some persons prefer to take blood from the temporal artery; others, from the jugular vein; others, from the foot; but I have never seen more good attend the taking blood from either of these parts than from the arm. With blood-letting we may associate the use of tartar emetic; not, however, until a certain quantity of reaction comes on. Many persons believe that the irritation it excites in the digestive tube serves to lessen the chance of inflammation of the brain. Desault, towards the end of his life, had so generally employed this medicine, that, even in cases of compression, he abandoned the use of the trepan, and maintained that the antimony rendered it unnecessary. He, at one time, largely employed blisters upon the head, thinking that they exercised a salutary revulsion. He conceived the communication between the soft parts covering the cranium, and the membranes covering the brain, so direct and so intimate, that irritation within might be easily subdued by irritation excited without the cranium; but then it must be recollected that this reciprocal correspondence may convey to the meninges, and even to the brain itself, irritation set up on the scalp. If used when the patient has not recovered from his stupor, they should be associated with evacuants. If the pulse be small and feeble, the insensibility almost complete, the coma deep, it is by some thought necessary, after having shaved the head, to completely cover it with a large blister, which should remain applied for twenty-four hours. In some cases its good effects are very quickly manifested; agitation is developed, the pulse is raised, the face is animated, consciousness returns, and the patient seems as if to awake from a long deep sleep. They also advise that the irritation should be kept up by removing the epidermis,

and dressing the surface with mercurial or savine ointment. My own experience is more favourable to the use of blisters to the calves of the leg or soles of the feet.

The effects of concussion may be slow and insensible. Vessels may be ruptured within the cranium, or the brain or its membranes may be inflamed. The following case shews what accidents may follow slight concussion, and what a long interval may occur between the cause and the effect:—A bundle of hay, thrown from the window of a loft, fell on the head of a young man who was passing: he fell to the ground insensible; there was no wound, or appearance of contusion. Three bleedings so far restored him, that, on the fifth day, he was up and about his ordinary occupations. Three months after he became heavy and sleepy; he was unable to exert himself, and perspired profusely after very slight labour; his pulse was frequent, his appetite capricious. It was observed that during the night he ground his teeth, and that, though asleep, his eyes were often open. A medical man who saw him, knowing nothing of the accident, thought he had worms, and treated him accordingly, without success. He died of convulsions without having passed any worms. He was examined after death, and, in the middle of the medullary substance of one hemisphere of the brain, three or four table-spoonfuls of very fetid decomposed blood were found. In these internal extravasations, results of concussion, the signs which indicate their existence are not sufficiently positive or precise to justify our having recourse to the trepan. The evacuant system is the only one which can be followed. By means of such treatment as we have directed, the patient's condition may be greatly improved; but it is still necessary for some time to watch him very carefully. If any partial paralysis exists, tonics and stimulants will sometimes relieve it; sometimes blisters and electricity exercise over it a salutary influence.

To prevent the development of chronic inflammation of the brain, which occasionally supervenes some time after the accident, the patient must be rigidly dieted—must not engage in any laborious mental or bodily occupation; he should continue saline-antimonial purgatives; the digestive system and the head must be especially watched. If there be pain or confusion in the head, cold should be applied, and, in some cases, it becomes necessary to use blisters or even issues at the back of the neck; and, if necessary, blood-letting. In spite, however, of the best directed means, bleeding, blistering, and evacuants, inflammation is sometimes developed in the substance of the brain, or in its membrane, and is

usually manifested about the sixth, seventh, or eighth day from the occurrence of the accident.

COMPRESSION OF THE BRAIN.

Observation and experience have shewn that compression, exercised on the periphery of the hemispheres of the brain, when inconsiderable, often produces little effect, though occasionally a few drops of blood or pus seem to be sufficient to destroy life; that when it acts upon the base of the brain it destroys the senses, and suspends the intellectual faculties, and voluntary motion; that when compression is limited to particular points, the effects are varied; but experience has shewn so many exceptions to these rules, that it behoves us always to regard these cases with great suspicion. Not many weeks ago, I saw a case where a man was struck on the left parietal region with the edge of a flat iron; an incision, without any depression of the outer table, resulted. This man went to his work, as a plumber's labourer, next day, and continued to attend to his business for ten days: he was not well, certainly, but still sufficiently so to do what was required of him. He then took to his bed, continued there for ten days, and died. Thirty-six hours before his death I saw him; the pupils acted, he could readily move his arms and legs, and there was not even partial paralysis; and yet the man had, at that time, a piece of the inner table two inches long, and half an inch wide, driven into the brain, and five or six ounces of very foetid pus on the left hemisphere.

If, in a brute animal, we expose the brain, and place upon it a dry sponge, no marked effect follows it; but if we fill the sponge with water, the animal staggers; if, to the weight of the sponge, we add pressure with the finger, paralysis is manifested.

When the cranium is not opened, any substance interposed between it and the brain gives rise to more decided symptoms, because compression is then more completely exercised; and this is an argument used by the advocates for the trepan.

The effects of compression vary with the extent of surface compressed; the greater the extent, the more serious the condition, and the more difficult the relief; but compression, very limited in extent, may prove as rapidly mortal when it acts upon the base of the brain: thus counter-fractures of the base of the cranium are commonly fatal through the pressure of extravasation. It is, therefore, proper to endeavour to determine the seat of compression. As a general rule it may be said, that the nearer the vertex the less

severe the accident; less important parts of the brain are affected, and more opportunity of relief is afforded. The compression may be exercised external or internal to the dura mater or pia mater, and, in this respect, the situation has much influence on its gravity; for the deeper-seated the compression, the more direct its influence upon life, and the less probable is extraction or evacuation. Again, the nature of the compressing body is important; does it come from without, is it solid, is it smooth, is it blood, is it healthy pus? These different bodies will compress differently, and will give rise to different symptoms. It seems to be a well-established fact, that a spicula of bone, or the point of a sword, or knife, will more readily excite inflammatory action than a bullet. Extraction is as much more pressing as the body is more irritating. Blood is more easily supported than probably any other body, and there is more chance of its being absorbed. Again, there is a difference between coagulated and fluid blood; the former compresses more; therefore it is that the wound of an artery produces more rapidly the symptoms of compression than a similar wound of a vein or sinus; arterial blood soon coagulates; venous blood often remains for a long time fluid. Sanies and pus have a doubly fatal influence; they act as compressing bodies and irritating substances. The mode in which compression is applied is an important circumstance, whether suddenly or slowly: it is sudden when caused by bodies introduced from without, or by spiculæ of bone; it is less so when produced by blood; still less when caused by a morbid product. Sudden compression the brain cannot bear with impunity; its effects are almost instantaneously manifested, even though the amount be inconsiderable; whilst the brain may get accustomed to compression slowly produced, even though considerable. It might from this be concluded, that the latter is a less formidable condition than the former; but if we attentively examine the sources of the latter, we see that they proceed, commonly, from a lesion of the brain, or its membranes, and that the patient's condition is singularly aggravated by this circumstance. When the compression is caused by a foreign body or spicula of bone, its extraction may at once restore the functions of the injured part, while when it is produced by a morbid product, we scarcely hope for prompt or certain relief. Extravasation of blood, though occurring slowly, determines a compression which is more serious than that determined by a depressed bone, which acts suddenly; because we cannot calculate confidently on its being absorbed, and because we cannot be sure, even if we

apply the trepan, that we shall succeed in removing it; whilst a depressed bone can almost always be raised. Almost all the causes of compression of which we have spoken, may exist concurrently in a given case, and this seriously complicates the disease: we may have a foreign body, driving in *inspiculæ* of bone, and penetrating itself; a blood-vessel may be ruptured, blood effused, and pus secreted.

The most important point in these cases is the condition of the brain itself. When, with compression, there is no decided lesion of the brain or its membranes, the affection is simple; but if there be inflammation, or contusion, or violent concussion, the case is complicated, and even the trepan fails; and this is as easily understood as that the operation for empyema should often fail. The operation for empyema will often succeed, when all that is required of it, is to remove the contained fluid; but most frequently there is a disease of a contained organ, and the condition is reproduced. To open the cranium or the chest is not of itself an essentially grave operation, if the contained organs preserve their integrity. It would oftener succeed if cases for its employment were better chosen, and the operation performed at an earlier period.

We have already stated that a certain analogy exists between concussion and compression, since in both cases the brain is subjected to a physical action, which tends to compress it; but in the first case there is an impulsion or shock, the brain is hurt against the cranium, whilst in true compression there is no general shock. The symptoms fairly express the analogies and the differences of these two states. The most marked symptom of compression is paralysis, arriving sooner or later after the accident: the time, varying with the agent, according as it is blood, pus, or other substance. The symptoms may be manifested intensely; at the moment then they resemble those of apoplexy; there is a lethargic prostration; respiration is difficult or stertorous; there is hemiplegia, or only paralysis of a particular part; convulsive movements; hard and frequent pulse. Some authors have observed a contrary condition: Thomson speaks of a case of fracture, with a depression of the posterior part of the cranium, in which the pulsation suddenly declined to 36. Abernethy also noticed that the pulse was sometimes slow, and that it more frequently intermitted than in cases of concussion: sometimes there is dilatation, sometimes contraction of the pupil. I believe the condition of the pupil at the moment of injury has much to do with its after appearance. The symptoms succeed rapidly, or almost simultaneously,

when there is a sudden compression of the brain and nerves; but when the compression is slow and progressive, the symptoms make their appearance gradually, and after more or less considerable spaces of time. The patient may feel general numbness and heaviness, which materially interfere with voluntary motion; the senses are blunted; the head is heavy, and the hand is frequently directed to it; from time to time he is roused, but soon relapses; the lethargy increases; the breathing is stertorous; delirium comes on; convulsive action is frequent, and paralysis extends.

A great and very natural desire has always been felt to acquire the power of determining the seat of compression, and for this purpose the seat of paralysis has been much, relied on as a means of deciding upon the point where the trepan should be applied. The observations of the ancients have suggested to the moderns ingenious experiments to set at rest this question. Among the investigators (by way of experiment) of this subject, the principal are, Magendie, Serres, Fleurens, Bonillaud. Cleverly as their experiments were conceived, and dexterously as they were executed, they have done little for surgery, but have brought new facts to physiology. The ancients were not ignorant that the compressing agent is usually found at the opposite side to that of the paralysis; but facts often occur in which the rule does not hold good. As a general rule the seat of paralysis indicates that the seat of compression is on the opposite side; but as each side of the cranium is a region of considerable extent, attempts have not been wanting to fix more immediately the compressed point. For this purpose the paralysis is an insufficient guide, and direct examination of the cranium is useful. When with a paralysis of one side of the body an injury of the cranium exists on the other, we are justified in concluding that the compressing agent is seated under this point: if it be a simple contusion, the probability is great; if the bone be denuded, the probability increases; if there be a fracture, certainty is almost complete. Attempts have not been wanting to prove that we may acquire still more precision as to the seat of injury; but they cannot be relied on: it has been stated that if there be lesion of the optic thalami and corpora striata, that they are respectively indicated by the affections of the arms and legs. Such are the primary lesions of the cranium, which indicate the existence of a neighbouring compression: there are consecutive lesions which afford quite as much certainty; thus, when, before or with paralysis, there is separation of the pericranium, when the wound becomes pale and flabby, and yields a sanious or fetid discharge, we are justifi-

fied in acting upon the conviction that there is effusion under this point, within or without the dura mater. When there is no wound, if, with paralysis, a puffy tumor is manifested, such as is seen over a necrosed bone, we are justified in presuming that *there* is the seat of pressure. In fact this tumor is similar to that which occurs over a bone in the limbs, whose medullary membrane is diseased. Now the dura mater may very fairly be considered as the medullary membrane of the cranium; if it be separated the circulation in the bone is, to a certain extent, compromised, and the pericranium also; therefore the tumor is analogous to those manifested in the limbs under parallel circumstances.

Again, many persons are sanguine that they have not only the power of distinguishing, in all cases, between compression and concussion—that they can point out the seat of compression—but that they can determine by what kind of body it is produced. They say, if the signs of compression are produced at the moment of injury, it must be occasioned by a depressed bone; that if they gradually come on within forty-eight hours, it must be caused by extravasation of blood; that if they begin to be manifested after the third day, the chances are that they are occasioned by pus. If injuries of this kind were simple, uncomplicated, in many cases these circumstances would be important diagnostic signs; but as the simple cases are very few, we must not look for very important results from these signs. Supposing, for instance, a case of severe concussion: for hours the ordinary signs of compression may be present: before they have ceased hemorrhage has proceeded to a certain extent, and real compression is produced: how can we determine, in such a case, whether the compressing agent be blood or bone? Supposing the symptoms of compression not to be developed until after the fourth or fifth day, how can we distinguish between inflammation of the brain and local purulent secretion?

We have said that concussion was a species of compression; that the two conditions were analogous: they ought therefore to be represented by symptoms bearing a certain analogy with each other; and so they are; so completely, indeed, that before the time of Petit they were usually confounded. The brain being compressed in both cases, symptoms in both are manifested which indicate an enfeebled innervation. The intelligence, the senses, and even the functions of animal life, are suspended. Still, though these two conditions offer those points of similarity, it is of vital importance to you that I should enable you to distinguish between them.

Mr. Abernethy terminated his comparison of the symptoms produced by concus-

sion with those of compression, by stating that *compression* insensibly determined partial or general insensibility, according to the degree of extravasation. The pupil is dilated and immovable, the respiration slow and stertorous, the pulse slow, there is no vomiting, the limbs are flaccid, as in a dead person.

In *concussion* the insensibility is of short duration, and while it lasts the extremities are cold, the pulse is feeble and intermittent, the skin gradually becomes warmer, the pulse and respiration more frequent. Often the pulse is intermittent, but the breathing is never stertorous; the pupil is contracted, the countenance expresses suffering, there is often vomiting, and the state of the patient is like that of one in a deep sleep.

We must go farther: we must show you that the exceptions to the conditions above described as characteristic of concussion and compression are very many, and very complex. We will take the first two degrees of concussion; and in speaking of compression I shall exclude those produced by manifest depression of the cranium, or by foreign bodies: they may excite symptoms as promptly as concussion, but the external signs are so evident that they cannot be confounded.

We have seen that concussion was a momentary compression; its effects should therefore be prompt, and directed upon the whole economy; there is a great incapacity for action, because innervation is generally suspended.

The cause of concussion strikes a single blow. The effects remain, and they are most violently expressed at the moment; they are afterwards gradually lessened.

Concussion is a deep heavy sleep, which prostrates at a single blow, gradually becomes lighter, and ultimately vanishes, carrying with it the remembrance of the cause. It happens that patients, in recovering consciousness, totally forget the accident. In concussion the causes of the sleep no longer exist, nothing is opposed to waking, nothing weighs down the eyelids; they open of themselves.

Compression is established by degrees, and does not act upon the whole of the brain, and its effects are not manifested for some time after the accident. The absence of innervation exists in the part which corresponds to the point of the brain which is compressed.

The cause of compression acts slowly, and goes on increasing; when it does not increase it remains stationary; its effects follow the same course. They are at first little marked, but usually they soon increase. If the compression be extensive, it is at first a slight stupor, a fitful sleep, becoming afterwards as deep as that at the commence-

ment of concussion; but it is less soft and peaceful, there is always more or less agitation, there are efforts to rouse himself, but they may be ineffectual, because compression weighs the faculties down.

I have chosen as my illustrations a case of concussion without contusion of the brain, and a case of the simplest compression, that from extravasated blood.

If the characters of concussion and compression were always shewn as we have represented, if their features were all as clearly defined and as prominent as we have here described, no difficulty could be experienced in distinguishing them; but though our descriptions are truthful they do not tell the whole truth; and therefore it is particularly important to point out, and to direct attention to, another circumstance—the interval which separates concussion from compression, and to establish that when insensibility supervenes immediately after the accident, it is owing to concussion, whilst, when it comes on some time after, or after the symptoms of concussion have disappeared, it should be imputed to compression. But does this interval which separates concussion always exist? Is there always the intermediate period in which there is a cessation of the cerebral symptoms? Certainly not: it may happen that the effects are hardly completely manifested when those of compression begin: they are then combined and confounded. In such a case the progress of the symptoms should be attentively considered; if they persist with the same degree of intensity, and especially if they are aggravated, there is strong ground for presuming that compression exists. Concussion, it is true, does not always disappear without return. We may see patients rouse themselves from the sleep we have described, and again fall into it, and for a long time preserve that kind of torpor or numbness of the faculties which we have spoken of. Now this state might be confounded with compression; but if we carefully examine the case, we shall soon be sensible that the second sleep is much lighter than the first, and if it be repeated a third or a fourth time, it is less and less heavy; whilst in compression an opposite course is always observed.

Still there are exceptions: the oscillations of the brain in concussion are not always limited to enfeebling it; material injuries of its substance are occasionally produced, and a peculiar form of concussion is then presented, which may be termed *cerebral contusion*. It may occur directly at the point where the blow was struck, or a diametrically opposite point. It may present a simple ecchymosis, or have proceeded so far as to reduce the brain, at the point, to a reddish pulp. When concussion is joined to one of these de-

grees of contusion, more or less violent reaction occurs, and most commonly a fatal inflammation follows. Dupuytren thought that contusion of the brain was marked by particular symptoms: by violent contraction of the limbs, by continual agitation, by unconsciousness, but without stertorous breathing; that in the slightest cases there were contracted pupil, spasmodic twitching of the lips, difficulty in expressing certain words. If the contusion exist alone, these characters may materially assist in diagnosis, but it almost always is associated with concussion, and sometimes with compression.

Simple compression is more rare than concussion with contusion, because extravasated blood supposes rupture of vessels. There is therefore in compression a certain degree of contusion. What proves that compression is not simple, are the signs of nervous excitement which so constantly coincide with paralysis. It is even probable that in many, perhaps in most cases, the symptoms which we consider as effects of compression are owing to a certain degree of inflammation of the brain, or its meninges. This is especially the case when the extravasation has existed for some days. Even supposing the extravasation to be of blood, it almost always acts like a foreign body, and irritates the brain; at a later period this blood is more or less decomposed, and then is not only a mechanical but a deleterious irritant.

Prognosis.—The prognosis of compression, depends upon its degree, its causes, its complications, and the constitution of the patient. As to compression consequent upon depressed bone, it is, altogether, the most manageable; that occurring in young persons, and consequent upon extravasation, when inconsiderable, is occasionally absorbed; extravasation of blood at the base, or in the substance of the brain, is usually mortal. When to the phenomena of compression are added inflammation or its products, the prognosis is very serious.

The *treatment* of compression consists in removing the cause, if possible, and preventing inflammation. When the cause is a depressed bone, it must be raised, and, if necessary, removed; this can occasionally be done with an elevator; sometimes a Hey's saw may be necessary; sometimes an elevator and a trepan are required. If the cause of compression be within the cranium, it may be blood or pus. Extravasated blood may disappear either by absorption or the trepan, but it is probable that pus never does. We may take means to favour absorption when the symptoms are not pressing, when they do not increase, and when it is impossible to diagnosticate with any certainty the seat of the extravasation. The means which

should be employed for the purpose are repeated blood-letting, counter-irritants, evacuates, such as we recommended in speaking of concussion, and cold. It is the only course applicable to such cases, and to those in which we have reason to conclude that the extravasation is into the substance of the brain. The trepan is only indicated when the extravasation exists between the dura mater and the skull; but are these cases of frequent occurrence? I apprehend not. And certainly in many cases the blood shed, in these injuries, might, and in some cases it does, escape through the fracture. When the symptoms of compression are urgent, and when there is upon any point of the cranium a wound or a contusion, pain or tumefaction, we may make an incision; if we find the pericranium detached, or only slightly adherent, the trepan should be immediately applied to the part. Frequently the patient feels pains, which set out from the point where the extravasation is found. As I have already stated, experience has not invariably demonstrated that the extravasation is on the opposite side to the paralysis, though, as a general rule, it applies; neither has it demonstrated that paralysis of a certain part is a certain sign that extravasation exists at one part of the brain rather than another. When a crown of the trepan has been applied without having met with an extravasation, the symptoms being pressing, we should apply a second where another contusion exists, and in the absence of that we must be guided by any other circumstance which can serve as a probable guide. If the extravasation is seated immediately under the cranium, the fluid may escape as soon as the perforation by the trepan is accomplished; but you must not mistake for the fluid of an extravasation the blood which flows from the diploë. When the dura mater is tense, of a violet colour, and presents evident fluctuation, a crucial incision should be carefully made. If the extravasated fluid be seated below the pia mater, it is equally necessary to give it an opportunity of escape. If we do not meet with it we must content ourselves with the general means, which we have already indicated. What I have said of the complications of compression is directed against the improper use of the trepan; now if the cerebral symptoms are owing to any other cause, for instance to inflammation, the trepan cannot, I apprehend, remove it, and must therefore be injurious. I know that there are surgeons who regard the trepan as an antiphlogistic—an anti-apoplectic—that is to say, who have proposed it in encephalitis, as we employ incision in certain tissues, to relieve the strangulating effects of certain

varieties of inflammation, with a view of allowing the brain to expand; and in apoplexy to seek for the clot and extract it; but I do not think that a well-regulated surgeon would think it necessary to occupy himself long with this idea, still less to carry it into practice.

CASE OF EMPYEMA WITH PNEUMOTHORAX.

To the Editor of the Medical Gazette.

SIR,

If you consider the following notes sufficiently interesting, be pleased to give them a place in your valuable GAZETTE, and favour

Your most obedient servant,
J. B. THOMSON.

Tillicoultry, August 3, 1840.

A. C., ætat. 18, came under my care in the month of June, 1838, when he was suffering from a smart attack of pleuritis. He was of a florid complexion, and strumous diathesis. The pleuritic attack was soon subdued, and in order to recruit his health he went to reside with a friend on the sea-coast, where he had another and more violent inflammatory attack, which was followed by serious results. It was the month of October when I saw him again, and he presented the following symptoms:—Considerable emaciation; hard cough, with white viscid expectoration, tinged with blood; some dyspnœa; right side of the chest enlarged; dulness on percussion in the lower part of that side; when patient shakes himself there is a distinct sound of fluctuation on right side, similar to that produced by shaking a half-filled bottle of water: he can only lie on the right side. It was now evident that there was empyema and pneumothorax in the right side; the sound of fluctuation was distinct, and from the dulness on percussion in the lower part of that side, the clear sound above, and the absence of respiratory murmur in both, there could be no doubt that there was a communication between the cells of the lungs and the sac of the pleura on that side.

The treatment adopted for this case was in a great measure palliative. Local bleeding, and repeated blistering of the right side, digitalis, light bitters,

with sulph. acid., light and nourishing diet, and rigid cautions against exertion, cold, excess, or irregularity, were particularly attended to. These means were enforced with occasional variation, *pro re nata*, during some months, but without any benefit; on the contrary, the constitution rather gave way.

In the beginning of January, 1839, I resolved to give a trial to the hydriodate of potass, and as this was the only medicine followed with any good effects, the result merits attention. It was administered in the form of solution, to the amount of three grains three times a day. Within a month from the date of commencement, I was surprised to find a singular change had taken place since my last visit, which was two or three days ago.

Jan. 31st, 1839.—The pneumothorax was gone; the air, which was certainly contained in the right side of the chest, had disappeared. Patient can lie upon either side, which he has not been able to do for the last four months and upwards; the sound of fluctuation, when shaken, is not heard; the general health is decidedly improving, and the pulse more firm. These more favourable symptoms continued for nearly nine months.

June 1839.—At this time there occurred at intervals copious and bloody expectoration, which was relieved by acet. plumbi and tart. ant. with morphia in small doses; but which at intervals occurred occasionally during the whole history of the case.

January 1840.—A return of the pneumothorax discovered in the beginning of this month, attended with aggravation of all the symptoms. Pulse 120, feeble; emaciation increasing rapidly; occasional copious expectoration of tough mucus tinged with blood; inability to lie on the affected side; some hectic; no sweatings.

These symptoms slowly but seriously increased in severity, with occasional intermissions, and my patient gradually sank, and died on the 6th of May. It is matter of regret that no post-mortem inspection could be procured.

REMARKS.—The foregoing seems to be an example of a collection of matter in the thoracic cavity spreading from without, which is the more rare history of the disease. Empyema is generally an effect of ulceration of the lungs in the course of phthisis spreading outwardly; but in this case we have re-

peated attacks of pleuritis followed by ulceration of the pleura, extending inwardly to the lungs. There was little or no appearance of phthisis, and the dry and unperspirable state of the skin, so different from phthisis, was very remarkable during the whole history of the case I have just narrated. Indeed, I believe the absence of night sweats, except in the latest stage of empyema, is one of the most marked symptoms of the disease.

The only part of the treatment to which I request particular attention is the administration of the hydriodas potassæ. Was the disappearance of the pneumothorax at this stage of the complaint the result of this medicine? Whether it was *post hoc* or *propter hoc* I leave for further experience to determine. During the progress of the case the patient was repeatedly seen by Dr. Alison, and received his valuable advice. With reference to an operation, this accomplished and experienced physician says, "From all that I have seen of such cases, I cannot recommend paracentesis of the thorax. I have seen the same thing repeatedly terminate quite favourably, sometimes by absorption of the fluid; sometimes by its making its way through the lungs; in a few cases, by making its way outwardly; and from all that I have seen I think the prospect is better without than with the operation of paracentesis, at least at his age."

PUERPERAL CONVULSIONS.

To the Editor of the Medical Gazette.

SIR,

As the following case of puerperal convulsions, which occurred to me whilst assisting in the practice of Mr. Wood, may prove interesting to some of your numerous readers, I have taken the liberty of forwarding it for insertion in your valuable journal.—I remain,

Your obedient servant,

HENRY CHAMBERS.

Ledbury Dispensary,
Aug. 7, 1840.

October the 6th, 1839, I was summoned about six o'clock p. m. to attend Sarah Thomas, æt. 21, residing at Little Marele, then in labour with her first child. She was a stout, florid, robust

woman, of strong muscular fibre, thick-set form, and short neck; such an one, indeed, as might be considered predisposed for apoplexy. Upon my arrival I found that she had had one or two convulsive attacks, and was then labouring under another. Her countenance had assumed a most hideous appearance, the face being turgid, livid, and swollen; breathing hurried and irregular; pulse remaining at no settled standard, varying much, alternately full and slow. Her head was thrown considerably back; the superior and inferior extremities were at times firmly set, at intervals relaxed, being tossed about in almost every direction. As soon as the paroxysm had in a great measure subsided, I readily availed myself of that powerful auxiliary, the lancet; and with "*neque timide, neque temere*" in mind, drew from a large orifice in the arm from xxxx. to xxxv. of blood, with a decidedly beneficial effect, as she received considerable relief, only complaining of slight pain and some fulness in the head. Upon making an examination per vaginam, I found that the membranes were ruptured, and os tincæ dilated to about the size of half a crown, yet still so rigid as to preclude the possibility of either the forceps being applied or the hand introduced, to finish the case by turning. The head was presenting in the first position, the face being in the hollow of the sacrum, the occiput opposed to the pubis. She remained perfectly tranquil and free from any other attack for about four or five hours; the labour proceeding favourably, at the same time very slowly, the uterine contractions being weak and ineffectual. Between twelve and one o'clock she had a slight convulsive attack, which lasted but for a short time; another quickly succeeded, followed by others still more lengthy and alarming. A second time I had recourse to the lancet, and abstracted about xxx. or more of blood, but, in this instance, without any apparent good effect. Her hair was entirely cut off, and cold water applied to the head. Affairs beginning to assume a more serious aspect, and finding that the only possibility of saving her life depended upon immediate delivery by aid of instruments, I sent for Mr. Wood, who speedily arrived, bringing them with him. That latter gentleman promptly decided upon using the forceps, but the attempt was rendered difficult, and

in no small degree hazardous, from the violent struggles of the patient, who, during the whole time of their application, was in convulsions, the continued effort of four assistants being unable effectually to hold her. This difficulty was still more augmented by the fact of the head being placed very high up within the pelvic cavity: the os tincæ, though dilated, was still sufficiently so to admit of the use of the forceps, but "*nec posse vehement malo, nisi aque vehemens auxilium succurrere.*" The forceps, after being applied and firmly locked, in two instances, upon moderate traction being employed entirely slipped from their hold, without in the least advancing the head, a circumstance which, in no one instance, I ever saw before occur, (nor, indeed, had Mr. W.,) and one for which I am unable to account, unless there might be some narrowing in the pelvis, which I think was probably the case. From this occurrence they were rendered ineffectual, and we were compelled to have recourse to the only alternative that presented itself, viz., craniotomy. This operation was rendered less painful to contemplate, feeling assured, from the length and nature of the attack, that the child was dead. Indeed, had such not been the case, that well-known axiom in obstetric practice fully warranted the operation, as in a very short time the woman, had she not been delivered, must have sunk. Less difficulty was experienced in using these latter instruments than the former; the perforator readily entered the head, and the greater part of the parietal bones were soon extracted: this done, some little difficulty was experienced in the passing of the shoulders, (probably from, as I before hinted, a narrowing of the pelvis); ultimately delivery was accomplished about four o'clock, A. M. on the Monday. By gentle pressure over the uterus, that organ was incited to expel the placenta, less hæmorrhage occurring than might have been expected. As soon as delivery was accomplished the convulsions ceased, the woman remaining in a state of insensibility, from which she did not recover for ten or twelve hours, and when reason had resumed her empire was quite oblivious as to the past, scarcely crediting that she had so easily become a mother. It were foreign in this instance to particularize her subsequent treatment, or the nature of our visits, as nothing further of interest oc-

curred: no unpleasant symptoms followed, gradually she became convalescent, and now happily is restored to her sound health.

OPERATION FOR SOLUTION OF CATARACT.

To the Editor of the Medical Gazette.

SIR,

THE perusal of Mr. Middlemore's paper in your last number but one, "On the Treatment of certain Injuries of the Eye occurring in Infants and Young Persons," in conjunction with a case lately treated by me, which perfectly confirms the opinion of this gentleman, induces me to offer a few remarks as regards the operation for solution of cataract, as performed by Professor Jüngken of Berlin, and by myself.

Mr. Middlemore observes, "that in performing either the anterior or posterior operation of solution, we are very properly directed to destroy the anterior capsule to an extent at least equal to the size of the natural pupil; but that this important direction is by no means sufficiently attended to." In confirmation of this statement, I will first relate the case above alluded to.

A few weeks since Dr. Swaine placed under my care a young gentleman, aged 17, who had been the subject of congenital cataract, for which he had been three times operated upon within the first six years of his life. The right eye had collapsed after the second operation, in consequence of a severe iritis. In the left eye, when first examined by me, the whole of the anterior wall of the capsule was entire, presenting merely a perpendicular division, about one-sixth of an inch in length, situated so far from the centre of the pupil towards the inner angle of the eye, that only when the pupil was dilated by a strong light, this opening was seen just behind, and corresponded with the nasal margin of the pupil. The capsule itself was thickened in texture, very tough, inferiorly adherent to the uvea, and the whole resembling mother-of-pearl in appearance. This state of the capsule necessarily impaired vision to such an extent, that he could distinguish but little more than light from darkness. Under these circumstances the operation of extraction was indicated, and accordingly performed

by me in the presence of Dr. Swaine. After the separation of the capsule from the uvea, and its extraction, a large portion of the lens, probably the nucleus, presented itself in the pupil, the removal of which was readily effected, and left the pupil now perfectly clear and black. Had the first operation in this case been effectually performed, the three subsequent operations would at once have been prevented, and therefore "the necessity," as Mr. Middlemore states, "of making a free laceration and extensive comminution of the anterior hemisphere of the capsule at a first operation," is so evident, as to become a rule never to be deviated from.

The best method of following this indication, and attaining the end desired, is, in my opinion, a modification in the operation for solution, which I have seen adopted with great success by Professor Jüngken, and which I have not met with in any of the numerous writings on ophthalmic surgery in the English language, and therefore think worthy of submitting to the profession. After passing the needle either through the cornea or sclerotica, Professor Jüngken divides the anterior wall of the capsule in its whole diameter, in four different directions, through its centre. By these means eight flaps are formed, which soon retract behind the iris, and thus leave the pupil perfectly clear. The lens is now divided in different directions, more or less according to its consistence. A few smaller pieces of the lens are brought into the anterior chamber, and the nucleus, or one or two larger pieces, are pressed backwards into the vitreous body through the centre of the posterior hemisphere of the capsule, which is partly destroyed. The needle is now withdrawn from the eye. This method insures the entire removal of lens and capsule from the pupil, and as the smaller pieces of the lens in the chambers of the eye are soon absorbed, a cure is more readily accomplished.

I have again modified this operation, and perhaps improved upon it; for as in pressing the nucleus of the lens into the vitreous body through the centre of the posterior capsule this latter is not entirely destroyed, and the ramifications of the arteria centralis in the posterior capsule are greatly injured, which lesion might have for its consequence an opacity in the centre of the capsule, I prefer pressing the nucleus not through the

centre of the capsule, but through a point somewhat nearer to its periphery. On this principle I have already operated, and in lacerating the capsule out of the axis of vision, and in offering less injury to the small branches of the artery, all possibility is removed of an opacity following, which might interfere with sight.—I remain, sir,

Your obedient servant,

AUG. FRANZ, M.D.

19, Golden Square, August 3, 1840.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

As there appears little probability of Mr. Warburton being able to bring forward his proposed measure for medical reform during the present session, the House having been counted out on the 28th ult., and as there is at present no specific plan before the public, will you allow me, through the medium of the *MEDICAL GAZETTE*, to state my ideas on this so-often reiterated subject, in order that, during the parliamentary recess, the members of the profession may not only compare my scheme with their own ideas, but be induced to explain to the several members of parliament with whom they may be acquainted the absolute necessity for the interference of the legislature—a fact of which I believe very few of them have any idea. It must be confessed that the subject is surrounded with difficulties; but let it be remembered that there are few difficulties but what may be surmounted by a steady and well-directed perseverance; and I feel confident that if the members of the medical profession would fully and fairly explain what they mean by reform, and, laying aside all petty jealousies, submit to the legislature a clear well-defined scheme, their wishes would not only meet a ready attention, but be cheerfully granted. But, in order to accomplish this, the two great governing bodies, or rather what ought to be the two great governing bodies, the two Royal Colleges of Physicians and Surgeons, must cordially go hand in hand.

It is of little use to ask parliament for medical reform without clearly specifying what are our grievances, and what regulations we wish to be enforced by law in order that those griev-

ances may be removed. The utmost that we can expect without such statement is the appointment of a committee to inquire into the condition of the medical profession. This committee was appointed some six or seven years ago, and what have they done? Accumulated, no doubt, at a vast expense of money, time, and labour, an immense mass of evidence—an almost incredible number of valuable but conflicting facts, which tend rather to embarrass than elucidate the question; and for the present there it rests.

Now, sir, in my opinion, the first questions to be asked are—what are the demands—what are the real and absolute wants of the public, in respect of medical attendants? and how are these wants supplied? The questions are easily answered; the public demand, and they ought doubtless to be supplied, with a sufficient number of duly qualified and legally authorized men, to treat the various diseases to which the human frame is liable. And are not the public so supplied? Most assuredly they are.

The next question is, are these qualified men effectually and legally protected from pretenders—unlawful intruders and interlopers of various descriptions? Most assuredly they are not. This, then, is the medical reform that is wanted—legal protection for the legally-authorized practitioner. At present he has none. Suppose, for instance, he is a physician who has regularly graduated at Oxford or Cambridge, and subsequently been admitted a member of the Royal College of Physicians in London, he fixes his residence in some large town, Bristol or Liverpool, perhaps; yet, after all his expensive education and preparation for practice, with all his University honours and degrees, of which he may justly be proud, he has no protection against an illiterate impostor, who, without any degree, license, or authority whatever, foists himself upon the public as a doctor of physic, and absolutely commences practice in his immediate neighbourhood. And why is this? Because, forsooth, the jurisdiction of the Royal College of Physicians extends but to London and its environs; and any one who thinks fit to assume the title may call himself an M.D., and practise as such in any other part of her Majesty's dominions, not only with impunity, but without any let or hindrance whatever.

With surgeons it is, if possible, worse. A young man, at a very great expense, attends the prescribed number of years to the various lectures, hospital practice, &c. &c., and in due season, being considered competent, presents himself at the College, and having passed the ordeal of a strict examination in anatomy, surgery, physiology, &c., obtains the College diploma; this is certainly a license to practise, but it is no protection, no, not even in London, against any adventurer who may think proper to call himself a surgeon, and practise as such — aye, even if such adventurer should fix his dwelling at the very next house to the President of the Royal College of Surgeons, and write his name as surgeon on the door, the President of the College has no redress whatever. But how is all this to be remedied? By proper laws, properly enforced.

In the first place, I would propose that the duty of examining candidates, and the privilege of conferring degrees, should be vested in a Committee or Board, formed by an equal number of fellows of the Royal College of Physicians, and members of the Council of the Royal College of Surgeons, as at present existing, and that no person should be allowed to practise in any part of her Majesty's dominions unless authorized by this Committee or Board.

Second.—Every person so authorized should be allowed to practise both branches of the profession (that is, medicine and surgery) indiscriminately, and be entitled to demand a sufficient fee or remuneration for his advice and assistance, but he should not be allowed to prepare or dispense any medicine, or to sell any drugs or chemicals, or to enter into partnership with any chemist, druggist, or apothecary.

Third.—No medicine should be prepared by any person but the apothecary, who should not be permitted to visit the sick or prescribe for them, or perform any surgical operation, or sell any drug or chemical preparation, or prepare any medicine but what was prescribed by the physician or surgeon; and such apothecary should be obliged to keep every article and compound specified in the Pharmacopœia of the London College, and he should retain the original prescriptions of the physicians and surgeons, in order that they may be afterwards produced if necessary; and these

prescriptions should each of them contain the name or title of the patient for whom they were written, the name or initials of the physician or surgeon prescribing, and the date of the month and year in which they were written; and the apothecary should be bound to prepare the medicines exactly as prescribed, without any alteration; and he should be allowed to make a sufficient charge for the medicines he so prepares.

Fourth.—No chemist or druggist, or any other person except the physician or surgeon, should be allowed to prescribe for the sick, or perform any surgical operation; neither should any chemist or druggist dispense any medicine, or sell any patent or quack medicines; but all chemists and druggists should confine themselves to their proper business of preparing chemicals and selling drugs.

Fifth.—No candidate should be admitted for examination as a medical or surgical practitioner, who has not attended the usual lectures and hospital practice, according to the regulations at present in force; and in order that all candidates may possess a competent knowledge of pharmacy, the apothecaries should be allowed to take pupils for the purpose of giving them proper instructions in their art.

Sixth.—The two Colleges of Physicians and Surgeons should be equally empowered to prosecute for the purpose of fining, or otherwise punishing, any person or persons practising or acting in defiance of, or contrary to, these regulations.

If these, or somewhat similar regulations, were enforced, I am persuaded that the medical profession would very speedily attain that respectability it ought to possess; but in order to render them efficient the alteration should be made immediately and simultaneously by all persons at present in practice.

Perhaps, sir, my second proposition may be considered objectionable, as blending the physician with the surgeon, to which I must reply by asking if they are not already blended in the practice of the most eminent surgeons in the world; and can any man tell me where the one ends and the other begins? Physic and surgery are so closely allied that they cannot be separated; they are like twin sisters, and should go hand in hand; few, if any diseases, however local in appearance,

but have some constitutional origin; even in accidents which have been considered purely surgical cases, constitutional derangement so constantly occurs that medical treatment not only becomes proper, but is absolutely necessary; and *vice versa*, cases deemed purely medical so frequently require surgical assistance, that the practitioner who confines himself to medical treatment alone will perpetually find himself at fault and obliged to send for surgical assistance. Imagine, for instance, a person attacked with apoplexy: a physician may prescribe, and very judiciously, but a surgeon must be summoned to bleed the patient, or the prescription will be of little avail. Again, are the various forms of syphilis medical or surgical cases? Does erysipelas belong to the physician or the surgeon? Scarcely a disease can be named that does not require the assistance of both. How much better, then, would it be, that the physician and surgeon should be combined in the same person? The various parts, the individual organs of the human body, although differing widely in structure, are all intimately connected with, and subservient to each other, and all concur in one common object, the subsistence of the individual.

No man can successfully practise either medicine or surgery who is not well versed in anatomy and physiology. Why, then, attempt to separate medicine from surgery, as though you could make them distinct sciences? Let a man take the degree of Doctor in Medicine, if he think fit so to do, but let him not be debarred from relieving his patient by a surgical operation, because he possesses this degree, which entitles him to the appellation of Doctor—a very vague and indecisive title after all. But do not mistake me; I do not affect to despise or undervalue titles and honorary distinctions. On the contrary, I consider them so essential, that I would rather increase than diminish their numbers; but I must repeat, this title Doctor, although not absolutely improper, is very indefinite, and, therefore, objectionable: for instance, I hear a man spoken of, or accosted, as Doctor such a one; but whether he be a doctor of divinity, a doctor of laws, a doctor of physic, or a doctor of music, I have no means of ascertaining, without asking the direct question, even if he be present;

for neither his dress, age, nor demeanour, contain any thing whereby he may be distinguished from other individuals. No; not even the highly accomplished scholar, who, after years of intense study and application, at length receives his degree of Doctor at either of our own “time-honoured” and still justly-celebrated Universities, can, by this title, Doctor, be distinguished from the impudent advertising quack, whose placards meet our eyes in every street, who boasts the boundless virtues of his trash, and chalks his name upon our cities’ walls. What a pity it is that the author of “The Doctor,” &c., has not noticed the subject; his powerful pen would, indeed, have done it justice. I have but given a sketch. He would have drawn a picture.

Let us now, sir, proceed to inquire what would be the effects of this great change in the medical profession, who would be benefited, and who would be aggrieved? And, first, as regards the public, surely they would have no cause to complain; they would still have their usual medical attendants; and the only difference they would perceive would be in the mode of remunerating him for his services. According to the present system, the general practitioner, as he is termed, is under the necessity of charging such a price for the medicines he sends, as will, in some degree, although very inadequately, recompense him for the exercise of his skill; but, according to the plan I am proposing, he would be paid for his attendance and advice, and the apothecary for the medicines supplied. This would at once put an end to cramming the patient with, to him, needless drugs, put up in the most expensive form, in order that the surgeon may be satisfied for his attendance and the exercise of his talent—*avile scheme*, which every liberal minded person, whether surgeon or patient, will, I should imagine, be thankful to get rid of.

Secondly.—With respect to the physician, how will he stand affected? He will, as heretofore, prescribe for his patient, and take his fee; nor can he justly consider his province encroached upon; on the contrary, it takes nothing from him, but permits him to act in the capacity of an operator whenever he may think proper; and, in addition to this, it gives him a legal power to recover

his fees, which at present he does not possess.

Thirdly.—The surgeon need not complain, since, as regards his practice, he remains exactly where he was, with the additional power of preventing any person from practising surgery who has not undergone a proper examination, and can prove himself legally authorized to practise.

Fourthly.—The apothecary would be exactly what the old apothecary used to be; the person to whom the physician and surgeon might look with confidence for the preparation of their various prescriptions: he would be, in short, precisely what he describes himself by his motto, "*Opiferque per orbem dicor.*"

Fifthly.—What is now called the general practitioner would be raised to that position he ought to occupy. Indeed, to give him this station, and to protect him from the invasions of the druggists, or other unqualified persons, is the principal intent of the scheme I have proposed. As to an equality in the profession, no man of common sense would harbour the idea for an instant. You may give men equal opportunities of attaining knowledge, but cannot give them equal capacities; as well might you attempt to reduce them all to one standard height, or one tint of complexion. We shall still have our Halfords, our Lathams, our Havilands, and our Babingtons, among physicians; and our Coopers, our Lawrences, and our Brodies, among surgeons, whatever laws are made, and whatever schemes are proposed.

Sixthly.—The chemist and druggist I have no doubt would growl at losing what he calls his "counter practice;" but as he has obtained this surreptitiously, I can only recommend him to attend to the old adage, "*Ne sutor ultra crepidam.*"

There is still one portion of the subject on which I have made no comment—I mean the attendance on the sick poor: hitherto I have purposely omitted them, not that I consider them of no consequence—far otherwise—I consider it a matter of such paramount importance, that if my present essay should happily find favour in your sight, I may at a future opportunity claim your indulgence for a paper expressly devoted to the subject of medical attendance on the poor. According to the scheme I have just pro-

posed, the several Boards of Guardians would be under the necessity of forming one contract with the physician or surgeon for his attendance, and another with the apothecary for the medicines supplied. Even this I conceive would be greatly better than the present mode, as it would tend to convince the Poor Law Commissioners and the several Boards of Guardians, that medical and surgical attendance and medicines absolutely possess some intrinsic value—a fact which at present they are either very unwilling or utterly unable to comprehend.

I will now, sir, conclude what I fear you will call a tedious detail upon a threadbare subject, by subscribing myself

Your very obedient servant,
G. HARVEY.

Castle Hedingham, Essex,
August 9, 1840.

OBSERVATIONS
ON THE
OPERATION FOR STRABISMUS
CONVERGENS.

To the Editor of the Medical Gazette.

SIR,

HAVING had frequent opportunities at the London Ophthalmic Hospital, Moorfields, in private practice, and amongst my professional friends, of observing the comparative advantages of the different modes employed for the division of the internal rectus muscle in cases of strabismus convergens, I beg to state that I have, in several cases, derived great advantage from the use of a blunt hook, designed by Mr. James Adams, of Broad-street, and which this gentleman proposes offering to your notice. This instrument enables the operator to secure the muscle at its narrow part, and in a very confined space. We thus avoid the necessity of making a large incision in the conjunctiva, the healing of which wound has been slow and unsatisfactory in most of the cases which I have seen operated on by other means. It has always been found desirable to draw the eye outwards during the operation, and *hooks of various forms* have been used for holding the sclerotic, but almost all

the patients wh m I have seen have complained that much pain was caused by the pressure of the hook, whilst it was fixed in the sclerotic near the inner margin of the cornea, and passed over the globe, from within outwards, for the purpose of bringing into view the tendon of the internal rectus. It has been suggested that we may fix the globe without the assistance of any hook; glad indeed shall I be if we can hereafter effect this, and thereby save our patients some suffering. I have recently fixed the eye by means of a *delicate hook*, which has been made by Mr. Weiss, for my friend Mr. James Adams, and it appears to answer its design very satisfactorily, inasmuch as the *acute angle* which it forms allows the surgeon (as intended by Mr. Adams) to draw the eye outwards *without seriously wounding the sclerotic, or exercising any pressure on the globe*. I have used in different operations, and seen others use, the curved scissors, with the outer blade blunted at its extremity, or a narrow blunt-pointed knife, for dividing the muscle after it has been raised by means of the large blunt-hook. The knife appears to me the preferable instrument; but as, is the case with every new operation, we shall, no doubt, have numerous propositions offered to the profession, each in its turn, advanced as the best mode of performing this operation, and experience alone can determine which plan may possess the greatest merit. I have seen cases at our ophthalmic hospital, as well as in private practice, wherein the eye continued to turn *slightly inwards* for a short time after the operation, although the internal rectus had been completely divided; but in a day or two this obliquity has been lost. In some of the cases which I had under my notice the *external* rectus has for a short time after the operation drawn the eye *outwards*; but this obliquity has likewise disappeared. I have not seen any instances in which it has been necessary to divide other muscles than the internal rectus for strabismus convergens, although I have heard of such cases. I consider, sir, that the profession and the public owe much to our continental brethren who originated this operation, and to those gentlemen who, by their talent and ingenuity, have simplified it. The operation can now be performed in less than one minute, and in some cases

with but little pain: it becomes our duty to watch carefully its effects, and to act accordingly. Apologizing for the length of this communication,

I am, sir,

Your obedient servant,

GILBERT MACKMURDO, F.R.S.

Lecturer on Anatomy and Physiology at St. Thomas's Hospital, &c., &c.

7, New Broad St., August 1, 1840.

MEDICAL GAZETTE.

Friday, August 14, 1840.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

HEALTH OF THE NAVY.

SHOULD medicine ever advance from the rank of an art to that of a science, it is clear that statistics must have a chief share in the happy change. If we wish to know, for example, whether fever is best treated by purgatives, or calomel, or the cold affusion, or the *méthode expectante*, we cannot arrive at a just conclusion from the picked cases published by the partisans of each system, and the ingenious explanations appended to them; we must examine the records of hospitals, where fever has been treated on the large scale, and form our judgment accordingly.

Those physicians and surgeons, therefore, who preside over such establishments, will do well to recollect that it is from them that improvements in medicine may most reasonably be expected; while those who can combine these results, and demonstrate what ought to be done from what has been done, may hope to rank among the great benefactors of mankind.

Some of the first-fruits of this conviction may be expected from the practitioners of the army and navy, as they are amenable to military discipline, and not liable, like civil practi-

tioners, to be drawn aside from their daily task by caprice, or prevented from fulfilling it by other avocations. Several valuable contributions to the annals of medicine have, therefore, proceeded, of late years, from the medical officers of the army; but the master mind is still wanting, to read the future in the past, and discover Truth in the deep recesses where she lies concealed!

Meantime, each step towards this important end must be commended; and we hail with pleasure the appearance of a parliamentary return on the health of the navy, drawn up by Dr. John Wilson, R.N.*

He states simply and forcibly some of the difficulties which stand in the way of drawing up such documents regarding the naval service.

Sometimes the returns for particular ships have been wanting for one or more periods, from the change of medical officers or other causes. Sometimes invalids, on their passage home from foreign stations, are transferred from one ship to another, and may be reckoned in the returns of both vessels.

Again, ships, in peace-time, are rarely more than three or four years in commission; they then return to England, the crews are paid off, and it is uncertain where the men re-enter the service; and it is, consequently, difficult to trace the slower operations of climate in bringing on disease. In a similar manner, the frequent removal of a ship from one station to another, as from the Cape of Good Hope to the East Indies; or, which comes to the same thing, the great extent of some stations, as the West Indies and North American one, which stretches from the equator to the 60th degree of north latitude, makes it diffi-

cult to ascertain the effect of either climate, singly, on the health of the crews. However, it is obvious that, if we do not learn the effects of a long stay at the Cape on sailors, we solve the more complex problem—what is the result of three months' cruising off the Cape, *plus* a voyage to Calcutta, and half a year's cruising in the Indian seas?

The influence of age on health is striking, says Dr. Wilson, and it would be desirable to know its amount in sea-life; but it seems that it is not easy to find out the age of seamen. Unlike the members of civil society, who often remain at some pleasant fashionable age for twenty years together, your sailor grows old suddenly. Dr. Wilson assures us, that a sailor, eighteen months after being thirty-nine, may become sixty years of age. These sudden transformations (a ship of war being, as it were, the converse of Medea's cauldron) are sad baulks to tables of ages, and calculations deduced therefrom. The ages given, moreover, are often erroneous; not only from design, but from ignorance or carelessness. It would be interesting to know what influence the various diets on board a ship of war have on the health of those who enjoy them. These are of four kinds. "First, there is the admiral's, or captain's, table; second, the ward-room mess for naval lieutenants, marine officers, master, pursers, surgeons, chaplains, and schoolmaster; third, the mess of the mates, midshipmen, assistant surgeons, and clerks; fourth, that of warrant officers; and, last, of seamen and marines."

The first and second table do not much differ; but they both differ from the other two sufficiently to influence health. In the returns of sick and hurt, however, the patients are not classed.

The victualling of the navy is now on

* Statistical Reports on the Health of the Navy for the years 1830, 1831, 1832, 1833, 1834, 1835, and 1836. South American, West Indian, and North American, Mediterranean and Peninsular Commands. Ordered by the House of Commons to be printed, March 24, 1840. Folio, pp. 323.

a pretty liberal scale, having been materially improved in 1825; it was then, we believe, that banian-days, or days of vegetable diet, were abolished. Every person serving on board her Majesty's ships has a pound of bread, a gallon of beer, an ounce of cocoa, an ounce and a half of sugar, and a quarter of an ounce of tea, daily; besides a pound of fresh meat, and half a pound of vegetables, or else three-quarters of a pound of salt beef, and the same weight of flour, alternating with the same quantities of salt pork and peas. There is also a weekly allowance for oatmeal and vinegar; and suet, currants, and raisins, may be substituted for a portion of the flour. There is a table of equivalents, which seems just and sensible enough, but is too long to quote; specifying, for instance, that a pound of butter is to be considered equal to a pound of sugar, &c. &c. The ration of beer, it seems, has been altogether discontinued since the year 1831; a quarter of a pint of spirits is given daily instead; or, a pint of wine, which however, is issued only on the Cape station. We should have thought it might have been issued to the Mediterranean force likewise, instead of liver-burning spirits. To estimate the effect of the daily dose of rum on the sailors' health, it would be requisite to know what measures are used on board: if acts of parliament are observed, and the Imperial measure is used, each man's daily modicum is $\frac{3}{4}$ v.; if the measure of wine-merchants and publicans is adopted, it is about half that quantity. After using salt provisions for a fortnight, there is a daily allowance of lemon-juice and sugar. Till 1796, scurvy continued to infest the fleet; in 1797 the victualling was changed and greatly improved, and since that period still farther ameliorations have taken place; and scurvy, fever, dysentery, and ulcer, have declined, as the bodily and mental vigour

of seamen has increased. * Previously to 1797 the rations of seamen and marines were at least a third less than they are now. They are not in excess at present; what must they have been fifty years ago? Sir Gilbert Blane, when asked if he did not attribute the prevalence of scurvy to the deficiency of diet, answered, that some said it was the salt food, but he believed it was the want of food.

Water, at once essential to life and health, was formerly kept on board ships of war in casks. "It became slightly fetid, from the disengagement of hydrogen, in a few days, and in a fortnight or three weeks, so loathsome, as to be swallowed with repugnance, even when called for by urgent thirst." * * *

"Water so putrid and offensive, often so thick, and green from vegetable admixture, and decomposition, and emitting so strongly the fætor of rotten eggs, as to disgust at once the sense of smell and of taste.*"

All this is now remedied by the use of iron tanks. There is a slight admixture of oxide of iron in the water, especially in stormy weather, or when the tank is nearly empty. The greater part of the suspended oxide, however, falls to the bottom of the vessel into which it is drawn, and what remains is neither injurious nor offensive. It is to be regretted that the water which is taken on board is not always wholesome. In some foreign ports good water must be paid for; and to save a small charge, bad water is taken instead—a most pitiful piece of economy!

The table of diet for patients in the Royal Naval Hospitals and Marine Infirmary is judicious, and if the articles are the best of their kind, leaves little to be desired on that score. Thus, a patient on full diet has daily one pound of bread, one pound of beef or mutton, one pound of potatoes or greens, twenty-

* Dr. Wilson, in Statistical Reports, p. xiii. & xiv.

five drachms of herbs for broth, fourteen drachms of barley, eight drachms of salt, sixteen drachms of vinegar, four of tea, sixteen of sugar, one-third of a pint of milk, one pint of broth*, two pints of small beer, or one and a half of strong; together with wine or porter, at the surgeon's discretion, not exceeding a pint of the former, or a pint and a half of the latter. The medical officer may prescribe veal, fowl, or fish, in lieu of beef and mutton; and also, rice or flour-pudding. And while the tonic diet is regulated on this liberal scale, food is withheld from febrile patients with equal discretion. The fever diet consists of eight ounces of bread, or four of sago, four drachms of tea, twenty drachms of sugar, one-third of a pint of milk for tea, and one-fourth of a pint for diet.

The anterior administration of a ship, though conducted with care, seems to admit of improvements. The sailors are excessively crowded in their hammocks, and the washing of decks is often carried to such a pitch, that the health of the men suffers from the constant evaporation. Dr. Wilson prefers dry stoning, or, at any rate, dry cleaning; though we suppose that the scrubbing-brush and pail must come into requisition occasionally. Personal cleanliness is strictly enforced in the navy. Shirts, frocks, and duck-trowsers, are changed at least twice a week; besides bathing in fine weather, and regular ablution, shaving and combing, at other times.

Something has been done, too, to supply sailors with amusive and instructive reading. Religious works were first

sent for their use; and by an Admiralty order, dated August 1838, a library of 270 volumes is to be established on board of large ships, and of 100 volumes in small ones. A previous order had directed elementary instruction to be given to sailor boys, and other seamen, and marines, who may require it. The able compiler of these documents justly thinks that intellectual improvement advances the physical state of those who are the subject of it.

Free ventilation between the decks is still a desideratum; wind-sails are very partial in their operation, and even the apparatus lately invented by Captain Warrington is liable to strong objections. Our author suggests a remedy for its imperfections.

These reports do Dr. Wilson great credit, and we are glad to find that a continuation of them is promised.

IRISH COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

You will, I trust, permit me to address to you a few observations on the subject of your editorial article of the 24th of July. I should have asked this favour ere now, but that I have only this week seen the article for the first time.

It is not my purpose to enter into the question how far the curricula and examinations of the several Colleges are too high or too low, too severe or too lenient; but only to call your attention to the justice of the charge made, of the imputation cast, upon the Irish College of Surgeons by a gentleman high in professional character, high in public estimation, and high in his pretensions to professional precedence; by a gentleman who is an old member of the body which he accuses, who has enjoyed the highest honours which that body can confer, and has acquired an ample fortune by the exercise of the professional privileges which it bestows; by a gentleman, in fine, who might be supposed to be acquainted with the sub-

* According to the "note" at p. xv. the meat for the full and half diet is to be boiled together with barley and vegetables, which will make a sufficient quantity of good broth to allow a pint to each patient on full and half diet, and half a pint to each on low diet.

If we understand this aright, first, the patient on full diet will obtain in his broth the essence of no more meat than if he was on half diet. Secondly, no patient will ever have his beef or mutton roasted; which would certainly be a good form of giving it in many cases.

jeet on which he speaks, who has no apparent motive for misrepresentation, and who, if he cannot be grateful, ought, at least, to be just. This task I consider a duty, inasmuch as the address of Mr. Carmichael, which contains the imputation, has been now circulated, not only among the profession, but also among the public, through the medium of a newspaper. It is a duty, too, which you have, and I think with reason and candour, called upon the Irish brethren of Mr. Carmichael to undertake; and it is one of which I am obliged thus to acquit myself, because I have been debarred the opportunity of doing so in the manner which I considered the most fitting, by the friends, by the party, of Mr. Carmichael. Having seen the address in a public newspaper I intimated, at a meeting of our College, that it appeared to me incumbent upon the body to notice the aspersion cast upon it. I could not persuade myself that Mr. Carmichael had given utterance to sentiments so injurious and so unfounded, and, before making a motion upon the subject, I called his attention, by letter, to the paragraph of his address which contained the charge. I received a reply from Mr. Carmichael, in which he adopted the charge, and intimated his readiness to meet any motion I might make upon the subject. At the first opportunity I accordingly gave notice that I would bring the address of Mr. Carmichael under the consideration of the College at its next meeting. In this course I acted in accordance with the double obligation of courtesy towards Mr. Carmichael, and attention to the established order of business in the College; but it would seem that the principle by which I regulated my conduct is not recognized by the friends and party of Mr. Carmichael. By an extraordinary coincidence they were present in force, while, the matter being one of course, there were but few upon the other side; they made a motion in defiance of order, "that my notice be not received;" the president, despite of my remonstrance against so irregular a proceeding, put their motion from the chair; when I protested against such a course they attempted to silence me by clamour; an insult—one of the grossest which can be cast upon a gentleman—was offered to me; and when, in consequence of the necessity imposed upon me by the insult, I retired from the

meeting, they carried their motion in my absence, and thus, by a violation of order, of courtesy, and of duty, they stifled inquiry, and left the institution of which they were members and officers to lie under the imputation which had been thrown upon it. And these, sir, are the members of the Irish College who please to *call themselves Reformers!*—these are the men who complain of the abuses of existing institutions!—these the men who are to be acknowledged the sole judges of right and wrong!—these the constitution-makers, from whose hands we are to receive the boon of equal rights and equal laws! What think you of a constitution from which inquiry should be banished, or in which it must hang upon the pleasure of a party or of an individual? In which some favourite leader might violate its laws, libel its character, betray its trust, or commit any enormity; secure from detection and from punishment so long as he has a faction at his back to screen him from inquiry. And what other kind of constitution can be expected from men such as these? But now, sir, for the justice of Mr. Carmichael's charge. His language is, that the Irish College of Surgeons have, from a very disreputable motive, lowered their examination to the level of the other Colleges. You will not understand me to pass any judgment upon the examination of the other colleges. You have undertaken their justification, and I may safely leave it in your hands; but, for the Dublin College, not only has it not lowered, but it has "of late years" considerably extended its examination, as well in deviation as in the range of subjects which it embraces. Formerly the examination of the Dublin College was confined to anatomy, physiology, and surgery, with some pharmacy. It was one examination divided into two parts of one hour at least, on each of two days. Within late years, however, there have been added to the examination, as originally instituted, and which continues still of the same duration, two other distinct examinations; one upon chemistry, materia medica, botany, jurisprudence, and pharmacy; the other upon midwifery, and diseases of women and children. Thus, whereas a student had formerly, when, as Mr. Carmichael says, "the Irish College maintained a high character for the rigour of its examination," to undergo but one examination, and to

be examined only upon four subjects, he must at present submit to three examinations, and be examined upon twice as many subjects as previously, in order to obtain the license of our College. Such sir, is the present discipline of the Dublin College; and, whether it be superior or inferior to that of the other Colleges, manifestly it has not been lowered, but on the contrary, raised to a higher standard. If the character of the examinations given has been altered, that has been the doing of the Examiners alone, for no instructions to such effect have ever been given by the College. If the examinations have been altered for the better, *reformer* as he is, Mr. Carmichael ought surely not complain, and his party cannot feel greatly flattered if he do, for they form the majority—the great majority of the Examiners. If they have been altered for the worse, then Mr. Carmichael's party, the *reformers*, deserve the blame, for, again, they form the great majority of the Examiners. If, either from incompetence or misconduct, the Examiners have impaired the examination, is it not the duty of the *reformer*, Mr. Carmichael, to lay the matter before the College and the profession, and to move for their dismissal? In any case, the charge, if it has taken place, cannot be made a charge against the College, and in my humble judgment our examinations may have been greatly changed without having been at all impaired.

I trust, sir, that our College now stands acquitted in your estimation from the aspersions of Mr. Carmichael, and that you will agree with me that he and his party would do well to furnish better proofs of their ability and their honesty in the case of reform, than maligning an institution whose character they are bound by honour and by oath to maintain.—I have the honour to remain,

Your obedient servant,
BENJAMIN ALCOCK, M.R.C.S.I.

THOUGHTS ON MEDICINE.

SOME papers have appeared under the title of *Esquisses* in the *Gazette Médicale*; the following is a part of their contents.

Do you wish to know the most subtle, the highest, and the most complicated equation, and consequently the most difficult one to solve? It is a disease. Great fineness of perception, exquisite discernment, unbroken attention, and profound judgment, are all required. Every thing

escapes in probabilities, and a cruel *perhaps* is always present, like a two-faced demon, to neutralize our induction, and disquiet our mind. But go into the world, and you will find men born blind who are always quite sure, who cure infallibly, and shrug up their shoulders at the least doubt; and there are persons who believe and admire them; nay more, who strictly execute what they prescribe. What then are life, health, and disease, in the opinion of the laity? What idea do they form of medicine?

I love that thought of an oriental poet; “we must cling to virtue by the root, and to knowledge by the summit.”

Facts are stubborn, it is said, but how can we believe it? On the contrary, they seem very supple, malleable, complaisant, and elastic. Facts say and prove pretty nearly what we wish, for all depends on the interpretation. And yet they disclose the truth; just as a block of marble contains a Venus; but then she must be extracted from it. For two thousand years, theories have been framed in medicine with the same facts; the same will be done two thousand years hence, for absolute truth remains for ever veiled from our eyes. Relative truth alone is possible, and alone is known; with this systems and theories are built up, but their base is always fragile and moveable; they pass away, and the facts remain.

A German physician appropriated a special organ to sleep, which he defined to be “an adynamic polarity of the organ of interior intuition, produced by the polarity of the organ of sleep.” This is transcendental science. I am equally pleased with Aristotle, when he defines motion to be “the act of a being in power as far as it is in power.”

Bleeding is very efficacious in pneumonia—good; tartar emetic, in large doses, undoubtedly cures this inflammation—capital; opium has its successes to boast—no question; musk has succeeded in a number of cases—this is admirable! But inform us, with rigorous precision, when we ought to bleed, or give tartar emetic, or opium, or musk? It is just the same with all pathological affections. Shall we ever see the time when it will no longer be allowed to hesitate, or to pronounce an opinion founded on uncertain signs? When indications shall have arrived at this point, medicine will be really great and powerful. Worshippers of science, then hasten to the temple, and sacrifice a hundred cocks to Æsculapius!

Why is practitioner so furious against practitioner? why does he blame him in

every thing, about every thing, *apropos* to every thing? The reason is this; he has laboured on the same subject, and has not succeeded so well. Do you not see the caterpillar depreciating the work of the silk-worm; for the caterpillar spins too.

"The gods are going from us," is the cry on all sides. Let us not believe it; the gods are immortal. Reason, good sense, virtue, and truth, will for ever remain among men, to enlighten, guide, and console them.

The philosopher Ariston, of the island of Chios, substantially recognised but one virtue—*health*. According to him, all other virtues were mere modifications of this essential, primitive, physical, and moral quality. There is great profoundness in this idea, for health means *harmony*.

Write according to your theory of writing, say what you choose of medical style, compose a work where there are facts and nothing but facts (the fashionable style), and laugh at rhetoric and phrase-makers. Nevertheless, remember two things: first, that even in medicine style is the immortal stamp of good and beautiful ideas; and secondly, that a book which wearies is a book which has ceased to live.

Do you wish to know what it is that preserves and perpetuates error, particularly in medicine? It is the portion of truth which is mixed with it, and the authority which it derives from this portion; men are deceived by it for ages.

At the bottom of every fact there is an idea. The hieroglyphic has a meaning; the question is to give the truest interpretation—a great and difficult problem.

Young man, take care that it is not too soon; old man, take care that it is not too late.

I shall always continue to say as a person of sense did: men of elevated mind fall down before merit; ordinary men fall down before success. With the latter, success justifies every thing; with the former, success itself requires to be justified.

According to Plato, the mind is that which makes use of the body. A religious philosopher of our time, taking hold of this thought, defines man to be an intelligence served by organs. Well, but the inverse definition is equally true; man is a compound of organs served by an intelligence.

Oh! peace of the soul! thou happy concord of opinions with sentiments, actions, conduct, and social position. It is thou that allayest the fire of the passions, that soothest the nerves, renderest the blood calm and sweet, that maintainest the forces of the frame in wholesome equilibrium, that givest to the vital rhythm the regularity so favourable to our well-being; in thee are found health, happiness, the life of our life, the sovereign good—if, indeed, this exists upon our unhappy planet!

[To be continued.]

CLINICAL

LECTURES ON ERYSIPELAS,

Delivered at the Hospital of La Pitié, Paris,

By M. VELPEAU.

*Various diseases confounded with erysipelas—
Erysipelas properly so called—Angioleucitis—
Phlebitis—Phlegmonous erysipelas—Causes.*

ERYSIPELAS, although very frequently met with both in medical and in surgical wards, is one of those affections which is the least understood. If, indeed, we submit to a severe analysis the various descriptions of erysipelas which authors have given, it soon becomes evident that they have confounded under the same name various diseases; and this accounts for the discrepancy that exists between them with respect to the treatment of the malady. The ancients appear to have confounded, under the term erysipelas, even a greater number of inflammatory affections than modern writers, as is proved by the multiplicity of names under which it is designated. Thus, we find it described by them as the sacred fire, the red fever, the rose, St. Anthony's fire, &c. These terms, however, were evidently applied not only to erysipelas but also to other eruptive diseases. At a later period, and indeed in our own times, erysipelas has been confounded with erythema, with various bul- lous and dartrous affections, with angio- leucitis or inflammation of the lymphatic vessels, and with external phlebitis. As long as this confusion lasts it is impossible to form a correct opinion of the nature of the disease; it is equally impossible to decide what plan of treatment ought to be adopted, as some of these affections are easily cured, whereas with the others it is quite the reverse. J. Frank, for instance, informs us that erysipelas is extremely frequent in Lithuania, and that it readily

yields to judicious treatment. But on examining the account he gives of the disease, we recognise, instead of erysipelas, over which no plan of treatment appears to exercise much influence, a simple erythema, such as we often meet with in young persons who are arriving at the age of puberty, and in all old people, badly fed, or of a deteriorated constitution. If we really wish to understand the nature and treatment of erysipelas it must be separated from the other diseases with which it has hitherto been confounded: this we will endeavour to do.

Setting aside erythematous, bullous, and dartous affections, the diagnosis of which is too simple to require comment, I shall proceed to the examination of the anatomical and physiological characters of erysipelas itself, and of those affections which are most commonly mistaken for it, and also most frequently combined with it, viz., diffusive phlegmon, or phlegmonous erysipelas, angioleucitis and phlebitis.

ERYSIPELAS PROPERLY SO CALLED.

This, the simple or real form of erysipelas, may be recognised in many of the descriptions which authors have given of the disease. The characters which it presents are seen to the best advantage on the limbs. When it attacks the genital organs, the perinaeum, &c. these characters are much less distinct, owing to the subcutaneous cellular tissue in these regions being generally more or less infiltrated with fluid, when the skin, which is extremely thin, is inflamed. The following are the anatomical symptoms of the malady: the skin suddenly assumes a red colour, the redness presenting itself in patches slightly raised above the level of the healthy parts. The patches do not, however, acuminate, but appear as if they were applied on the skin, between the cutis vera and the epidermis. The tumefaction and the redness do not decrease gradually, as in other inflammations of the skin, but terminate abruptly. The line of demarcation between the healthy part and that which is affected is, therefore, exceedingly well marked. The colour of the inflamed skin is generally a yellowish red, but it is subject to variation according to the constitution of the individual, or the state he is in when attacked. With persons of a lymphatic temperament, who have been weakened by loss of blood, the skin is sometimes of a milky yellow. In cases of this nature, you will find that although the skin presents this white appearance it offers all the other physical characters of erysipelas: the tumefaction might not inaptly be compared to a liquid

pourred over the healthy surface. This slight but general tumefaction of the skin, accompanied by the irregular festooned margin, is not met with in any other disease. The subcutaneous cellular tissue does not appear swollen, except in some few regions, as I have already stated. If the skin is attentively examined you will often find minute vesicles, some as small as a pin's head, some larger. These vesicles frequently increase in size so as to form phlyctenæ, and when this occurs the erysipelas has been called bullous. The skin is the seat of burning heat, and becomes acutely sensible, contact with foreign bodies giving rise to more pain than in any other cutaneous inflammation.

Before the local phenomena make their appearance there are nearly always general symptoms, the intensity of which varies. These premonitory symptoms are similar to those which are observed in eruptive fevers, such as scarlatina or variola. Indeed, it is exceedingly difficult, in this stage of the disease, to say what it will eventually be; the constitution of the patient, the state in which he is at the time, and other circumstances, must guide us in forming our opinion. The patient is first seized with chills or rigors, to which succeed great heat, burning thirst, and extreme restlessness. These symptoms are often accompanied by nausea, vomiting, sometimes by violent abdominal pains. They may be present from one to seven days, and generally persist, and sometimes, indeed, become more violent when the erysipelas has appeared. In variola, &c. on the contrary, three days after manifestation of the general symptoms, the eruption breaks out, and as soon as it has taken place they disappear, or at least are sensibly mitigated. Ataxic or adynamic symptoms may be present, as in all other eruptive fevers.

When once developed the progress of erysipelas is peculiar. It may be termed a creeping or ambulatory disease, the red patches never remaining in the same spot, but gradually spreading to the adjoining parts. In some cases, however, it is called fixed, when, for instance, it attacks the head, but the entire surface of the head can never be affected at once.

The creeping nature of erysipelas must always be kept in mind, as it exercises the greatest influence over the duration of the disease. Each patch of inflammation lasts but four or five days; consequently, were the eruption to take place at once on the entire surface which is to be affected, the malady would terminate in the course of a week or ten days. As, however, the patches appear successively, and may, gradually progressing, invade the entire

surface of the body, the duration of erysipelas is very uncertain. It may thus perpetuate itself during a month or more, and when this is the case, even this, the simple form of erysipelas, becomes a very dangerous malady.

Erysipelas, as characterized by the anatomical and physiological symptoms which I have enumerated, may be early recognised and separated from other diseases. We will now briefly examine the characteristic symptoms of Angioleucitis.

ANGIOLEUCITIS.

Angioleucitis, or inflammation of the lymphatic vessels, differs in nearly every respect from erysipelas, with which it has lately been confounded by many writers. It may either be spontaneous or secondary: that is, it may appear under the influence of a peculiar state of the economy, or it may be the result of local injury.

The forms under which it presents itself are extremely diversified. When the consequences of a prick, a wound, &c., the lymphatic vessels of the wounded part are often inflamed before the ganglions to which they direct their course, and give rise to irregular, red, ribbon-like streaks. These vascular streaks follow a tortuous course, extending in the direction of the ganglions either a few inches, or the entire length of the limb, and do not offer any tumefaction either to the eye or to the touch. Thus, when the hand, arm, or fore-arm, are the seat of the lesion, the superficial lymphatics are generally inflamed primitively, and it is only subsequently that the ganglions of the axilla become tumefied and painful. In other instances, on the contrary, the ganglions appear to be first affected. When, however, this is the case, a close examination will generally shew that some vascular streaks are to be found in the vicinity of the lesion. The patches are irregular; sometimes there are several, sometimes there is only one. Their colour is a livid red, not a yellowish red, as in erysipelas. The skin is smooth and even, does not present any vesicles, and seems rather more elevated in the centre than at the circumference, so as to form a slightly acuminate surface. These patches also terminate insensibly, so that it would be difficult to point out the precise spot where the skin ceases to be inflamed. In erysipelas, on the contrary, as we have already seen, the tumefaction is universal; indeed, if one part is more elevated than another, it is rather the circumference than the centre. In erysipelas the tumefaction ceases abruptly, and appears superficial, as if it were existing between the cutis vera and the epidermis, and not underneath the skin, as in angioleucitis. In this latter disease there are

generally several patches of inflammation, which although sometimes united by inflamed streaks are often separated from one another by healthy tissues, whilst in erysipelas the inflammation may extend irregularly in various directions, but nearly always remains connected with the principal seat of inflammation.

If we now examine the physiological symptoms, we shall not find the same difference existing between the two diseases. The premonitory symptoms are nearly the same; indeed, before the eruption has appeared, it would be difficult to determine whether erysipelas or angioleucitis is about to declare itself. Thus angioleucitis is often preceded by thirst, nausea, fever; in a word, by all those symptoms which are observed in eruptive fevers. When, however, we find one or more ganglions tumefied and painful, there is reason to believe that angioleucitis and not erysipelas will ensue, unless there be erysipelatous patches already existing. It has lately been asserted by some authors, and among others by J. Frank, that tumefaction of the ganglions of the neck, accompanied by fever, is a certain symptom of impending erysipelas; but the assertion is by no means correct, as the cervical ganglions often become tumefied without erysipelas supervening; indeed, any injury done to the head will give rise to their tumefaction. The origin of this opinion may easily be accounted for. Erysipelas of the face and scalp is very frequent, and if the inflammation remains confined to the scalp, the nature of the affection is often not recognised at first. The ganglions, nevertheless, become inflamed, and when the erysipelas does become visible their tumefaction is considered to have preceded its invasion. It is, therefore, evidently difficult, in some parts of the body, to distinguish angioleucitis from erysipelas during the first period of the malady. Still, if attention be paid to the pathognomonic characters of these diseases, a correct diagnosis may be formed, even in such cases as those to which I allude. When the cervical ganglions become tumefied, and the fever is but slight, it is most likely that angioleucitis will supervene. When, on the contrary, the general symptoms run high, the tumefactions of the ganglions generally indicate erysipelas.

The more we recede from the commencement of the disease, the more we find that these affections differ. The erysipelatous patches only last, as I have already stated, four, five, or eight days, and if the disease is of longer duration, it is that, under the influence of a general morbid state of the economy, the inflammation successively attacks parts previously healthy. Erysipelas may termi-

nate by superficial suppuration, the serosity contained in the phlyctenæ becoming purulent; but never by suppuration or gangrene of the subcutaneous tissue, as in that case it is no longer simple but phlegmonous erysipelas. In angioleucitis each patch constitutes as it were a phlegmon, and may run through all the periods of phlegmonous inflammation, terminating by resolution, induration, or gangrene. Nor is the inflammation always confined to the superficial lymphatic vessels; sometimes it penetrates the deep-seated tissues, invading the lymphatics which are situated beneath the aponeurosis. The anastomoses which exist between the two layers of vessels at once explain this extension of the inflammation. The superficial lymphatics, and the cellular tissue which surrounds them, are first inflamed, and an abscess is formed: the inflammation is then propagated to the deeper-seated vessels, a new phlegmon taking place, and this may continue until the limb is penetrated in various directions by a chaplet of abscesses, if I may be allowed to use the term. Angioleucitis, when arrived at this stage, cannot be mistaken for erysipelas.

PHLEBITIS.

Phlebitis is a disease which has been confounded with erysipelas by J. L. Petit and others, although the difference between the two is even greater than that which we have found to exist between erysipelas and angioleucitis. Since, however, the spirit of analysis has become more prevalent, most practitioners have learnt to distinguish them from one another. Yet even now the inflammation of the cellular tissue which surrounds the veins, or external phlebitis, is occasionally mistaken for erysipelas. I need scarcely say that it is only with the external form of inflammation that this affection could possibly be confounded; internal phlebitis, followed, as it rapidly is, by purulent absorption, and accompanied by the usual train of symptoms, is too well defined a disease to be mistaken for a cutaneous affection. External phlebitis generally occurs in the arms or legs, after bleeding. The premonitory symptoms are but slight in most instances, merely consisting in a little pain and uneasiness of the part. The cellular tissue which surrounds the inflamed vein, as also the adjoining integuments, becomes swollen and red, and patches are thus formed along the course of the vein. These patches appear deep seated, and if they are examined with the finger it will be found that they rest on a kind of knotty cord, which is the inflamed vein. They communicate with one another, but differ, nevertheless, from the

patches we meet with in angioleucitis. These latter are, it is true, united by red streaks, but they do not present the cord I have just mentioned, and are scarcely perceptible to the finger. In external phlebitis, the ganglions are not generally painful, whereas in angioleucitis this pain in the ganglions is one of the first symptoms that appear. Erysipelas is even more easily distinguished from this affection than from angioleucitis. Indeed, it is only because the characters of erysipelas itself were not well defined, that the two diseases have been confounded. Scarcely any of the symptoms of that affection are to be traced in external phlebitis, neither the precursory symptoms nor the uniform tumefaction of the skin, nor its irregular festooned border.

In external phlebitis, as in angioleucitis, the inflammation may terminate by resolution, but the resolution is a much longer process than in the latter complaint, the veins long continuing to form knotty cords.

PHLEGMONOUS ERYSIPELAS.

We have now to consider phlegmonous erysipelas, or diffused inflammation of the subcutaneous cellular tissue, a much better term than the one usually employed. Were it adopted, the word erysipelas might then be reserved for the simple inflammatory affection of the skin which we have just described. This is one of the most serious diseases that surgical practitioners have to treat. It has only been separated from other affections within the last thirty years. It was first described at length by Duncan, and then by Dupuytren, and has, since then, been much studied, especially by hospital surgeons. It is, however, evident, from the treatment adopted by various practitioners, and from the various results which follow that treatment, that it is not always the same malady that is held in view.

The seat of this disease is the subcutaneous cellular tissue. This tissue is composed of two layers; the first, the one in immediate contact with the skin, may be called the areolar layer. It is formed by cellular lamellæ, interwoven with one another, and adherent to the internal surface of the skin; it is a mixture of fibrous, cellular, adipose, vascular, and nervous lamellæ. The second layer, that which is immediately applied to the aponeurosis, presents neither adipose nor cellular filaments, but offers a lamellated structure; it is what Chaussier called "the lamellated element." When the inflammation is situated in the first layer, it extends with difficulty, owing to the structure of the tissue, and thus tends to produce a circumscribed phlegmon. When, on the con-

trary, the internal layer is inflamed, finding but little resistance to its progress, owing to the lamellated nature of the cellular tissue, and being confined between the denser cellular layers and the aponeurosis, the inflammation may extend rapidly, and invade the entire limb in the course of a few days. More or less effusion of liquid also takes place, and, as no organic fluid can long remain out of the vessels which naturally contain it, without changing its properties, it becomes troubled, and then purulent. The vessels of the areolar layer passing through the effused fluid, also soon become mortified.

Let us now examine the symptoms by which phlegmonous erysipelas may be recognised. When it supervenes as the consequence of a wound, there are seldom any premonitory symptoms. The edges of the wound suddenly assume a swollen and tumefied appearance, and the surrounding tissues become soft and boggy. The part affected presents a regular, deep-seated redness, similar to that of phlebitis, but differing from the venous redness of angioleucitis, or the yellowish redness of erysipelas. This redness disappears on pressure, and does not return as quickly as in the affections we have just examined. The tissues also retain the impression of the finger, which is never the case in angioleucitis or phlebitis.

The march of this disease is also peculiar. Like simple erysipelas, it progressively invades the adjoining tissue; but, unlike that affection, it does not abandon the regions which it has already attacked. In the course of five or six days the cellular element becomes mortified, and, if an incision is made, escapes under the form of white flakes, as in simple phlegmonous inflammation, which has terminated by suppuration.

If these characters are attended to, it will be nearly impossible to confound this affection either with simple erysipelas, or with the other two diseases which we have examined.

These four forms of inflammation are frequently united, and may, in that respect, be compared to the inflammatory affection of the eye. This circumstance must be always borne in mind, as their progress, their treatment, and their consequences, are essentially different. Simple erysipelas may be accompanied by phlegmonous erysipelas, by angioleucitis, or by phlebitis, and reciprocally. Thus a patient is seized, after the usual precursory symptoms, with simple erysipelas, and the affection, during a variable period, follows its usual course. The inflammation, however, is propagated more or less suddenly to the subcutaneous cellular tissue, and thus gives rise to diffusive phlegmon.

This extension of the inflammation is more especially to be feared when the eyelids, the scrotum, the margin of the anus, &c. are affected, there being in these regions beneath the skin a very loose layer of cellular tissue. It is by no means difficult to ascertain when the complication has taken place. In simple erysipelas no swelling, to any extent, occurs; and when the skin presents the tumefied acuminate appearance which I have already described, we may be certain that the cellular tissue is inflamed. Sometimes it is angioleucitis which appears as a complication of the original disease, the ganglions which communicate with the seat of the erysipelas becoming tumefied and painful. The patient is again seized with rigors, complains of thirst, want of sleep, &c. If the affection of the lymphatics is slight, this is all that occurs. If, on the contrary, it is more serious, the red streaks and patches of angioleucitis make their appearance, and the ganglions become indurated. It is, however, easy to see that the erysipelas and the angioleucitis are in reality two different affections, the characteristics of which may be distinguished, although they be combined. Lastly, either internal or external phlebitis may supervene. The symptoms of internal phlebitis, the small pulse, the prostration of strength, the drawn features, are too well known not to be at once recognised; and the red patches, resting on an inflamed cord, and accompanied by partial induration, will sufficiently characterise external phlebitis.

These three inflammatory diseases may also exist primitively, and the erysipelas itself appear as a complication. Thus, I have frequently seen patients suffering under angioleucitis suddenly seized with nausea, and an exacerbation of the febrile symptoms, followed by the appearance of the erysipelatos eruption. In internal phlebitis, the entire economy is so deeply modified, that the skin seldom becomes the seat of active inflammation. In external phlebitis, on the contrary, erysipelas often supervenes; and this is easily explained when we consider that there is a certain degree of inflammation already existing. In some instances the erysipelas appears to cure the affection of the veins.

You see, therefore, that these four diseases may exist simultaneously in the same individual, and that you may, nevertheless, still distinguish the characteristic symptoms of each. When this is the case, the angioleucitis will be the first to disappear, then the simple erysipelas, after which the phlebitis, and, lastly, the diffusive phlegmonous inflammation. We will now examine the causes and the nature of erysipelas.

Causes.—The causes of erysipelas are of

two kinds; the determining, and the predisposing. The determining causes are everything that can irritate the skin; the predisposing are more difficult to discover. Sometimes for two or three months we do not see in our wards a single case of erysipelas; whilst, at another period, the slightest prick, the slightest incision, the bite of a leech, the application of a blister, is sufficient to give rise to it. But, although we are inevitably led to admit a predisposing cause, we know not where to look for it. It is not to be found in the age, the sex, or the temperament of the patient: these predisposing causes being in action at all times, it is impossible to explain through them the appearance of erysipelas. Many authors have endeavoured to account for its manifestation by the action of external agents. Thus, some have attributed it to cold, because they saw it in winter; others, to heat, because they saw it in summer; whilst others account for it by a sudden change from heat to cold, or from cold to heat. Are we, however, authorized to look upon appreciable meteorological phenomena as the predisposing cause of a disease which is met with in every season? In the surgical wards of La Charité, for instance, erysipelas has raged this year during the winter; the year before, during the summer; and the year before that, during the autumn. As it is a disease which exists epidemically, some again have accounted for its appearance by the supposition of a deleterious principle contained in the atmosphere, which modifies the state of the constitution. Many writers maintain that erysipelas is a contagious malady. Lawrence, in England, Gibson, in America, have defended this opinion, which certainly has arguments in its favour. But these arguments are not sufficiently powerful to carry conviction with them, and we may yet consider the question as far from being satisfactorily settled.

If we examine the action of this predisposing cause, we find that it greatly modifies the disease. Erysipelas cannot certainly be looked upon as a simple inflammatory affection. It neither presents the characteristics nor follows the course of simple inflammation; nor is it possible to produce it artificially. Its course appears rather to resemble that of eruptive fevers; we may, therefore, conclude that, in erysipelas, the inflammation is not the real essence of the disease. The pale lactescent form of erysipelas, which we sometimes observe on extenuated patients, is an additional proof of the correctness of this view of the disease. We have now in our female ward a remarkable case of this form of erysipelas. The patient in question entered the hospital about a fort-

night ago, labouring under a white swelling of the knee joint, and disease of the uterus, and was so extenuated by continued hæmorrhage, &c., that one would have supposed it nearly impossible for an extensive cutaneous inflammation to appear. Yet, after being preceded by the usual symptoms, erysipelas made its appearance a few days ago. The skin, however, instead of presenting the usual yellowish red tint, is of a pale colour, scarcely different from that of the healthy integument, merely offering the slight general tumefaction with the irregular festooned border of erysipelas.

Erysipelas appears to be a general disease, the origin of which is in extensive alterations of the fluids; it is, consequently, to this general modification of the economy that the attention of the practitioner should be chiefly directed. To resume in a few words, erysipelas is but the shadow of a much more serious affection; and its gravity depends less on the extent of the inflammation than on the intensity of the general symptoms which have preceded or accompanied it.

Some authors deny that the cause of this affection is general, because it often appears without any precursory symptoms. We often, it is true, meet with it in surgical cases when nothing has forewarned us of its impending invasion; but this cannot be considered a serious objection.

The appearance of a disease due to a general cause is not necessarily preceded by general symptoms. If an alteration of the fluids exists, whatever may be the cause, we can easily understand that the economy may resist in the same manner as it would had a poison been taken, but in too small a quantity to disturb the regular exercise of the functions, and that, in its efforts to get rid of the deleterious agent, the skin may become the organ on which that agent is carried.

If we now examine the nature of the erysipelatous inflammation, we shall find that there are many opinions on that subject. Formerly it was said that the skin was the seat of the inflammation. At a later period, it was thought that it occupied the sub-epidermic tissue, and then again the capillaries of the skin were named. In our own times, the venous capillaries of the skin have been fixed upon as the seat of inflammation. This opinion has been defended in France by MM. Ribes and Cruvelhier; in England, by Dr. Copland. I have often minutely examined the skin in persons who had died of this disease, but never found any appearance which could warrant the supposition; nor do the arguments brought forward in favour of this opinion appear very conclusive. How, indeed, is it possi-

ble to prove that the inflammation exists in the venous capillaries, when it has never been possible to examine them. M. Ribes has found small veins underneath the skin filled with pus; but this was not owing to erysipelas, but to phlebitis followed by absorption of pus. M. Cruveilhier also speaks of having seen veins underneath the skin filled with pus; but he has never remarked them in the cutis vera. When we consider that erysipelas often covers a surface of several square feet, it scarcely can be allowed that the capillaries alone are inflamed. It is much more probable that all the tissues which enter into the structure of the skin, the nervous, the adipose, the cellular, the vascular, are simultaneously attacked. Indeed, no symptom seems to indicate that one of the various layers into which the skin has been divided is affected sooner than another; they are all the seat of inflammation, which often extends, as we have seen, to the subcutaneous cellular tissue. Indeed, if we look upon erysipelas as a malady occasioned by a deleterious principle which the economy contains being thrown on the cutaneous absorbing surface, we can scarcely understand even theoretically that one alone of the various elements which enter into the composition of the skin should be inflamed.

These views are of great importance with regard to the treatment of erysipelas. There is an immense difference between those practitioners who look upon the affection as local, and those who consider it to be attributable to an alteration of the fluids. In the eyes of the first, the treatment of the disease is already well known, and little or nothing remains to be done. With the latter, on the contrary, it is very different. Thinking that but little is known about the treatment of erysipelas, they feel convinced researches have yet to be made.

[To be continued.]

MERCER'S HOSPITAL, DUBLIN.

New Instrument for Tapping.

DOCTOR LENDRICK remarked, a few days since, to the pupils of this institution, that he had often, both to the classes of this and Sir Patrick Dun's Hospital, animadverted on the common trocar, which is liable to many objections, especially if used in cases of ascites. It is altogether a rude and clumsy instrument, and can seldom be rendered sharp, except by a very skilful cutler: the canula also rarely fits it. For these reasons it enters the parts with difficulty, and such force becomes necessary, that the viscera are sometimes reached and injured. The canula is liable to be

blocked up by omentum, or, if sharp (and otherwise the canula will not fit,) to wound the vessels of that membrane. For the rectification of these defects many contrivances have been attempted.

Dr. Lendrick shewed the pupils a new instrument, made under his direction by Mr. Milliken, of Grafton Street. He stated that he was not aware of a similar plan having been resorted to. The instrument is the "exploring needle," on a large scale, as to breadth, being about three inches long, two lines and a half broad, and one line and a quarter deep. It has an oblique handle, like that of a gorget. There is a groove on the surface, and the extremity is lancet-shaped, with only two edges, extending not quite to the shoulders of the blade. The integuments may or may not be divided with a lancet, according to the wish of the operator. The instrument is introduced with great ease, and the penetration of the sac is at once known by the gush of fluid along the groove: the operator, who holds in his hand a catheter (No. 4 or 5), nearly straight, and either of silver or elastic gum, immediately passes it along the groove, and its penetration of the sac is simultaneous with the withdrawal of the sharp instrument. The fluid is now allowed to flow through the catheter, pressure with a swathe being applied as the abdomen becomes flaccid. The whole operation may be performed without varying the position of the patient from the recumbent posture in bed. The wound is somewhat valvular. The operator ought to hold the trocar in one hand, and the catheter in the other. The introduction of the second is to be accompanied by the withdrawal of the first. Thus the aperture of the sac is at once hit off.

The operation of paracentesis abdominis was performed this day (27th July.) at Mercer's Hospital, with Dr. Lendrick's trocar, by Mr. Auchinleck. It was done without any previous incision, the instrument entering at once with the greatest ease, and almost without being felt by the patient. A gum catheter (No. 5,) was used; but No. 7 might easily have been introduced. The fluid passed away slowly, and the patient, who was much debilitated, preserved the recumbent posture throughout. One precaution is necessary to be attended to, if a gum catheter be used. After the stylet is withdrawn, the tube is liable to be compressed by the edge of the swathe, and the exit of the fluid impeded. The difficulty is overcome simply by removing the edge of the swathe from the orifice. It is preferable that the catheter should be furnished with two apertures.

Dublin, 27th July.

APOTHECARIES IN RUSSIA.

BUT, in this analysis of the more respectable part of the population of a Russian town, we have omitted one conspicuous person—the apothecary. He is always among the wealthiest in the place. None can sell drugs without a patent; and as only one or two in a provincial town, willing to gain their bread in this way, have influence enough to obtain the emperor's permission, there is but little opposition in the trade. Nothing is paid for the patent, so that the free profits of such a business are often very large. A German, whose daughter is married to the second apothecary of a government town near this (Koursk), told us, that he had seen his son-in-law's books, and seldom found the profits less than 32,000 roubles (or more than £1200) a-year; while the first apothecary, as our informant asserted, draws 50,000 roubles, or £2000 a-year. He instanced a smaller town, in which the two dealers in physic draw 15,000 and 25,000 roubles respectively. There are other parts of the continent where apothecaries are equally wealthy; as in German towns, where they are always among the richest citizens.—*Brenner's Excursions in the Interior of Russia.*

OPERATION FOR CATARACT.

To the Editor of the Medical Gazette.

SIR,

IN your notice of Mr. John Northon Thompson's Pamphlet "On Blindness from Cataract," in your No. for July 24, you have fallen, inadvertently no doubt, into the error of attributing *priority to him* as it regards the recommendation to perform an *early* operation for the cure of that disease. You will find, on reference, that such practice was inculcated some years ago, in a work "On the Nature and Symptoms of Cataract, and on the cure of that disease in its *early* stages, by a mode of practice calculated to prevent the occurrence of blindness, and to render unnecessary the operations of couching and extraction, by John Stevenson," &c., &c. From your well-known liberality, and disposition to give merit where merit is due, I have no doubt you will do justice to Mr. Stevenson, by rectifying the mistake as soon as possible.—I am, sir,

Your obedient servant,

A SUBSCRIBER.

Nottingham, July 27, 1840.

COURT APPOINTMENTS.

Buckingham Palace, Aug. 11,

His Royal Highness Prince Albert has been pleased to appoint—

Sir James Clark, M.D. F.R.S., and Henry Holland, M.D. F.R.S. to be Physicians in ordinary to his Royal Highness.

John Forbes, M.D. F.R.S., and Theodore Gordon, M.D. Deputy Inspector General of Hospitals, to be Physicians extraordinary.

Sir Benjamin Brodie, F.R.S., Benjamin Travers, F.R.S., Chas. A. Key, Esq. to be Surgeons in ordinary, and Alex. Nasmyth, Esq. M.R.C.S. to be Surgeon Dentist.

RECEIVED FOR REVIEW.

A Practical Work on the Diseases of the Eye and their Treatment, medically, topically, and by operation. By Fred. Tyrrell, Senior Surgeon to the Royal Ophthalmic Hospital, &c. Vols. I and 2. Churchill, 1840.

ROYAL COLLEGE OF SURGEONS
IN LONDON.

LIST OF GENTLEMEN ADMITTED MEMBERS

Friday, July 31, 1840.

R. B. Newhouse.—J. S. Evans.—C. T. Weston.—J. G. Mitchell.—W. J. Dunsford.—N. Blythe.—T. Marchant Tomkin.—S. M'Morris.—Evan B. Jones.—J. Lister.

Tuesday, Aug. 4, 1840.

E. O. Wildman Whitehouse.—T. H. Black.—W. D. Blades.—R. R. Shillitoe.—A. Tucker.—J. Fox.—G. Smithwaite.—A. B. Middleton.—J. Beavor.—E. S. Emmott.—J. Davies.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED
CERTIFICATES.

Thursday, Aug. 6.

C. E. Firth, Warwick.—H. Powell, London.—W. Smith.—W. M. H. Day, Bristol.—W. Angas, Newcastle-on-Tyne.—W. H. Fife, Newcastle-on-Tyne.—J. D. Hewson, North Shields.—J. King, Liverpool.—W. J. Lomax, London.—T. Jacob, Cardiff.

METEOROLOGICAL JOURNAL.

Kept at EDMONTON, Latitude 51° 37' 32" N.
Longitude 0° 3' 51" W. of Greenwich.

<i>August.</i>	THERMOMETER.		BAROMETER.	
	from	to		
Wednesday 5	53	73	30.08	30.02
Thursday 6	56	80.5	29.98	29.96
Friday 7	60	77	29.95	30.01
Saturday 8	56	77	30.05	30.15
Sunday 9	49	78	30.17	30.14
Monday 10	52	70	30.04	29.80
Tuesday 11	53	70	29.60	29.55

Wind N.E. on the 5th and three following days; N. on the 9th; S.W. on the 10th; S.W. and W. on the 11th.

Except the mornings of the 5th, 8th, and 11th, clear. Raining very heavily during the morning of the 11th.

Rain fallen, .125 of an inch.

CHARLES HENRY ADAMS.

WILSON & OGILVY, 57, Skinner Street, London.

OF
Medicine and the Collateral Sciences.

FRIDAY, AUGUST 21, 1840.

LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

INJURIES OF THE HEAD, *continued*.—INFLAMMATION consequent upon. *Its Nature and Treatment*.—THE OPERATION OF THE TREPAN. *Circumstances under which its employment is justifiable.*

INFLAMMATION OF THE BRAIN, OR ENCEPHALITIS.

INFLAMMATION of the brain itself, or of its membranes, may succeed to many of the injuries of the head to which I have directed your attention; from a simple wound of the scalp to the most complicated fracture of the skull; from the slightest extravasation of blood to the presence of the most irritating foreign body. It may be excited at the moment of an injury, or it may supervene in the first, five, or six days; in either case it may be directly caused by the injury: it may not be developed before the tenth to the fourteenth day, and is then a secondary affection, consequent upon, but not actually produced by, the injury itself. It may not be manifested for months; and then it is usually caused by a spicula of a bone, or other foreign body. Paré thought a hundred days not an uncommon period; and that the later the period the more serious. It may be acute, passing rapidly through its different stages, or it may be excessively slow and obscure in its course; but, in either case, it is too commonly fatal. It is in itself an extremely grave affection, but most so, because of its pro-

ducts—a sero-purulent, or purulent fluid, which may compress the brain. When it affects the membranes, it is usually extended over a considerable surface, and this circumstance almost destroys any chance of relief from the use of the trepan. When it is confined to the brain it is often circumscribed, and gives a greater opportunity of relief.

Inflammation of the brain and its membranes may, altogether, be regarded as the most formidable complication of injuries of the head. At first, we ordinarily see the symptoms of concussion; they may be followed by compression, and then those of inflammation. Boyer thought that, *cæteris paribus*, the symptoms of inflammation supervening on concussion are much more grave than those produced by contusion, and that those from contusion are more fatal than those from wounds, or from a foreign body, which can be easily removed.

If you were not aware that inflammation is often set up after many days, you might, too soon, allow the patient to resume his ordinary occupations, and in the midst of them the symptoms of encephalitis would be developed. The cases in which it has occurred when the medical attendant has dismissed his patient are by no means rare. Sometimes, indeed, the wound only affects the soft parts; there has been no concussion; nothing excites suspicion of its being more than a simple wound; but, in a fortnight, a mortal encephalitis is developed: this inflammation, however, is more probable when there has been concussion; still more so after compression.

Petit had great apprehensions, as to such cases, in children, because they have no fears from the accident; they dread to say any thing about it; and if a servant be in charge, she often says nothing about it, lest she should be blamed for inattention; and when cerebral symptoms are developed, they may be mistaken for

those which precede eruptive fevers, or accompany dentition. Of these things you must by no means lose sight, because cases are on record where a child has had a fall; cerebral symptoms, which accompany the above mentioned diseases, supervened, and where they have been conceived to be a consequence of the fall, and the trepan has been used. Twice Petit stayed the hand of the operator when the symptoms were consequent upon dentition; once when they were the precursors of an eruptive fever.

Symptoms.—It is almost impossible to see a case of encephalitis, as a consequence of a wound of the head, without meningitis; therefore the symptoms of these two affections are almost always combined. Thus, to an intense headache, vomiting, excitement of the intellectual faculties, and delirium, are added, stupor, with excited sensibility, contractions, and convulsions; we may observe languor, depression, coma, paralysis; the pulse may be, at first, quick, small, and hard; afterwards, full and slow. The carotids beat strongly: it is this beating, with that of the temporals, the redness of the eyes, and the livor of the face, which induce us to suspect inflammation, even before the symptoms of concussion may be dissipated. Then the symptoms of nervous excitement may proceed, in company with opposite symptoms, and the latter may succeed them; this is probably because there are points of the brain which are only irritated, or excited by the affection of the membranes. I have already stated that some persons believe that the symptoms fairly indicate the affected point; but observation has proved the contrary. Thus Foville and Pinel-Grandchamps, some years ago, maintained that, when one arm is affected, the optic thalamus of the opposite side is the seat of disease; when one leg is affected, the corpus striatum of the opposite side is diseased. Cazes believed, that facts proved that isolated paralysis of the tongue indicated disease of the cornu ammonis. Bonillaud thought the loss of memory of things indicated disease of the anterior lobes of the brain. No doubt it looks imposing to be able to point out the exact seat of disease, but I advise you not to rely greatly upon it, or you will be very often disappointed.

I have already said that rarely does inflammation immediately supervene on concussion, or follow, uninterruptedly, compression from a clot; there is almost always an interval. It is sometimes when the patient thinks himself quite well that the first pains of inflammation are felt. If there be a wound of the scalp, it is on the point of healing, when, suddenly, a new pain is felt there; at first it is limited to

that point, but gradually it extends to the whole head. There is languor, moral depression, vertigo, vomiting, pulse quick and hard, sleep rare, and agitated; the face is animated and injected, and the heat of the surface is increased; but, for many days, the symptoms are equivocal. However, unless we find that there has been very improper food taken, there can be little doubt of the supervention of encephalitis. Soon the pain of the head increases, the cerebral functions are disturbed, the sensibility is so excited that the least shock causes painful subsultus, the eye cannot bear the light, the most familiar odours are impatiently borne, the ear is painfully affected by sounds, the patient is irascible, the sleep is troubled by unpleasant dreams, the taste is depraved, the appetite is capricious or lost; delirium continues, interrupted only by sighs and groans; the countenance becomes more animated, the eyes haggard, the vomiting more frequent, the pulse becomes harder, the heat and the anxiety increase, the tongue is dry and cracked. At last, the patient, perfectly unconscious of all around him, relaxes into a state of continual agitation; his hands are frequently directed to a particular part of the head; the eye is fixed, the pupil contracted, the pulse irregular, the stools involuntary, the teeth grinding. If he^{*} does not sink at this period, symptoms of compression come on, and predominate over the others; the coma is more decided, the delirium is less violent or ceases altogether, the heat of the surface is frequently abated, rigors occur irregularly, there is a clammy cold sweat, especially on the forehead, the pupil is large and immoveable, and the patient glides towards the bottom of the bed as if pushed down. It is at this time that the smell of mice is usually perceived, and that paralysis of one side of the body is discovered, with convulsions of the other, or a permanent state of contraction, in which the muscles of the back not uncommonly participate: the neck is rigid, respiration is laboured, but becomes slower, interrupted, and at last ceases, with or without tetanic spasms.

These symptoms succeed each other with more or less rapidity; the entire course of the disease is usually from six to nine days, but it may not exceed three or four from the occurrence of the pain of the head. The rigors and lethargy may succeed immediately upon the equivocal precursory systems: we have seen patients die with all the comatose symptoms which ordinarily terminate inflammation of the meninges, in whose brains we have found no effusion of any kind.

There are local anatomical characters which indicate what is going on within

the cranium; we have already spoken of them. If there be a wound it assumes the character we spoke of; the bone is denuded, it presents the appearance of necrosis. If there be no wound, at the injured point there is pain; and a tumor, such as that described by Pott, may be developed. If, by the trepan, or after death, we expose the dura mater, we find it brown or blackish, and easily destroyed. In consequence of this circumstance much importance naturally attaches to the separation of the pericranium.

Treatment.—The principles upon which inflammation of other organs is treated are entirely applicable to that of the brain; but they should, in that case, be very energetically employed. Among the means to be used, practitioners, in all times, seem to have regarded blood-letting as the most important; but all are not equally agreed upon the vein which should be opened; some say those of the arm, others the jugulars, others those of the feet; and others rely greatly upon the wisdom of opening the temporal artery. My advice is, that you should take blood where it can be most readily procured, the arm; but I see no objection to open the jugular vein, or one of those of the feet, provided the quantity taken be sufficient; you should never rely alone upon local abstraction by cupping or leeches; they are good auxiliaries, but ordinarily insufficient as principals; and section of the temporal artery is not always free from inconvenience, particularly that of compression for the purpose of restraining hæmorrhage. Many modes of abstracting blood have been practised: some are content with bleeding in proportion to the urgency of the symptoms; others think it best to anticipate them. In a case mentioned by Paré, he bled to the extent of 27 *palettes* (a measure of 4 ounces). Petit proceeded still farther; he felicitates himself upon the result of a case in which a young nobleman was thrown from his horse; two medical practitioners were opposed to a seventh bleeding; he insisted on it, and saved his patient. The custom of the present day, in our country, is to bleed largely when any symptom indicates the necessity of abstracting blood; but we do not wantonly take it several times when there are no symptoms to indicate the necessity. Instead of pursuing this system, Gama thought it best to keep up a continued abstraction, by applying leeches, and supplying the places of those which came off. His plan is, when there is a wound, and strips of plaster are used to bring it together, to apply, according to the gravity of the symptoms, twenty or thirty leeches between the strips, and as the bleeding from their bites begins to lessen, to apply

others; and this plan was to be continued from two to six days if the symptoms required it. He believes that in this way a sufficiently large quantity of blood may be taken without producing an equal degree of debility with general bleeding. My opinion is formally opposed to Gama. I believe that when the symptoms of encephalitis are sufficiently developed to render the abstraction of blood necessary, that the system should be quickly prostrated by a prompt removal of a considerable quantity of blood, so as to cut short the progress of the disease. I most readily admit that in some cases twenty or thirty leeches will produce faintness; but it is a faintness from which the system soon recovers, and in many cases fifty or sixty applied at the same time will produce none. The disease will insidiously steal on, its symptoms masked by these bleedings, and ulterior mischief will be very likely to follow. When Gama considers the loss of blood to be sufficient, he lessens the number of leeches by a third, until no more are necessary; he then places certain increasing intervals, such as 24 and 48 hours, between the applications, until he entirely discontinues them. In this way, he says, the treatment continues from eight to fourteen days, during which he conceives the most important principle to be the continued abstraction of blood. He prefers to apply the leeches as near the wound (if there be one) as possible; next to that he prefers the forehead and temples; he does not approve of the mastoid region, or that of the neck.

With blood-letting we associate rigid diet, and antimonial or other purgatives. When by this mode of treatment we have failed in subduing the inflammatory action, it is very rarely that other means will succeed. Desault urged, and most surgeons have experienced, the good effects of tartar emetic; he gives cases in which he thinks, in the last period, even where there was extravasation, it has saved life.

Another very important plan is cutaneous counter-irritation by blistering; it may be applied upon the head itself, upon the back of the neck, or upon the limbs; but practitioners are much divided in opinion as to the wisdom of using blisters in the first period of the disease, from an idea that they may exasperate the already-existing inflammation.

In various modes *cold* has been applied to the head, for the purpose of restraining the inflammation of the brain. Schmucker, who was a very strong advocate for the system, used a mixture composed of four ounces of nitrate of potash, two ounces of ammonia, sixteen ounces of vinegar, and ten pints of water. Other persons have

used cold water by way of lotion or irrigation; others have used evaporating lotions; and others ice. I have often admitted the powerful sedative effect of cold, but I have always maintained that it is a double or quits remedy; that if it do no good it may do much harm: that if the sedative effect be not maintained, decided reaction may follow. Associated with blood-letting, and properly watched, it is unquestionably an agent of considerable value.

When, under the influence of treatment, the inflammatory action still persists, with symptoms of compression, the question of applying the *trepan* upon the injured point arises: the object of applying it is to evacuate the products of inflammation which give rise to the symptoms of compression. But what is the state which justifies a recourse to the *trepan*? A strong conviction that those products exist, and that they are producing the cerebral symptoms attributed to compression, coma, and paralysis: but then these symptoms may be produced by meningitis or disease of the brain, such as softening; in that case the *trepan* would be useless, or worse. It is also necessary, before the *trepan* is applied, to ascertain the exact seat of the morbid product; and this is in many cases by no means an easy matter. It may be between the dura mater and the cranium, between the layers of the arachnoid, under the pia mater, or in the substance of the brain. The existence of a denuded point of the cranium, consequent or not upon a wound, and the paralysis of the opposite side, indicate with tolerable certainty that the extravasation is beneath that point. But, though we may be right in that, we cannot determine either the depth or limits of the compressing agent: neither can we in all cases ascertain its nature, or whether it be susceptible of absorption. Even supposing we have made out the existence, the seat, the limits, and the nature of the extravasation, it is important to ascertain whether there be inflammation; whether the functional disorder do not depend upon this condition, rather than upon its products. These are among the difficulties which will assail you when the question of the *trepan* arises, and unless you can resolve them you should abstain from operating. It is astonishing to us in the present day that the older surgeons so readily undertook this operation; but it is not less astonishing that in the present the *trepan* is rarely used. Certain it is that in a large number of desperate cases success attended its employment: whether that success was consequent upon the ancients using it as a preventive method, employing it as soon as they ascertained that a fracture, or even a contusion of the bones of the cranium existed, before inflammation was de-

veloped, I do not know, though I incline to the opinion that it was. Although, in frequent instances, this may have been their rule of action, in other cases they used it to relieve compression. When success attended the operation, it was usually done for the removal of a spicula of bone: when it was performed to remove some fluid on the surface or in the substance of the brain, the cases of success were comparatively rare. Still, when, under the influence of blood-letting, rigid diet, emetics, cathartics, and cold in the first or acute period, and associated with counter-irritation in the second, the inflammatory action is not dissipated, and symptoms of compression are urgent, whether there be a wound or not, we are justified in applying the *trepan* where the blow was struck and the pain is felt, provided the result of compression be exhibited on the other side. By this operation we may sometimes remove the causes of inflammation, if it consists of a spicula of bone, and it allows of the evacuation of purulent matter if it exists. Some surgeons have attached great importance to the operation in such cases, by its occasionally affording facilities for taking blood from the sinuses, but you had much better take blood from a vein elsewhere than incur risk from opening a sinus.

As to the chronic or sub-acute inflammation, which is developed occasionally long after the injury, it is often possible to prevent it: for this purpose, in all cases of injury of the head, the scalp should be well examined; the patient jealously watched, and subjected to a severe antiphlogistic treatment: cold should be applied for some time, and tolerably copious action of the bowels kept up. But when symptoms of inflammation of the dura mater are marked, cut down through the pericranial tumor, and use the *trepan*. If, however, there be reason to think that the inflammation extends far, it will be worse than useless. We must never, however, lose sight of the circumstance, that certain conditions of the abdominal viscera may give rise to phenomena analogous to those of inflammation of the brain, and that emetics and purgatives may dissipate them.

THE TREPAN.

To point out the cases and circumstances under which it is prudent to use the *trepan* is almost impossible; still it is necessary that I should endeavour to lay down some rules for your guidance.

Practised from a very early period, strongly supported by one party, and as strongly repulsed by another, probably no operation in surgery has been so keenly discussed, from the time of Hippocrates to the present day, as that of the *trepan*.

And this is not wonderful, when we consider the frequency and gravity of the diseases for which it is proposed as a remedy; the importance of the affected organ; the almost miraculous effects which sometimes follow its use. These circumstances sufficiently explain the rank which it holds among the operations of surgery. That no definite judgment has been pronounced upon it, the numerous essays upon it, by celebrated men, are at the same time a sufficient proof, and a reason why we should approach the subject with much diffidence.

The earliest data which we possess upon the subject are those of Hippocrates; but no one can read his observations without being convinced that the operation was practised before his time. It is, therefore, at this time of day, rather humiliating to subscribe to the opinion of Metzger, (*de lésionibus capitis*): "*Si capitis læsionum, quæ exstant fide dignissimus historiarum attento animo perpendere velis, intricatissimum sanè hic intrabis labyrinthum.*"

Hippocrates considered the trepan as the last resource; to be used, rather than abandon the patient to certain death. Celsus taught that still more reserve should be shown in its use. Archigenus recommended its employment in many cases. Galen, as in most cases, remains faithful to the doctrines of Hippocrates. Albucasis modified the instrument to a certain extent, but made no change in the employment; and for a long period it seems to have been almost forgotten, or at least left in the hands of those quacks termed "*circulatores.*" Beranger trepanned for the purpose of raising a depressed bone, which compressed the brain, or irritated the dura mater. He trepanned over the temporal bone, spite of Galen's interdict, and over the sutures, although Hippocrates condemned it. Although Paré adopted the maxims of Hippocrates, he did not servilely follow them; he showed that vomiting and coma, though regarded as signs of fracture, might exist without it, and that fracture might exist without these symptoms. Fabricius ab Aquapendente proposed that the trepan should be used whenever the opening was insufficient to allow of the escape of sanies. From the time of Dionis, the trepan was used in France not only in all cases of fracture, but even in cases of simple denudation. Petit sought to distinguish whether the symptoms were owing to concussion, to compression, or to inflammation; which, since the time of Hippocrates, was the most important circumstance connected with the trepan. Quesnay maintained that it was unnecessary to trepan for primary accidents, and that it should only be used in compression and inflammation. About the same time Pott entered upon the question, and was dis-

posed to recommend it in a very large proportion of cases of wounds of the head. Heister objected to its use unless the symptoms were very pressing; so thought B. Bell and Morgagni, who says, "*ut injustum sit illud præter modum abhorre.*"

Taking the opinions of the greatest modern authorities, we find that Desault, Richter, Abernethy, A. Cooper, Brodie, Langenbeck, Walther, and Dupuytren, thought that its use should be greatly restrained; they only advised its employment in consecutive accidents, such as irritation and secondary compression, if manifested with a certain intensity. Pott, Sabatier, Louvrier, Mursiana, Zang, Schindler, and others, employed it more generally, not only when consecutive accidents were declared, but in all lesions where, in consequence of the structure of the parts which protect the brain, consecutive accidents were to be apprehended.

The former base their opinions upon the following facts:—"Experience shows that fractures of the cranium, with or without depression, are frequently cured, whether the bones be elevated, or the brain has become accustomed to their compression;" therefore, say they, the trepan should not be used until consecutive symptoms are urgent. Again, experience has demonstrated that extravasated blood may be more or less completely absorbed; that the operation of the trepan is not without danger, for to a serious existing injury is added a new one, whose consequences may be very serious; that exposing the membranes of the brain is a very serious though necessary part of this operation; that if inflammation be developed, the brain may project through the opening made in the bone; that the dura mater may be ulcerated; that fungous excrescences may form, (Abernethy). To these objections the answer is, that the internal table, in consequence of its brittleness, is more liable to fracture than the external; that radiating fractures, with detached spiculae, usually extend farther along the inner than the outer table; that the vessels which unite the dura mater to the cranium are frequently destroyed, and occasion extravasation of blood; that if it be admitted that these accidents in wounds by contusing bodies supervene with as much more certainty—that in all these injuries the diploë is so contused that inflammation and suppuration almost necessarily follow—we must see that the absence of compression and irritation ought not to inspire us with confidence; that when these symptoms are developed, the brain and its coverings are already altered, so that the operation can only be regarded as a powerful therapeutical agent, which under those circumstances has not fair play: the same remarks apply to

extravasations of blood, for if the surgeon deceives himself with the hope of absorption, and postpones the use of the trepan to the moment when the symptoms are developed in all their energy, we have the probability that violent inflammation may attack the brain and its membranes, and that the trepan offers then small chance of safety.

We cannot deny that fractures of the cranium, with or without depression, may in some cases do well; we may even admit, that of ten cases trepanned under the circumstances before stated, two might have been cured without the operation, though of this there could at the time be no certainty. But when consecutive accidents are developed, the trepan is fatal in a large majority of cases. The operation of the trepan is not of itself dangerous; and if the consequences are regarded with so much apprehension, it is because it is seldom applied except in desperate cases.

Sir A. Cooper thinks that it is indicated only when blood is extravasated between the dura mater and the cranium; in fractures complicated with compression, if not relieved by blood-letting; in fractures with depression, even when there is no wound of the integument, if the symptoms of compression persist; in cases of purulent effusion. He thinks also, that while there is a simple fracture, with a denuded cranium, or depression, the case is very dangerous. He advises that when a spicula of bone is pushed into the brain, but produces no sign of compression, that we should not seek to remove it, because we shall very probably produce extravasation, and favour the development of acute inflammation. Yet he proves how uncertain are his data, when he says: "In complicated fractures ordinarily inflammation is manifested; it is necessary, therefore, to trepan before it is developed, for afterwards the operation would be useless; it will even aggravate the patient's condition when inflammatory action is already developed." Brodie's opinions are similar.

In the course of treatment of a wound of the head the trepan may be indicated; when irritation and compression of the brain are manifested, and the symptoms do not abate under appropriate treatment, and we are certain of the point upon which violence has been inflicted, and when the products of the wound have no free exit, the diploë being affected, and the dura mater detached.

In estimating the operation, the pain and apparent cruelty need scarcely be taken into account; they are much less than those of many other operations. Its dangers, what are they? not great. It is said, the saw may open or lacerate the dura mater. If we argue in that way the simplest operation may be made formidable; those reproaches attach to the operator,

not to the operation. The action of air, what have we to fear from it? In many cases the wound already exists. If the air be so injurious as some persons think, it must be equally so in wounds of the head, with loss of substance; yet the impression is very general, that inflammatory complications are in an inverse ratio with the dimensions of such wounds. No doubt many persons die after the operation of the trepan, but why refer this to the action of air rather than to other causes? My own opinion is, that the action of air has nothing to do with the accidents which follow the operation; that its dangers have been much exaggerated; and that, as an operation, it is not in any way difficult. It is simply in determining the exact point upon which it is to be applied that difficulty is experienced. But that is nothing as against its absolute value; it is only a proof that the diagnosis of surgical diseases of the cranium is far from perfect.

As in many other questions, the great diversity of opinion on this subject is mainly owing to the absence of precision in the indications, and an incomplete analysis of the principal phenomena determined by wounds of the head. In most cases the signs of concussion and of inflammation have been confounded with those of compression; the evidence of this is contained in the works of Pott and Dease, Sir Astley Cooper, Richter, Zang, Quesnay, and Desault. The doctrines of Pott were opposed by Dease, whose ideas were espoused by Desault; analyse their facts, and you will see that the attacks on the trepan were not justified.

Dease having lost the patients he trepanned, tried severe dieting. This he found equally fatal; while he saw persons who were careless about diet often do well. From this he concluded, that in cases of simple fracture and contusion it was unnecessary to trepan. Of his twenty-five observations, twelve were cases in which there were contused wounds and a denuded cranium *without fracture*; almost all resulted from contusing bodies. Of these twelve cases eleven were trepanned; in the twelfth the operation was proposed on the fifteenth day, but opposed by the consulting surgeon, and the patient died on the twenty-second day. Of the eleven who were trepanned nine died, two were cured. Three were trepanned before the tenth day; three from the tenth to the fifteenth; five after the fifteenth. In any case the accidents were not manifested before the seventh day, nor later than the nineteenth day. The symptoms which served as indications were, eleven times, rigors; in one case only were the rigors wanting. Dease believed they must have been present in this as in every other case he saw, but were forgotten by the patient.

With rigors there was an irregular pulse; more or less intense headache, followed by delirium. In all cases the trepan was applied upon the denuded point.

Eleven were cases of wounds *with fracture*; nine produced by swords, one by a watchman's staff. Of these, in eight the trepan was applied, six times before the third day; and of those six cases four were cured. In all the cases the patients were largely bled and purged.

It would seem from these results that cases of simple contusion of the cranium are more grave than those with fracture; for of twelve cases without fracture ten died, while of twelve with fracture only four died. As in the first cases the operation was not performed before secondary accidents were developed, whilst in the second series it was, in most of the cases, performed before the manifestation of any bad symptom, we are justified in concluding, against the opinion of Dease, that the trepan, applied early, is successful.

Perceval Pott, one of the most accomplished surgeons this country has produced, was qualified for the task of estimating the real value of the operation of the trepan. He based his observations on twenty-eight cases of wounds of the head, in all of which he applied the trepan. In nine, to obviate accidents which accompanied or followed contusion of the cranium, and separation of the dura mater; in one to remove a spicula of bone; in ten cases to relieve the accidents of fracture without depression, and in five cases those of fracture with depression; in three cases to relieve the patients from the consequences of extravasation of blood within the cranium. Of the nine cases, five recovered, four died; of the ten cases, six recovered, four died; of the five cases, two recovered, and three died; of the three cases, two recovered, one died.

We are therefore, I think, justified in assuming, that Dease did not well understand the indications for the trepan, and resorted to the operation when it was improper. He lost the greater part of his patients; and, instead of referring his want of success to error in judgment, he referred it to the operation, and rejected it as a dangerous and almost useless resource. Pott, on the other hand, resorted to the operation when nature indicated the necessity for it, and succeeded fifteen times in twenty-eight cases, and showed that the operation had little to do with the loss of the remaining thirteen.

Whilst Pott in England, and the Academy of Surgery in France, pointed out the advantages and the necessity of the trepan, they seemed to neglect to point out the cases in which it was applicable; so thought Abernethy, Desault, Dease, and

John Bell. Abernethy sought to supply the deficiency. He said, that fractures without depression, as well as fractures of the cranium with slight depression, are susceptible of cure without the trepan; that the bone will rise up, or the brain will accommodate itself to the compression. He mentions many observations in support of his opinion. In his second case the depression was to the extent of a quarter of an inch; but whoever reads his too shortly described cases, will come to the conclusion that, in some of them, the operation might have been used with advantage. He admits that where there is considerable depression the trepan should be employed. "If there be much extravasation, it should be used; if not, we may wait." In concension he thinks the operation inapplicable. His conclusions are, that of seven cases in which the trepan was employed two did well; of eleven others, consequences of fracture, or inflammation, in which probably Pott would have operated, but he did not, three died, and eight recovered. John Bell, Hennen, and Sir A. Cooper, more strenuously opposed the trepan. J. Bell rejected it as a dangerous operation, but admits its necessity when pus is effused at the surface of the brain, or when compression is produced by blood or by bone. Sir A. Cooper does not base his formidable opposition on any conclusive fact or reasoning; he objects even to shaving the head, unless the necessity be obvious; and so do we. If, says he, the fracture be complicated, and inflammation supervene, death will follow, whether you trepan or not. He excludes the operation in all cases except where evacuants have failed, and there is decided compression. Hennen admits only two cases in which it should be employed. Fracture with depression, or complicated with a ball or other foreign body, which cannot otherwise be removed; and urgent symptoms of compression, without fracture. There is, in such cases, a difficulty in determining the point. Of Hennen's eight cases of fracture, from gun-shot, three were trepaned—one death: two were not trepaned, but spiculæ were removed—one death: one, ball extracted, bone depressed, but left to itself—cured: two, treated without trepan, and without removing spiculæ—cured. Of the eight cases five were cured; and among those trepaned two were cured. Richter's opposition to the trepan is much more strenuous than that of Dease. The first volume of Schmucker's Surgery contains fifty cases of wounds of the head received at the siege of Schweidnitz. The first twelve cases were apparently comparatively unimportant wounds; but the result of treatment was so very unfavourable, that he deter-

mined to use some new method: he resorted to the use of cold water: but any one who is at the pains to look through Schmucker's cases must feel that there is much want of ability to appreciate the cases in which particular modes of treatment are indicated.

Chelius, and many other German surgeons, are warm partisans of the trepan. He employs it in all cases of fracture, with or without depression; in penetrating wounds, and disjunction of sutures. Graefe and Schneider strongly opposed its use in almost every case. But, of the German works on the subject, Schindler's is the most remarkable. He says, as in fracture or fissure of the skull the life of the patient depends upon the timely use of the trepan, I place, as a principle deduced from several hundred observations, that whatever may be the form of the lesion of the bones of the cranium, whatever be the form of the instrument by which the injury is done, we ought at once to expose the part, and ascertain the extent.

When the bone and the diploë are much injured, even the opponents of the trepan maintain that immediate recourse should be had to it. If there be fracture, with depression, there is less accord. Surgeons may, then, be ranged in three groups: among the first, who would trepan before they have tested ordinary therapeutical agents, are Desault, J. Bell, S. Cooper, Richter. Among the second are Celsus, Benjamin and C. Bell, Hennen, Abernethy, Richerand, Larrey, Himly, Langenbeck, Dzondi, and Graefe, who do not resort to it until "cerebral symptoms" are developed. The third group includes Petit, Heister, Pott, Louvrier, Mursinna, Zang, Chelius, Klein, Rust, Walther. They see, in depression, an indication for the trepan, and employ it whenever it occurs.

I think it must be admitted that the almost entire abandonment of this operation, in this country, at the present day, is as senseless as many other changes with which fashion has something to do. The operation has had this disadvantage—it has been employed indiscriminately, and where death has followed it has been referred rather to the trepan than to the accident: and, on the other hand, many bad cases have done well without it. "Therefore," say many, "it is at least useless." We have no right to assume, because an apparently desperate case has got well without it, that we were justified in neglecting to use it, or to say that the operation was not the proper—the appropriate remedy. As well may we say, because a case condemned to amputation got well without it, that, therefore, amputation was not the proper remedy. Supposing we leave twenty such cases to themselves,

and five get well; supposing, in twenty others, amputation be performed, and we save twelve; would the five limbs saved in the first case compensate for the loss of seven lives in the second? Many cases, requiring the trepan, are, in appearance at the moment, slight; others are more serious; others very urgent. If, in the first, we operated early, the results would naturally be favourable. If, on the contrary, we wait until bad symptoms appear, the results would be very unfavourable.

In speaking of this operation, therefore, something more is necessary than to say I have employed the trepan so many times with such results. The rules which I propose to lay down for and against the use of the trepan are as definite as the subject admits of; but the exceptions to them may be many. The indications for the use of the trepan are, wounds of the head, with contusion of the bone, and separation of the pericranium and the dura mater, when of limited extent. Necrosis, of limited extent, affecting the entire thickness of the bone. Fractures, without depression or spiculae, when there is much contusion or extravasation between the cranium and the dura mater. Fractures with depression, unless the depression be slight, and without evidence of compression. Foreign bodies, when so situated as to be removable by surgical means. Extravasation, of whatever kind it may be, whenever the signs of compression are so clear and so severe as to threaten life. In some cases where, upon a point formerly injured, a fixed pain persists, and produces cerebral disturbance.

Counter-indications are presented when death seems near, and the bronchial tubes are obstructed by mucus; when the contusion is slight and uncomplicated; when the fracture is situated at the base of the cranium; when the fracture is simple and uncomplicated; when foreign bodies, though present, cannot be discovered; when there is reason to think that an extravasation of blood or pus is not limited; when the symptoms are evidently those of concussion; when there is general inflammation of the brain; when the patient is affected at the same time with some other, probably, mortal disease.

It is important to keep in mind that all regions of the cranium are not equally eligible for the application of the trepan. Many surgeons hold that it should not be applied *over sutures*, because the dura mater is too intimately united to the cranium at these points, and because they generally correspond with venous canals which may be endangered by the operation, and because extravasation between the dura mater and the bone scarcely ever happens at these points. These circumstances are

entitled to have a certain weight attached to them; but, in case of necessity, they must not prevent our applying the trepan at these points. If there be necrosis, separation of the dura mater, extravasation, a foreign body, a fracture, or a contusion, the operation is scarcely more dangerous, and little more difficult, than in other parts; it is true it is rarely done, but that is because the occasion is rarely presented. Over the *venous sinuses* many persons have objected to apply the trepan, fearing hæmorrhage; but those fears are exaggerated, because so inert are they that a very little pressure would restrain it. Champion removed from a child's skull the superior two-thirds of the occiput: at the moment of removing it, a spicula fixed in the membranes; he opened a sinus; the blood spouted out to the distance of two yards; he placed a bit of lint on the point, held it there for a few minutes, and the hæmorrhage ceased. Cheselden, in a wound of the longitudinal sinus, restrained the hæmorrhage by similar means. A variety of instruments have been invented for the purpose of restraining hæmorrhage of this kind. Some surgeons have regarded a puncture of a sinus with less apprehension—have proposed it as a therapeutical agent in bad cases of concussion (Leveillé.) Hoffman actually employed it. But it is easy to trepan over the sinuses without wounding them, and, if necessary, it should be carefully done. The region of the *frontal sinuses* is more objectionable, in consequence of the great distance which occasionally exists between the two tables at these points. Verheyen feared the wound would remain fistulous. Quesnay thought that, if necessary, these objections must not have too much weight. There are on record cases where no fistula followed. Among the moderns, Larrey has done it twice without serious inconvenience. But the operation must be to a certain extent modified. It has been recommended to apply a large crown over the anterior wall, and a smaller one over the posterior, but certainly it is a region that must not be selected without absolute necessity. Again, the temporal region is proscribed because of the necessity of cutting through the temporal muscle; this is a serious proscription, because this region is precisely the one where the trepan is most frequently useful. However, the trepan has been frequently applied, and with occasional success, in this region. Over the meningeal artery the operation has also been proscribed; certainly, if it be done, the chance of wounding the artery is considerable; but then the hæmorrhage has rarely been great, and in most cases has been quickly arrested. For this purpose

Larrey twice employed successfully a red-hot needle. I know of no case in which the wound of this artery, in the operation of the trepan, has caused death. The *occiput*, from the unequal thickness, and the contiguity of the sinuses, must be trepaned with caution, but, if necessary, there is no insurmountable obstacle to its performance. If applied low down, the soft parts to be cut through are rather thick, the splenius and complexus interfering; there are, however, many examples of success even there. As to the *base of the cranium*, the only region where we are not justified, under any circumstances, in attempting it, is that around the *sella turcica* and that of the *ethmoid*.

In all serious injuries of the head the scalp must be shaved, to enable us to ascertain the points implicated, as well as their probable extent. If the symptoms are pressing, if the bone be not laid bare, we do it with reserve, bearing in mind the necessity of placing the parts in the most favourable circumstances for cicatrisation. With this idea some persons make a ∇ , others a T, others a semi-elliptical or semi-circular incision, and some prefer a simple longitudinal incision; but this could only make room for a single crown. The head of the patient should be conveniently placed in a good light, the integuments should be made tense with the finger and thumb of the left hand, and the necessary incision made boldly, if there be no fracture; cautiously, if there be: the pericranium must be fairly incised and detached where the trepan is to be applied. We then project the centre piece, and perforate the bone so as to fix the crown, which must rest perpendicularly to the surface of the cranium; we then cause the crown to revolve until it has made a gutter deep enough to maintain the instrument, when the perforator may be withdrawn. From time to time the crown must be removed, the teeth brushed, and the furrow in the bone cleaned out with a feather, and with the quill end of the feather we ascertain whether, at any point, the bone has been cut through. As we get deeper we press more lightly, and incline the instrument to the side where the gutter is most superficial. In this way we proceed until there is penetration at several points of the circle, and the disc is moveable under the left indicator nail; then by inclining the trepan to either side we often detach the disc and bring it away: some persons prefer using a bullet screw for the purpose. When removed by either means, if there be at the circumference any sharp spiculæ, we remove them with the lenticular. If it be necessary to use more than one crown, we leave between them a kind of bridge, a line or two wide, which can be easily

removed with a Hey's saw: If we do not want the whole space of a second crown, we apply the instrument so that a fragment of the size we wish may be included in the circle. When the operation is achieved, the subsequent treatment depends upon the kind of injury for which recourse has been had to the operation: the evacuation of blood should be favoured by a convenient position, by the application of a sponge or dry lint. If the extravasation be below the dura mater, that membrane may project into the opening made in the skull, and may present a fluctuation and a violet colour. It must be cut down upon; the incision should be crucial. All these matters having been accomplished, the soft parts should be brought together, and the dressing should be very simple: some persons recommend that the disc should be replaced if the bone be healthy, but it is rarely done, and if it were it might form an obstacle to the escape of fluids. A pellet of lint, properly secured, will do better. The patient should be kept very quiet, rigidly watched and dieted; the apparatus should be removed once a day, or oftener if there be much suppuration. When all goes on well the dura mater gradually loses its glistening colour, secretes pus, and is covered with granulations; these are gradually raised, project through the opening made in the bone, unite to those of the integument, and even of the bone itself, and form a solid cicatrix. When matters proceed thus, we use slight compression to assist in producing a firm cicatrix, and the diet may be gradually improved. If the pus assumes an unhealthy character, and if there be no cerebral disturbance, tonics, externally and internally, may improve it. If it be kept up by some irritation, that should be removed; if it be a fragment of bone it should be cautiously extracted.

As so much obloquy attaches to this operation, it may be well to inquire what are the immediate consequences of the use of the trepan. There is usually, when the brain is exposed, a tendency to protrusion, and if the opening be a small one, the protruded portion may be, as it were, strangulated, and present a fungous or cauliflower appearance; but when the opening is large, or when there are many, that tendency is less decided.

Whether the dura mater have been incised or not, a tumor may form and completely fill up the trepan hole: in this tumor the cerebral substance may not be at all implicated. Difference of opinion exists as to the cause of these tumors. Abernethy thought that they were generally formed of coagulated blood deposited in the medullary substance of the brain, and variously transformed. He believed

that most of the tumors described as *hernia cerebri*, and which were considered by Louis as aneurismal, or erectile, were similar tumors. He thought that unless the symptoms were very urgent they should be left to nature. Hill punctured and scarified them. Ficker applied escharotics, and afterwards a ligature, but it was followed by convulsions. Walther recommended enlarging the trepan hole, and if necessary ligature or section.

When the trepan has been used, some persons bring the soft parts together, as in a simple wound; others replace the osseous disc. The ancients used to support the brain by applying a perforated gold or silver plate, but in the present day they are no longer used. In the first mode, the dura mater and the cranial integument unite at the centre of the perforation, the edges of which are gradually rounded or blunted. In the second case, some persons, among them Walther, have believed that the disc is again united and revived. In brute animals this union has several times been seen, and in a case on the human subject, referred to by Walther; but supposing we admit the possibility, of what use is it? When we use the trepan, we often act upon a diseased bone, which it would not be safe to reintroduce. Ordinarily, when the flaps are brought together, the borders of the bone are thinned, and seem to be elongated towards the centre, not absolutely coalescing, and this space never entirely disappears: it may happen that the cranium is flattened, and contracted at the point, as the chest is in empyema; and some faculty of the mind may be interfered with. The bone may thicken at the point. In the museum of Dr. Physick, at Philadelphia, was a skull taken from a young man who had his cranium fractured in a duel; he was trepaned, cured, pursued his ordinary avocations, but died suddenly a year after. It presents around the trepan hole a thick collar of bone, which compressed the brain. That the cicatrix is usually sufficiently resistant to support the brain, is well shown in the following cases:—Pouperinne perforated a skull with a trepan at five points; Pages and Schmucker the same: Spigelius at seven; Solingen, on the Prince of Orange, at seven; Gooch, at thirteen; Chadborn, on the Duke of Nassau, at twenty-seven points. Loyseau states that the King of Navarre, being at Bergerac in 1386, a poor man, wishing to save his goods from some of the soldiers who were quartered on him, fractured the skull of one and left him for dead. Loyseau removed nearly the whole of both parietal bones; after a long time he partially recovered, and for thirty years lived a mendicant. Many cases of the same kind might be mentioned. In some cases, how-

ever, the cicatrix is not sufficiently resistant, and then the same inconvenience may be experienced; a kind of encephalocoele may result. Paré, Lapeyronie, and Larrey, in such a case recommend, in preference to a plate of metal, one of leather or card board.

CLINICAL

LECTURES ON ERYSIPELAS,

Delivered at the Hospital of La Pitié, Paris,

By M. VELPEAU.

Reported for this Journal by J. HENRY BENNET,
B.L. & B.S., Sorbon.

Treatment of Erysipelas—Phlegmonous Erysipelas—Angioleucitis—and Phlebitis.

Treatment of erysipelas.—The treatment of erysipelas is both general and local. We will first direct our attention to the general treatment.

Some diseases are produced by a cause which becomes exhausted in giving rise to the malady. Thus, the inflammation which follows the introduction of a foreign body into a tissue is easily overcome when the cause which keeps up the irritation is destroyed by its removal. In other affections, on the contrary, the cause continues in action for a longer or shorter period after the appearance of the disease. This is the case with erysipelas; but as, unfortunately, we are totally ignorant of the nature of the general cause to which the malady is to be attributed, we have no satisfactory means of attacking it. We well know that erysipelas depends on an alteration of the fluids—innumerable arguments prove that such is the case, but we know not what is the real nature of the disease: we know not what is the deleterious principle which pervades the economy; whether it be this or that element which is increased or diminished. In this instance, reason is powerless, and we are reduced to empiricism, the results of which have thrown, however, little or no light on the subject. Some practitioners advocate tonics; others, purgatives and blood-letting; others, again, look upon nearly every kind of treatment as useless; the great difference of opinion which exists between most of those who have written on the subject shewing at once that no treatment yet proposed is really efficacious. If we study attentively the treatment which men of talent have adopted in various epidemics, we shall find that some employed one class of therapeutic agents, and some another, whilst many did nothing at all, and that, nevertheless, they all succeeded, to a certain extent, in curing

their patients. This, at first, appears strange, but it is easily accounted for by the old practitioner, who has passed through many epidemics of erysipelas, and has remarked the variable physiognomy which the malady assumes, as he finds that his own experience, confirming that of previous ages, justifies the adoption of an altogether different plan of treatment, in some cases, to that which is followed in others. It is certain that the general state of the patient varies exceedingly in different epidemics. Sometimes inflammatory symptoms run high; sometimes, on the contrary, gastric symptoms seem to prevail, the tongue being furred, the abdomen distended, and more or less nausea existing. Epidemics are occasionally seen, in which the patient is in a state of adynamia, the pulse being small, the tongue and skin dry. There are also epidemics of erysipelas, in which there is a tendency to gangrene, eschars rapidly appearing on those parts which support the weight of the body.

It is by these indications that we ought to be guided in the general treatment of erysipelas. Whenever the patient is young, robust, and the pulse is full, great benefit will be derived from bloodletting. If, on the other hand, he is advanced in years, or weak, if the tongue is furred, the skin of a yellowish colour, and there are other symptoms of a disordered state of the digestive organs, recourse must be had to emetics or to purgatives. When there are symptoms of adynamia, especially in old people, bloodletting and purgatives must be laid aside, antispasmodics being then most likely to prove beneficial. In cases of this nature I often give, every day, six, eight, or ten pills, each of which contains one or two grains of camphor, to two or three grains of the nitrate of potass. I do not, however, place much reliance on the efficacy of this prescription.

With regard to general treatment, as directed more especially against erysipelas itself, I have but little to say on the subject. It is very questionable whether any general medicine which has hitherto been proposed is capable of extinguishing erysipelas properly so called. General measures, such as bleeding, purgatives, emetics, &c., may be so far useful as to moderate the intensity of the disease, and prevent its assuming the phlegmonous form, but their efficacy does not appear to extend any further. Statistical accounts have been published, in which the progress of the disease is represented as having been at once arrested, and the disease itself as having been eventually and entirely subdued by general bleeding. But on comparing the date of the invasion of the malady with that of the cure, we always found that it had lasted from eight to

thirteen days, which is, as we well know, the natural duration of erysipelas. General bloodletting is merely a useful means of diminishing the violence of the inflammation, but nothing more; and in many instances it is impossible to resort to it, from the state of anemia in which repeated loss of blood has thrown the patient. No general remedy, indeed, with which we are acquainted, can cure this disease.

Local Treatment.—If the conclusion to which we have come with regard to the general treatment of erysipelas is correct, but little can be said respecting the local treatment; as, however, many practitioners do not adopt this view of the question, I will briefly examine the various remedies which have hitherto been employed in the local treatment of erysipelas. Entertaining the theoretical opinions which I have just brought forward, it is impossible to place much reliance on local measures; you may, however, rest assured, that whatever theoretical ideas I adopt in pathology, they will never prevent my trying, with the greatest possible impartiality, any plan of treatment which may be recommended by other practitioners.

The remedies used in the local treatment of erysipelas are extremely numerous, and this circumstance alone is, to a certain extent, a proof that none of them are very efficacious, although each has numerous advocates. In the history of the local treatment of this disease you will find that there are two periods. Before the eighteenth century, and in the twenty first years of the nineteenth, they were generally condemned. If we consult Pinel, for instance, we shall find that the only topical application he allows is very fine flour, which he merely uses to preserve the parts from the action of the atmosphere, and the friction of the bed-clothes, or a lotion consisting of a decoction of elder flowers. He thinks that all ointments, plasters, oils, &c., becoming rancid, increase the sensibility of the skin, and thus prolong the duration of the disease, making it last eighteen or twenty days instead of ten or fifteen. Within the last ten or fifteen years an immense number of local remedies have been proposed, the most important of which are, cauterisation with the nitrate of silver, or with the actual cautery, mercurial ointment, hogs' lard, camphor, and blisters.

Cauterisation.—Cauterisation of the inflamed surface with the nitrate of silver was first proposed by Mr. Higginbottom, who wrote a work on the subject. It was then practised in England, and afterwards in France; but the miraculous effects which it first produced have not prevented it falling into discredit. The entire sur-

face of the part affected, as also a small portion of the healthy skin, is cauterised either with the solid nitrate of silver, or with a pencil brush steeped in a strong solution of the salt. The practice of carrying the cauterisation beyond the inflamed parts is perfectly rational, as the inflammatory atmosphere no doubt extends to the skin which surrounds the tissue actually the seat of the erysipelas. Mr. Higginbottom says that he has succeeded in a great number of cases by adopting this plan of treatment. Within the last seven or eight years I have repeatedly tried this method of cauterisation, and have sometimes, like Mr. Higginbottom, seen the erysipelas extinguished; but I have much more frequently seen it continue its course as if nothing had been done. On examining the result of my experiments I find that in some cases the disease lasted from five to eight days, and in others from ten to twelve; and on consulting the cases of Mr. Higginbottom, I also find that in those of which he gives any details, the erysipelas lasted six, seven, or eight days. Now this being the natural duration of the disease, we cannot place much confidence in the remedy, and must come to the conclusion that if the erysipelas stops when cauterisation with the nitrate of silver is resorted to, it is because it has exhausted itself, and that, had its virulence not been exhausted, cauterisation would not prevent it continuing its course. We have now in our female ward a case which, if superficially examined, would seem to confirm the efficacy of this treatment. The patient in question, a young girl eighteen years of age, affected with a white swelling of the left knee, was seized a few days ago with erysipelas of the same leg. Until yesterday the erysipelas had gradually extended towards the thigh and towards the foot, emollient applications and mercurial frictions having failed to arrest its progress. Yesterday I cauterised the leg with the nitrate of silver, and on examining the patient this morning I found that the erysipelas had stopped. Many persons would feel inclined to say that this was owing to the application of the nitrate of silver, but if we attentively scrutinize the facts of the case, we shall find that they do not authorise such an induction. Erysipelas does not last forever; in this case it had attained its usual term, and the general symptoms having subsided, not only did it cease superiorly where it had been cauterized, but also inferiorly, where nothing had been done.

The actual cautery has been much extolled by some practitioners, and especially by M. Larrey, and other army surgeons. It is, however, evident that the remedy has only been applied to them in cases of

phlegmonous erysipelas; it is, therefore, difficult to say what would be the result, were it resorted to in simple erysipelas. Indeed, few surgeons are likely to propose such a measure in the treatment of the simple form of this disease.

Some surgeons recommend superficial scarification of the inflamed part, and a French practitioner, M. Lassus, has claimed the invention of this plan of treatment, although it really is not worth claiming. Others advise moxas to be applied; as, however, they do not make the necessary distinction between the simple and the phlegmonous form of erysipelas, but little reliance can be placed on the results of their experience.

Mercurial frictions have many advocates. I myself was perhaps the first who resorted to mercurial frictions in France. In 1823, being entrusted with a lying-in ward, I wished to ascertain the efficacy of mercurial ointment in peritonitis, and therefore employed it in many cases, in frictions on the abdomen, repeated every hour. I then thought it was the means of saving the lives of several females; it has since been employed by most practitioners in peritonitis, and has been generally recognized to be a very valuable remedy. The success which I met with induced me also to try it in erysipelas, and in 1831 I had had already twelve successful cases, when M. Ricord published several cases in which he had successfully adopted the same plan of treatment. My confidence in the remedy was, however, staggered, by two or three cases which resisted its action, and these were immediately followed by seven or eight in which it was equally unsuccessful. This convinced me that my previous success was mere coincidence, and subsequent experience has confirmed the idea. Since then I have every year employed mercurial frictions in a great number of cases, and have long since come to the conclusion that they possess little or no efficacy. This being the case, it is better not to resort to this plan of treatment, as there are several considerations which ought to prevent making use of mercurial ointment, unless it be absolutely necessary. It is, generally speaking, disagreeable to the patient, owing to the popular opinion which connects all mercurial preparations with the idea of syphilis. Being also used in large quantities, it may give rise to salivation, and thus render the state of the patient worse than before it was given; indeed, before long it will, I think, cease to be used in the treatment of this disease.

Hogs' lard has been substituted by many practitioners for mercurial ointment. I was also, perhaps, the first who in France used this substance in the treatment of

erysipelas. It was when I began to doubt the efficacy of mercurial ointment, that I first tried hogs' lard, and I was for some time quite surprised at the success I obtained; but I soon found that in reality it did not possess greater efficacy than the remedy I had previously employed. I have since frequently given this substance, but do not now consider it to be of any use as a remedial agent, unless as a means of keeping the skin soft, and preserving it from the contact of the air. Indeed it is by no means improbable that the irritation to which it may give rise often favours the progress of the erysipelas. Had I to choose between mercurial ointment and hogs' lard, I should certainly prefer the latter remedy; not that I believe it to possess greater efficacy, but because it does not expose the patient to those inconveniences which often follow the administration of mercurial preparations.

Camphor, pulverised, and thrown lightly on the part affected, has been used by some practitioners against erysipelas. M. Malgaigne says he has employed it in this manner with great benefit to his patients. I do not, however, feel inclined to place much confidence in its properties.

Some surgeons have applied *compression* in the treatment of simple erysipelas. Judiciously managed, compression is a powerful remedy against simple inflammation, but I do not consider it to be of much avail in this form of the disease. It has been said that I was the first to employ it against erysipelas; but this is to be attributed to a misconception of what I said on the subject. I certainly did state, in 1826, that compression is an heroic remedy in the treatment of erysipelas, but I distinctly said, at the same time, that I was speaking of the phlegmonous or subcutaneous form of inflammation only; I had, indeed, at that time, some idea that it might, perhaps, be efficacious in the simple form of the disease, but experience has shown me that this is not in reality the case; I have frequently tried it, but the erysipelas has nearly always escaped from underneath the bandage.

Blisters have been a favourite remedy with many practitioners. They were often employed by Ambrose Paré, and were much resorted to in Spain during the last century. They were but little known in France some thirty years ago, and were introduced into practice by M. Rodemel, who spoke of them in his Thesis, and by Antoine Petit, of Lyons. Dupuytren, however, told me that he was far from placing that reliance on them that it was asserted he did. I myself have tried blisters in every possible shape, and in every possible manner, large and small, above or below, around or in the centre of

the inflamed surface, and have come to the conclusion that they are of no use whatsoever in erysipelas, properly so called. In cases in which the erysipelas has occupied both legs, I have applied a blister to one and not to the other; and I have seen its course arrested on the one only on which the blister was applied. But then, again, on repeating the experiment, I have seen the reverse occur. Nothing, indeed, seems to be more uncertain than the course of this disease.

Having brought to a close our examination of the local treatment of simple erysipelas, I will recapitulate my opinions in a few words. I do not believe that any local remedy with which we are now acquainted can extinguish simple erysipelas, and I even doubt whether there be any capable of arresting its progress. The only local treatment, therefore, which in the present state of science the disease requires, is the application of linen steeped in a decoction of marsh mallows, or slight frictions with hogs' lard. When the skin is very delicate a little fine flour may be used to protect it from the action of external agents.

If such is really the value of these various agents in the treatment of simple erysipelas, how is it that we find them lauded and recommended in the works of numerous talented men who have written on the subject? They cannot always have been mistaken with regard to the treatment they employed. The examination of the treatment of those affections which are confounded with erysipelas will, perhaps, throw some light on this part of the question.

TREATMENT OF PHLEGMONOUS ERYSIPELAS.

The inflammation in phlegmonous erysipelas occupying a tissue which very soon becomes modified, the treatment must necessarily be energetic. The remedies which are generally directed against this affection are the same as those which I have mentioned in speaking of the treatment of simple erysipelas, and as several of them are extremely useful agents we must again pass them in review.

Bloodletting has always, and very justly, been considered an important feature in the treatment of phlegmonous erysipelas. When the patient is strong and robust it is proper to bleed from the arm; when, on the contrary, he is weak and emaciated, recourse must be had to leeches. It is well, however, not to place too much reliance on the efficacy of local depletion, especially when the inflammation occupies a considerable surface, as we have, in the first stage of the disease, a much more efficacious plan of treatment at our disposal, when, at least, the form of the part

affected is such as to allow us to employ it, viz. compression. If applied before mortification of the cellular tissue has taken place, or before a certain quantity of pus has been deposited between its lamellæ, it often entirely destroys the inflammation. Nor need we be deterred from adopting this plan of treatment when pus has been formed, by the fear of increasing the inflammation, as even then compression is useful. It destroys the inflammation in those parts in which suppuration has not yet taken place, and thus tends to circumscribe the purulent collection. In cases of this kind, however, we must not attribute the formation of matter to the compression, as a person prejudiced against the remedy would be very apt to do. Some few months ago, we had in our wards a man who, owing to a fall, had violently sprained his ankle. The opening of an abscess which had formed near the internal malleolus, was followed by the appearance of phlegmonous erysipelas, which began to spread rapidly. As there appeared every probability that the inflammation would extend to the articulation, I determined at once to try compression, and had both the foot and the leg bandaged, leaving only the wound exposed. The next day, not only the local inflammation, but also the general symptoms, had considerably abated, and in the course of a few days the phlegmonous erysipelas had entirely disappeared. In fine, I believe compression to be a most valuable remedy in this disease; but one which, like all other mechanical plans of treatment, depends in a great measure on the person who applies it.

You will no doubt remember that I told you that blisters were of little or no use in the treatment of simple erysipelas; but this is not the case in the phlegmonous form of inflammation, against which they are employed by many practitioners. They are generally placed in the centre of the inflamed part, with a view to fix the purulent collection to the spot where they are applied, and thus to change the diffusive inflammation into a circumscribed phlegmon. Having repeatedly adopted this plan without any beneficial result to the patient, I modified it by substituting very large blisters for the small blisters which are generally used. The very idea of the immense blisters to which I have recourse sometimes creates alarm in the minds of those who have not seen them employed, but there is, in reality, nothing to warrant such a feeling; the pain which they cause, contrary to what might be expected, is not much greater than that which is occasioned by blisters of the usual size. I have, I believe, in several instances, saved the life or the limb of my patient by adopting this

plan of treatment. I remember very well a case of this kind which occurred in my wards last year. The patient, an old man, of a weak constitution, was affected with phlegmonous erysipelas, extending over the leg and part of the thigh, and was in a very critical state. As it was impossible to have recourse to general bleeding, I applied an immense blister on the entire leg and thigh, in the form of a pantaloen, and the patient was cured.

When recourse is had to cauterization in phlegmonous erysipelas, it is necessary that the entire thickness of the skin should be acted on; superficial canterization with the nitrate of silver would be of but little use in a disease the seat of which is underneath the integuments. M. Baudens says that he has employed the actual cautery in Africa with great success. He uses an olive-shaped cautery, heated to whiteness, with which he cauterizes the skin in ten or twelve places. M. Larrey employs the cautery in the same manner, but uses a differently shaped instrument. I have several times adopted this plan of treatment in very severe cases, but always lost the patients. It does not, however, follow that the cauterization had any share in their death. I think it may prove beneficial in the first stage of the disease, but as there are other remedies in which greater confidence may be placed, I have not since resorted to it. Incisions have always formed part of the treatment of erysipelas, from the days of Galen, who distinctly alludes to them; but these incisions, when not made to evacuate the pus which might have formed, were slight, and consequently can only be looked upon as a modification of local bleeding. In the present century deep incisions have been made merely with a view to arrest the progress of the inflammation. Since the year 1810, M. Beauchere has had recourse, with great success, in the treatment of this affection, to numerous incisions, which entirely divide the skin. In 1828, I saw him, in a case of amputation of the thigh, make numerous incisions on the stump which had been attacked with phlegmonous erysipelas. I was rather surprised at the audacity of the treatment, for it certainly appears rather a singular way of diminishing inflammation, to make ten or fifteen deep incisions in the part inflamed; but on the following day I found the man much better. Since then I have very often had recourse to these incisions, and have found the remedy heroic. Whenever, therefore, you think that compression or the application of blisters will not prove sufficiently powerful agents to arrest the progress of the inflammation, you must resort to incisions without hesitation. As, however, patients, and especially women, are not very partial to this

mode of treatment, it is well not to adopt it unless it will be really necessary. The incisions must be an inch or two in length, and ought entirely to divide the skin; they must be made wherever the inflammation seems to extend. No fear need be entertained of carrying them too far, if we are guided by this rule, as the subcutaneous cellular tissue is always mortified when the skin becomes red, and if an opening is not made with the bistoury, nature will herself make one at last, but not until the skin has been separated to a considerable extent from the tissues underneath.

I might mention several other remedies, but as they are of no importance I shall abstain from so doing. What indeed can poultices, ointments, &c., effect in a disease of the nature of phlegmonous erysipelas? We must, however, make an exception in favour of mercurial ointment. This substance may possibly modify the disease during the inflammatory stage; still, for my own part, I must confess that I place but little reliance on it. Suppuration has or has not taken place. If it has, frictions with mercurial ointment will not cause the pus to diminish, and if it has not, compression is infinitely preferable, when it can be resorted to, or blisters when it cannot.

With regard to internal medication there is but little to say on the subject. You have merely to follow the general rules which guide us in the treatment of disease.

From what I have just said, you will perceive the various plans of treatment recommended against erysipelas; now find their application: that they are not to be entirely laid aside, but merely applied to the treatment of the disease, against which they are really beneficial.

Treatment of angioleucitis.—Angioleucitis is a very common complaint, and one which has often been confounded with external phlebitis and simple erysipelas. Indeed, there can be no doubt that many pretended cases of erysipelas or phlebitis, cured by the application of leeches to the ganglions of the groin, were merely cases of angioleucitis.

When there is nothing specific in the affection, its course may be arrested, or the inflammation may even be completely destroyed, provided it can be attacked at the commencement, before suppuration has taken place. In the first period of the disease, in the period which is marked by rigors, heat, thirst, &c., copious general bleeding must be resorted to, and abstinence from all food must be enjoined. The patient must also introduce into the economy large quantities of some non-irritating liquid. Locally, pledgets of linen, dipped in a decoction of marsh-mallow or elder flowers, may be applied.

If, although the general symptoms are slight, the ganglions, to which the lymphatics of the part affected direct their course, become tumefied and painful, leeches should be placed on them. When the limb, which we will suppose to be the seat of the inflammation, presents not only red ribbon-like streaks, but also patches of inflammation, formed by circumscribed hardened portions of the integuments, from thirty to forty leeches must likewise be applied on these inflamed patches. If they are superficial, and occupy the leg, the foot, the arm or the forearm, compression may be resorted to, and is then nearly as efficacious as in phlegmonous erysipelas. Mercurial ointment is also really useful in this disease; indeed, I am inclined to believe that many of the cases of erysipelas, which are said to have been cured by mercurial ointment, were merely cases of angioleucitis.

Blisters may be employed when the disease has existed long enough to lead us to believe that suppuration has actually occurred. When this is the case we cannot expect to derive much benefit from the other measure that I have just mentioned, and as blisters both favour the resolution, when it is still possible, and hasten the formation of purulent collection, when resolution is no longer to be looked for, they are evidently indicated.

PHLEBITIS.

External phlebitis may be arrested in its progress, and effectually cured by judicious treatment; a result which it is of the greatest importance to attain, as, although in itself by no means a serious malady, it may lead to an extremely dangerous one—internal phlebitis. No surgeon, indeed, can be free from anxiety, when he knows that he has under his care a patient affected with inflammation of several large veins, as he must be aware that he is on the brink of a precipice; energetic measures must therefore be resorted to. All that has been said respecting the treatment of angioleucitis will also apply to the treatment of this affection. Thus, at the commencement, general bleeding is often indicated; in many cases, however, the application of twenty or thirty leeches will prove sufficient. Even when general bleeding has been resorted to, it is often necessary to apply leeches along the course of the inflamed vessels. If, after these measures have been adopted, the inflammation still persists, mercurial frictions may be tried. Compression, if equally applied, is also serviceable. Uniform pressure may be attained by means of a bandage, provided the inequalities which exist are filled up with lint or pledgets of linen. Hunter advises the compression to be established above the vein, but such a plan of treat-

ment is altogether indefensible. It is not by the strangulation of a vein that we can hope to arrest the inflammation of which it is the seat. Indeed, it is very doubtful whether Hunter, with his wise and cautious disposition, had ever had recourse to the plan which he recommends. Some practitioners advise the vein to be divided above the part inflamed, but the operation would be attended with considerable danger, as it might give rise to internal phlebitis. Beanhene advises scarification of the inflamed issues. As, however, the desired effect is nearly always obtained by the application of leeches, and incisions are seldom submitted to by the patient without great reluctance, I have never adopted this plan of treatment. In America blisters have been much used; they may be beneficial, but leeches still deserve the preference; at least in my opinion.

Although every possible measure calculated to arrest the progress of the disease may have been resorted to, both phlebitis and angioleucitis occasionally terminate by suppuration. When this occurs, the characters which the collection of pus presents are the same as those which are met with in common phlegmon. In phlebitis the abscesses are numerous, small, and developed along the course of the vein, or in the cellular sheath which surrounds it. In angioleucitis they are also numerous, and are found in the red, hard, circumscribed patches of inflammation, which I have already described. In both maladies they ought to be opened early, especially in external phlebitis, as it is rather an alarming circumstance for an inflamed vein to be surrounded by a collection of purulent matter. We have no reason to fear in angioleucitis, as in phlebitis, lest the economy should be poisoned by the pus which is formed; it is, nevertheless, well to make an early opening, by which the pus can escape, as it may make its way between the muscles, and as its presence also increases the suppuration. The incisions ought, in this instance, to be large, as the indurated tissues nearly always contain small caverns, which otherwise are not entirely evacuated. Sometimes, when abscesses of this nature appear small, a large quantity of pus is discharged, whereas in other instances, although they appear large, a comparatively small quantity of pus is found to exist. This may be accounted for, in the first instance, by a large cavern existing under the indurated superficial tissues; and, in the second, by the tissues on which the apparently large abscess rests being indurated. The quantity of the pus is generally greater when it comes from deep-seated parts.

You must not suppose that when the abscesses which occur in angioleucitis have

been opened that the disease is cured. Very often other abscesses supervened, although the inflammation has apparently been subdued. This remark also applies to phlebitis, abscesses often appearing one after the other along the course of the inflamed vessels. In external phlebitis the pus is sometimes of a reddish colour, but whether this is to be attributed to transudation or not, I am unable to say.

When the abscesses have been opened recourse must be had to emollient applications, with a view to diminish the tumefied state of the surrounding parts.

Such is the treatment of these diseases when they occur separately. But in practice we generally meet with them combined. How are we, then, to act when this is the case?

Without losing sight of the treatment peculiar to each affection, you must be guided by their comparative importance, and by the order in which they manifest themselves. Thus, supposing simple erysipelas should make its appearance on a patient affected with phlebitis or angioleucitis, the treatment must be the same as if the erysipelas were not present; no remedy with which we are acquainted appearing to exercise any control over this latter malady. The presence of the erysipelas may modify the prognostic, but ought not to modify the treatment.

Should, however, phlegmonous erysipelas appear as a complication of phlebitis or angioleucitis, your conduct must be very different. The phlegmonous erysipelas being the most dangerous disease, the treatment recommended against it must at once be resorted to. This may be done without the least hesitation, as the various remedial measures which the treatment of this malady embraces, such as blood-letting, compression, incisions, &c., are also of use in the treatment of phlebitis and angioleucitis. The treatment adapted to the most serious disease must be employed, because, strictly speaking, it agrees with the two other affections, whereas the treatment which would be adapted to them is not sufficiently energetic for phlegmonous erysipelas. Should simple erysipelas also be present the treatment would be the same, although the prognostic would necessarily be more serious.

It is by thus entering analytically into the examination of the elements which constitute erysipelas, that we become able to account for the action of the various agents which have been employed against it, and how it is that in some instances they have been successful, whilst in others they have produced no beneficial result whatever.

ON THE CIRCULATION OF THE MATERNAL BLOOD IN THE HUMAN OVUM

DURING THE EARLY MONTHS.

By ROBERT LEE, M.D. F.R.S.

[For the London Medical Gazette.]

IN the second month of pregnancy the ovum consists of the embryo, umbilical cord, amnion, and liquor amnii, vesicula umbilicalis, chorion, placenta, and decidua. The embryo appears to be made up almost entirely of head and abdomen, and the umbilical cord, by which it is attached to the membranes, is thick, short, and transparent. The amnion is a small pellucid sac, which contains the embryo and liquor amnii, and forms the sheath or covering of the umbilical cord. The amnion does not completely fill the cavity of the chorion, and the space between them is occupied by a peculiar delicate reticular texture, containing a gelatinous fluid. As the amnion enlarges this net-work disappears, and the outer surface of the amnion comes into contact with the inner surface of the chorion, and they adhere together. No blood-vessels, absorbents, or nerves, have been discovered in the amnion, although it is probably possessed of all these, like other membranes, and secretes the liquor amnii.

The *vesicula umbilicalis* is situated in the reticular texture, between the amnion and chorion, about an inch from the termination of the umbilical cord in the placenta. It is a small spherical-shaped sac, which contains a white opaque fluid, and from it there passes a duct which can be traced along the cord to the navel of the embryo, and from thence to the duodenum, which it probably enters. An artery and vein, from the superior mesenteric artery and vein, accompany the duct of the vesicle, and ramify upon its outer surface. These and the duct soon shrink, and become completely impervious.

The *chorion* is the middle membrane of the ovum. It is uniformly thicker and stronger than the amnion, and no blood-vessels have been seen in it. Its whole outer surface is covered with villousities, which arise from it by slender roots, and spread out like the branches of a tree under the decidua, which they are firmly united. The villi are most luxuriant on that side of the cho-

tion where the placenta is beginning to be organized; but every where they exist, and are united together at their summits or extremities, and are so interlaced that they form a great reticular tissue under the decidua, or between the outer surface of the chorion and inner surface of the decidua. The villi often terminate in irregular-shaped bulbous enlargements, and from their sides long smooth filaments pass off to connect them with one another. The villi of the chorion do not run in pairs like blood-vessels, and they have never been injected. Viewed through a microscope they resemble a mass of small, smooth, convoluted intestines, and do not appear to be hollow. They are probably membranous processes sent out from the chorion to the decidua to assist in forming the placenta, and to constitute a great cellular structure between the decidua and chorion, for maternal blood, in that part of the ovum to which the placenta does not extend. Between the roots and branches of the villi are large cells or spaces formed, which all freely communicate together, and also with the cells or interstices of the placenta, which at this early period are essentially the same as the cells of the chorion, and have no septum interposed between them. If ova expelled in abortion, with the membranes entire, be examined, the cells of the chorion and placenta are always found distended with fluid or coagulated maternal blood. If a blow-pipe be introduced into the cells of the placenta or chorion, it passes all round the ovum, and fills the whole space between the decidua and chorion: injections do the same. That it is maternal blood which distends the cells of the chorion and placenta is evident from this—that some morbid ova have the membranes formed without the embryo, or only with the umbilical cord, and a few small tufts of vessels, at its extremity, and that in some of these malformed ova the villi of the chorion have been fully developed, and all their cells, and those of the placenta, distended with maternal blood in a fluid and coagulated state. So invariably have the cells of the chorion been seen filled with blood, in ova expelled before the third month, that it is more than probable they are never filled with any other fluid. This blood can only enter the cells of the placenta and chorion through the arteries of the placental decidua.

The *decidua* is the outer membrane of

the ovum, and covers it as completely as the shell does the hen's egg. That portion of it which covers the placenta is called the placental decidua. At the circumference of the placenta it separates into two distinct membranous layers, which extend over the whole of that part of the ovum which is not covered by placental decidua. The outer of these layers of decidua is termed the uterine decidua, the inner layer the decidua reflexa, and between these there is always a large cavity called the decidual cavity. At the edge of the placenta, the placental decidua always divides into two distinct layers, between which there is a smooth cavity, the outer wall of which is formed by the uterine decidua, and the inner wall by the decidua reflexa. The outer surface of the uterine decidua adheres to the inner surface of the uterus, but the inner surface of the uterine decidua is smooth and free, like the pleura costalis. The outer surface of the decidua reflexa is also smooth and free, like the pleura pulmonalis, but its inner surface firmly adheres to the extremities of the villi of the chorion, as the pleura pulmonalis does to the substance of the lungs. Dr. Hunter's description of these layers of the decidua, and of the decidual cavity, is most accurate; but he assigned no uses to them, and does not seem to have suspected that the circulation of the maternal blood, in the early months, is carried on chiefly by the uterine and reflected deciduous membranes, and by the cavity formed between them.

The *placental decidua* is a thin delicate membrane which covers the whole uterine surface of the placenta, and, in the second month, is intimately connected with the villi of the chorion, which, at this period, constitute the greater part of the placenta. In a recent ovum, numerous small white curling arteries, filled with blood, are visible in this portion of the decidua. These arteries usually project a little beyond the surface of the placental decidua, and the orifices with which they had anastomosed, with the arteries in the lining membrane of the uterus, are very distinct. These arteries are seen in the placental decidua filled with blood, at the end of the ninth month, subsequent to labour, and during the whole period of pregnancy. They convey the blood from the arteries into the interstices of the placenta. Ellipti-

cal openings can also be seen in the placental decidua, which anastomosed with the oblique venous apertures in the lining membrane of the uterus. A communication is formed by these openings between the cells of the placenta and the veins of the uterus. As no arteries can be discovered in the uterine decidua in the second month, it may be inferred that the maternal blood enters the ovum solely by means of the arteries in the placental decidua. About one-fourth part of the ovum, in the early months, is covered with placental decidua, the remaining three-fourths being invested by the uterine and reflected deciduous membranes.

The *decidua reflexa*, when examined after the uterine decidua has been wholly cut away around the edge of the placenta, is very thin, and numerous small openings, with smooth edges, are every where visible in it; but they exist in greatest number near the edge of the placenta, where an angle is formed between it and the uterine decidua. Here, as Dr. Hunter has observed, the decidua is often extremely thin, and perforated with small openings, so as to look like a piece of lace. These openings in the decidua reflexa communicate with the cells of the chorion and placenta. I have filled all the cells of the chorion and placenta with air, mercury, and size, by means of a pipe introduced into one of these openings in the decidua reflexa, and, after the cells were filled, the air and injection have passed back through the surrounding openings in the decidua. Through an aperture artificially made in the decidua reflexa, the same has taken place; and in recent ova, by slight pressure, the blood contained in the cells of the chorion has readily flowed through the openings in the decidua reflexa. I have several preparations in which coagula of the fibrine of the blood are seen hanging out of these orifices in the decidua reflexa; and these could not have been formed if the blood had not been flowing from the cells of the chorion, through these openings, before the coagulation took place. The decidua reflexa is covered by a fine membrane-like epithelium, which is also reflected over the whole inner surface of the uterine decidua, and passes into the apertures in both membranes. This resembles the serous membrane of cavities containing blood. This fine membrane lining the whole

decidual cavity can be dissected off, and its existence clearly demonstrated. In several of my preparations this has been done both from the outer surface of the decidua reflexa, and inner surface of the decidua uteri, and I have had drawings made from these.

The outer wall of the decidual cavity is formed by the *uterine decidua*, which varies much in thickness. The outer surface of this portion of the decidua, which had adhered to the uterus, is usually very irregular, and long slender filaments from thick roots are often seen projecting from it: some of these filaments appear to be hollow. A great number of openings are also visible on the outer surface of the uterine decidua, which are the terminations of venous canals which pass obliquely through this membrane from the smooth inner surface or outer wall of the decidual cavity. Small sacs, with apertures in their sides or summits, as figured and described by Dr. Montgomery, are also frequently seen growing from the outer surface of the decidua uteri: these are smooth within, and a communication can often be traced between the interior of these sacs and the veins of the decidua. I have not been able to discover any arteries in this portion of the decidua similar to those I have seen in the placental decidua. The inner surface of the decidua uteri is comparatively smooth, and, seen through a magnifier, appears not unlike the convolutions of the brain: at the bottom of these are deep grooves or depressions, in which are situated numerous minute apertures of a circular or oval form. There are some of these openings on the raised portions of the membrane as well as in the grooves; into these openings the epithelium which lines the decidual cavity passes, and coats the venous canal in the decidua uteri. These veins pass obliquely through the membrane; they frequently communicate together so as to form a great plexus, and gradually increase in size as they approach the uterine surface. I have seen the decidua uteri adhering through its whole extent to the inner surface of the uterus in the second month, with all these veins distended with firm dark clots of blood. On separating the membrane gradually, these coagula were seen passing from the decidual veins into the veins of the uterus. The trunks of these veins were on the uterine side of

the membrane, and they had evidently been conveying blood from the decidual cavity to the veins of the uterus. All the veins of the uterine decidua, in several ora which I possess, are filled with coagula of the fibrine of the blood, and by following these the course of the veins from the inner to the outer surface of the membrane can be traced. Mr. Joseph Toynbee has filled all these veins of the uterine decidua with injection, and by these also the direction of the vessels, and their connection with one another, and their termination on the outer surface of the membrane, can be clearly perceived. It was by observing the manner in which coagula of the fibrine of the blood passed through the placental decidua into the veins of the uterus, and by following coagula from fibrous tumors of the uterus into the blood-vessels of the organ, that I first became acquainted with the precise manner in which the circulation of the blood is carried on in the placenta, and in fibrous tumors; and it was likewise by tracing the coagula which occasionally distend the veins of the decidua uteri that I was first led to suspect that these vessels do not convey blood or fluid of any kind from the uterus into the decidual cavity, but remove from this cavity that blood which had passed into it, through the openings in the decidua reflexa, from the cells of the chorion.

I had very lately sent me an ovum of two months, which had been expelled with all the membranes entire. The decidual cavity was filled with blood partly fluid and partly coagulated. Clots of the fibrine were hanging out of the orifices of the canals in the decidua reflexa. The blood could not have been forced into the decidual cavity by any accident, as Breschet alleges was the case with the ovum described by Heusinger, where the decidual cavity was likewise full of blood.

INVERSION OF THE UTERUS.

“REMEMBER, therefore, should inversion occur to you, (which I hope it will not, for its occurrence is not creditable,) remember, I say, that it is your office, as soon as you recover the accident, to replace the organ without the delay of a moment.”—DR. BLUNDELL, *Lancet*, vol. ii. p. 547.

“Whenever this serious accident (inversion of the uterus) has happened, (which, as it must always be the consequence of improper treatment, I trust will never occur in your hands), it may be known, &c.”—DR. F. H. RAMSBOTHAM, *Medical Gazette*, No. 48, August 30, 1834.

To the Editor of the Medical Gazette.

SIR,

AFTER the strong language of condemnation indulged in by the authorities above quoted, as well as by others whose opinions I have read, but have not considered it necessary to quote, it requires some moral courage and honesty of purpose to publish a case of inversion of the uterus; but I regard such remarks as hypothetical flourishes, sounding perhaps very bravely in a lecture room, but, like too many others, to be proved erroneous in practice.

They remind me of a statement which I once heard a London lecturer make, with great energy of manner, when he was on the subject of hæmorrhage occurring after labour: “If,” said he, “the patient breathe after you enter the room, and die of hæmorrhage, she dies a murdered woman!!!” And yet, (as I told him,) Smellie, Denman, Haighton, *ethoc genus omne*, including our modern illuminati, have witnessed such fatal terminations, and have escaped the inquisitorial impertinence of forensic examination.

Dr. Ramsbotham, after the remarks above quoted, goes on to observe, “For this purpose, (the replacement of the uterus,) the hand being half shut, the knuckles are to be pressed firmly against the most depending point of the tumor; when the part will yield, the fundus will pass up with a sort of jerk. Unless this restoration be effected within a few minutes of the time when the accident took place, I should presume either that the uterus could not be reduced at all, or that the hæmorrhage must be excessive.”

From this, of course, I am to infer that Dr. R. has experienced this “jerk;” and as it must have been “within a few minutes” of the occurrence of inversion, I also infer that this “improper treatment” happened in his own practice, and not in a consultation case; for I do not suppose that the assistance of a second person could be secured within the brief space of time here mentioned.

M. C. æt. 22, was attended by me in her first labour, August 4th, 1840. The labour was natural, and occupied only a few hours. She was delivered in a recumbent position; no secale was given, or other artificial means used: the liquor amnii was in very small quantity, and the membranes ruptured spontaneously just as the head was passing through the vulva. The child was very small, and, as it was weakly, the funis was not severed for about ten minutes; but as it was very long, and not kept tense, no dragging of the placenta could have been experienced.

As soon as the funis was divided, I felt the abdomen for the uterus, and found it occupying its usual situation, and not much contracted: a few minutes after she had a pain, and I introduced my finger, and did not feel the placenta; but another pain very soon followed, which made her complain more than is usual after the birth of the child, and the placenta immediately occupied the vagina; it was quite detached, and rested on the perineum, so that I merely had to receive it. As soon as the placenta was removed, I placed my hand on the abdomen to ascertain the state of the uterus, but I could not find it; I immediately examined by the vagina, and found in it a globular fleshy body, which felt exactly like a placenta, passing before the head of a child; I instantly perceived that it was a case of inversion of the uterus, and, without the delay of a moment, set about its reduction, which I accomplished without much difficulty, notwithstanding it had contracted to a small size; but I could not succeed with my knuckles, as advised by Dr. R.; it was pressing on too large a surface, and, consequently, the whole uterus receded before my hand. I then pressed the centre of the presenting part with the flat part of my thumb, which soon occupied a cavity instead of resting against a convexity, and, as it increased in size, my fingers followed my thumb until my hand was in the uterus, which immediately contracted on it.

There was not a severe hæmorrhage during the period of inversion, and that *not by gushes*, and after its reduction scarcely any; but the nervous system was instantly depressed by the inversion, and continued much influenced for about half an hour. There were no symptoms of importance afterwards.

I can easily imagine how *likely* inversion of the uterus is to happen from "improper treatment," by pulling at the funis, or from the other circumstances mentioned by authors; but this is not the question: *Can* it occur spontaneously, or altogether independent of the conduct of the practitioner, good or bad? I now say *IT CAN*; and this brings me to remark on the impropriety, as well as the injustice and cruelty, of authorities using such strong language of censure on merely *supposed* cases—language which may be quoted, and used as evidence, to the injury of a man's reputation when he is blameless.

I conclude by impressing the necessity of *always* examining over the abdominal coverings after delivery is completed, for the state and situation of the uterus. This, in reference to the present case, has saved me much mental distress; and I well remember, about fifteen years ago, a case which happened to a gentleman of long standing in the profession, and of deserved reputation: the delivery was completed, he went down stairs, congratulated the husband, and sat down to some refreshment: whilst taking it the nurse hurried into the room crying for aid; he ran up stairs, but the patient was in a few moments dead! It was a case of inversion of the uterus.

One last remark. It seems a work of supererogation to say, with Blundell, "as soon as you discover the accident, it is your office to replace the organ;" but I would again enforce the necessity of always making such an examination after labour as must necessarily detect this or any other important condition of the uterus, excepting laceration.

I have the honour to be, sir,

Your obedient servant,

JAMES HURD.

Yatton, Bristol, August 13, 1840.

HÆMORRHAGE FROM THE CONJUNCTIVA.

To the Editor of the Medical Gazette.

SIR,

THE following cases of hæmorrhage from the conjunctiva, although presenting but little of practical importance, may yet be deserving of publication as curious pathological occurrences.

Your obedient servant,

EDWARD HOCKEN.

Exeter, August 12, 1840.

It would seem that hæmorrhages are most likely to occur spontaneously from mucous membranes, being in the generality of cases the result of transudation through the coats of the vessels and the investing membrane, or more rarely from direct rupture of some vascular branch. When depending on transudation, the condition necessarily supposes a pre-existing condition of capillary hyperæmia, which may be either active or passive in its local and general symptoms, with every intermediate shade. As all the mucous membranes are predisposed to spontaneous hæmorrhages, so those are especially so which are most active in their functions, and receive the largest vascular supply: hence the frequency of hæmoptysis, hæmatemesis, and melæna, and the comparative infrequency of hæmorrhage from the conjunctiva. That hæmorrhages occasionally do take place from the conjunctiva the following cases will prove:—

CASE I.—A delicate strumous child, about four years of age, during the spring months of 1838 became affected with a severe catarrh. There was cough, coryza, and slight fever. At the same time both eyes were congested, and there was a slight catarrhal discharge from the conjunctivæ. On seeing the child one morning, I discovered that blood was slowly escaping from between the lids, and learned from the mother that one or two tea-spoonfuls had already been lost. The conjunctivæ presented an ecchymosed appearance. By a gentle local astringent this was readily suppressed, and did not recur during the continuance of treatment.

CASE II.—An infant was brought to the West of England Eye Infirmary, suffering from purulent ophthalmia, which had existed several days; but although there was considerable discharge, yet the corneæ of both eyes were sound and transparent. One morning of admission, the mother brought the child into the room in great alarm, stating that the eye was bleeding. In this case, blood slowly trickled from between the lids, mixed with the discharge. The conjunctivæ were deeply injected, and presented the appearance of ecchymosis as in the former case.

REMARKS. — In both these cases hæmorrhage was the result of active congestion, and connected with a mor-

bid increase of secretion from the mucous tunic, the membrane being placed for a time in that condition which I have before stated as predisposing to hæmorrhage by transudation. Although I have not met with a case, yet I have no doubt that a passive transudation might result from the conjunctiva in those conditions of the system where hæmorrhages take place from so many parts of the body.

FUNCTIONAL DERANGEMENT OF VISION.

To the Editor of the Medical Gazette.

SIR,

THE following case of disordered vision, depending upon functional derangement of organs distant from the eye, is a curious addition to that already too numerous class of affections which, from our ignorance of the minute links in the chain of morbid changes, we are as yet compelled to call "sympathetic." As such it will probably find a place in your valuable journal.—I remain, sir,

Yours, &c.,

THOMAS DORRINGTON.

Manchester, August 11, 1840.

On the 21st of February, 1840, I was sent for in haste to a lady who was stated by the messenger to be about to have a fit. I had been in attendance upon her about a week before to remove a constipated state of the bowels that caused her much pain in the head. She was a widow, of stoutish leucophlegmatic habit, of very lax fibre, great natural indolence, though liable to hysterical excitement, and about 30 years of age. She had suffered from illness which, from what I could gather from her statements, seemed to have been characterized by violent hysterical symptoms, for about a year, but had been convalescent for some little time before I first saw her.

She told me when I arrived that she had been seized with a "queer" sensation about the head just before she sent for me, and that she found a change in her sight, of the following sort, occur at the same time: When she looked with both eyes at objects, they seemed inverted and misty; but when she closed either eye, she could see naturally and clearly with the other. Her face seemed

a little flushed, and her pulse was about 98; she had no pain, but a confused feeling in her head. All these feelings had supervened suddenly whilst she was sewing. On inquiry I found that her bowels had been constipated for two or three days. Whilst I was with her the vision was restored to its natural state, and the feelings of confusion in the head left her. She remained quite comfortable for two hours, at the end of which time she went to bed. I prescribed an antispasmodic draught and purgative, after having assured myself that there were no symptoms which could be looked upon as premonitory of apoplexy in the case.

22d.—When I saw her to-day, she complained of the same derangement of vision as that which induced her to send for me yesterday evening. The purgative was ordered to be repeated, as the bowels had been very slightly moved.

Evening.—Her vision was still disordered, but in a different way. When she looked with both eyes at an object, she now saw dimly an object and a half; the superadded half being rather lower, less distinct, and to the right side of the whole object, and seeming at its edge to become diffused and lost in it. When she looked with either eye, having closed the other, she saw objects correctly, but they were not quite so clear as natural. She had no pain any where, but a sort of confused feeling in the head again. The eyes were quite natural in appearance, the irides acting perfectly. The pulse was 96, and the cheeks rather flushed.

She remained in this state for two days, her bowels being moved very slightly, though active purgatives were administered regularly during the time.

25th.—She still had a degree of disorder in her vision, but it was only that she saw indistinctly when objects were three or four yards distant; seeing them perfectly when they were brought near the eyes. Her bowels were acted on pretty freely, a considerable quantity of solid feces being evacuated; pulse 80, and the confused feeling about the head had disappeared.

26th.—She was so much better that I considered her fit to be discharged, although she had still slight dimness of sight. I ordered her to take a couple of aperient pills nightly.

She continued for a few days to be occasionally troubled with dimness of

vision, but soon got entirely rid of her disagreeable complaint.

I have strong reasons for suspecting that we must look upon this case as more or less connected with that protean malady, hysteria; for about two months after I had it under treatment, I received a letter from a medical gentleman in Liverpool, stating that the lady was then suffering from a most severe attack of this affection. The overloaded state of the large intestines, so common in hysteria, the curious morbid changes of sight that occurred, the suddenness of the attack, the intervals of natural vision that occasionally existed during its continuance, and the restoration of the healthy functions of the retinae when the bowels were unloaded, combined with the history of the former illness of the patient, as given by herself, and that of the latter, as given by her medical attendant after she left Manchester, seem distinctly to point to hysteria as the cause of her anomalous symptoms. A satisfactory explanation of the proximate cause of these—viz., the physiological condition of the retinae during their occurrence, can hardly be expected till we understand how an inverted image in the eye produces erect vision in the sensorium.

ADAMS'S IMPROVED HOOK

FOR STEADYING THE EYE DURING THE OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

An important step in the operation is that of steadyng the globe of the eye previously to the collection of the rectus muscle by means of the blunt hook. For this purpose various sharp hooks have been employed; and all operators, at least those who have had sufficient experience, are agreed on the advantage and necessity of an instrument of this kind, though to most of the hooks which have been hitherto used the serious objection offers itself, that they produce a distressing pain by pressure on the globe, and even thereby occasion sometimes sickness and fainting. In order, then, not to forego the advantages of a sharp hook, and at the same time to obviate the injurious effects, I venture to propose, with a con-

sidence resulting from repeated trials, a hook, the form of which, whilst it relieves the patient of the ill effects of pressure on the globe, facilitates the fixture of the globe with the least possible injury to the tunics of the eye, the sclerotica included.

The hook, or tenaculum, of which a figure is annexed, was made by Weiss. It consists of a slender stem, an inch and a half long, fixed in a handle of the length of four inches. The stem is bent near the point at an acute angle, so that the returning part, which forms the hook, is one line in length, and its extremity at the distance of half a line from the stem.

The use of this instrument I would, then, suggest to the profession; and it will be seen that the hooked part of the stem is bent upon itself at such an angle as to require its introduction into the sclerotica, not by a sudden thrust at a right angle with its stem, but by a gentle motion in a line with the direction of the handle of the instrument, and so as to enter the sclerotic obliquely, thus rendering all direct pressure on the globe unnecessary, as the motion is to draw the eye outwards, and not to press it backwards.

The acuteness of the angle of the improved sharp hook, and the shortness of its reflected extremity, are a sufficient protection against its being thrust through the sclerotica.

That it facilitates the operation, by bringing the parts more directly under the eye of the operator; that it gives him a perfect command over the motions of the globe, which must otherwise be difficult to control; and that it lessens pain by allowing all the steps of the operation to be conducted within view, so that there is no danger of inflicting unnecessary injuries in parts out of sight; are facts too self-evident to need further comment.

I may add, in conclusion, if there be one thing more necessary than another towards the success and safety of all operations on the eye, it is the being able to obtain the utmost steadiness of the organ by such means as shall cause the least pain, thereby rendering the operation more supportable, and less

liable to the accidents of resistance on the part of the patient.—I am, sir,

Your most obedient servant,

JAMES J. ADAMS.

27, New Broad-street, City,
August, 1840.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

On the Nature and Structural Characteristics of Cancer, and of those Morbid Growths which may be confounded with it. By JOHN MUELLER, M.D., &c. Translated, with Notes, by CHARLES WEST, M.D., &c. Part I. 8vo. pp. 182.

[Concluded from page 770.]

FROM this description of the several varieties of carcinoma, the author proceeds to the consideration of their development and softening. The former, we have already said, exactly accords with the laws deduced from the development of healthy tissues, and may be understood from the earlier part of this abstract; the latter, which is the result of inflammation, is the precursor of the ulcerated state of cancer. It may occur first in any part of a tumor; either in its centre, when the softened matter, which more or less resembles pus, occupies cavities in the interior of the mass; or on its surface, when the different elements of cancer are discharged from an ulcer, from which there commonly shoots forth a cancerous fungus.

The examination of the chemical characters of the different kinds of carcinoma shews that the greater part of the material of which they are composed is a substance similar to albumen, and insoluble by boiling. The gelatine they sometimes contain is only dependent on the cellular tissue in them. Caseine and fat are also occasional, but by no means essential constituents.

The ultimate conclusions at which the author has arrived may be thus briefly stated.

1. Carcinoma differs from simple induration not only in its nature, but also in its structure.

2. It differs also in its nature from ulceration of indurated parts.

3. It is no heterologous substance, and the minutest elements of its tissue do not differ in any important respect

from the constituents of benignant growths, and of the primitive tissues of the embryo.

4. Neither does it (independently of the sanies) possess any peculiar chemical constituents.

5. The peculiar nature of the destructive and productive activity of carcinoma does, however, determine in it general anatomical characters which may, in most cases, be distinguished with the naked eye, especially the destruction, or transformation into the same new mass, of all the adjacent tissues.

6. The development of carcinoma is the result of a diseased state of the vegetative process, which, whether general or local in the first instance, always tends to involve the whole constitution.

7. Although in most instances a general disposition to carcinoma exists from the time of its commencement as a local disease, yet it must be owned that a local disposition may give rise to carcinoma, which may afterwards contaminate the whole constitution; and this local disposition has been proved to be, in some instances, the result of certain external agents. (This conclusion is especially supported by the phenomena of chimney-sweepers' cancer, which would appear to be much more clearly known in this country than in Germany.)

8. Some tumors which by nature are not carcinomatous, and part of the character of which it is to remain local, may, under certain circumstances, originate the local disposition to cancer.

9. Many structures differing from carcinoma have, on the other hand, even though repeatedly mismanaged, no inclination to assume the cancerous disposition; or perhaps they may be more correctly said to have no greater disposition to pass into the carcinomatous state than is possessed by many other healthy tissues.

10. Each form of cancer occurs in persons of all ages and in all organs; but some organs appear to be especially liable to carcinoma at certain periods of life.

Such are the statements, each of which are supported by apposite illustrations, with which the first part of the work is concluded. The results of this portion of the author's investigations, if they do not go to establish any very important general principles, yet show what may be expected in this direction of inquiry,

in which he has at least the honour of being the first to make any way. It was scarcely to be expected that the microscope or chemistry should discover the essential nature of cancer; it must be sufficient if they have established more nearly its diagnosis from other growths, which differ from it as widely in their nature as, to the unassisted senses, they have hitherto seemed like it. This, however, is possible only by the same methods of investigation being applied to each other variety of tumor as to cancer itself. The results of such investigations form the second part of the work, which commences with the account of cartilaginous tumors, enchondroma, or chondroid sarcoma.

Enchondroma is a fungoid growth proceeding from bones or from soft parts, as, for instance, from glands, and curable by amputation. It forms a spheroidal, not lobulated tumor, which, when it appears in soft parts, is furnished with a thin covering resembling cellular tissue, but which, in the bones, where its occurrence is more frequent, retains the periosteum as its investing membrane. This disease presents itself as a soft expansion of the bone, developed either within its interior, or, more rarely, from its periphery. The articular surfaces of the bones are usually but very little altered by this disease; often they are not at all affected, even in instances in which the tumor has acquired a very large size, and it is very rare for the disease to advance beyond the articular surface, or for two tumors, when they arise from adjacent bones, to become confounded.

Enchondroma is usually developed slowly, and without pain or injury, more than that caused by the distension, to the surrounding soft parts. Its contents are soft, usually mixed with small spiculae of bone, and, when cut through, it commonly displays two constituents: a fibro-membranous substance, and a grey pellucid substance like cartilage or very firm jelly, or the hyaloid cartilage of cartilaginous fishes. The former forms both the large and small cells, which contain the latter, in friable and easily removeable masses. The intervention of the membranous structures with the masses imparts to enchondroma a conglomerated appearance, which does not occur in any other form of exostosis, and which is indicated by the slight inequalities which may be seen on its surface.

The fibro-membranous part appears under the microscope to be composed of an interweaving of transparent fibres; the hyaloid masses are in every respect precisely similar to true cartilage, and the whole tumor would exactly resemble a mass of cartilage, but for the membranous structures by which it is intersected. So close is the similarity, or, as it may be termed, the identity of the transparent parts of an enchondroma of the bones, and cartilage, both in microscopic structure and in chemical composition, that we pass over this portion of the work, which merely illustrates their common characters, and resume it at the history of the development of this variety of growths. There appears also in this respect to be a close analogy between it and cartilage; the chief, if not the only real difference, being the persistence in the morbid cartilage of that cellular structure, which exists in the embryonic state of the natural; a circumstance which, as already mentioned, is also illustrated in the formation of many other tumors. The most remarkable circumstances connected with these growths are the great length of time that they may exist without producing any serious mischief, (upwards of thirty years for example), the almost complete absence of pain, and the absence of any degeneration of the surrounding parts. When inflamed, as they may be in consequence of the distension of the neighbouring parts or of injury, they become painful, burst, and suppurate, and often excite necrosis of the bone on which they are situated; but, except by their irritation, they do not appear, even in this state, to affect the constitution.

The local causes of enchondroma are serious injuries to the vitality of the bones, and, in many instances, mechanical violence; but, in some cases, it cannot be regarded as a purely local disease affecting the bones, since it affects numerous parts of the osseous system coincidentally, and proves itself to depend on the existence of some general cause. Enchondroma occurs most frequently during childhood, as scrofula does, though there is no reason to believe that the same diathesis tends to the development of both. Its removal from the body is never followed by a return of the growth.

The diagnosis of enchondroma may be perfectly established. It has no resemblance in structure to any variety of

cancer of bone; albumen forms the basis of all of them, while it yields chondrine. If medullary cancer is developed in the interior of a bone, it very rarely produces perforation or expansion, as enchondroma does. It resembles scirrhus only in hardness: the contents of the cavities in cancer alveolaris are also widely different, both microscopically and chemically, from the transparent substance in the cells of this growth. Neither can there be any difficulty in discriminating between enchondroma and the fibrous tumor of bone, or the osteoid or bony tumor, or those other albuminous and more or less evidently fibrous growths that pass under the name of osteo-sarcoma, or hydatids in bone, by which its shell is sometimes expanded, as it is in enchondroma.

The next section treats of adipose tumors in three classes, including the varieties of lipoma, of adipose cysts, and of the laminated fatty tumor.

Most specimens of lobulated lipoma resemble in structure ordinary adipose tissue; their cells are of a round or oval shape, and the only distinction between the two consists in the former being made up of a mass of these adipose cells, inclosed by an investment of thickened cellular tissue, while the different lobuli are separated from each other by thinner membranous septa. The varieties are, *L. simplex*, the common fatty tumor; *L. mixtum*, which is of much firmer consistence than the preceding, from the development of strong septa in its interior; and *L. arborescens*, the well-known branching processes that grow into the interior of joints, and especially of the knee-joint.

Adipose cysts include such as are most common in the ovaries, containing fat in globules, or in a fluid state, with hair growing from follicles in their walls, and the cysts beneath the skin, which are formed of enlarged and obstructed sebaceous follicles.

Laminated adipose tumor or cholesteatoma is a non-lobulated tumor, composed of concentric layers of polyedrous cells, which have a lustre like mother-of-pearl. It is of the consistence of tallow, and is usually invested with a thin membrane, which forms a complete cyst. The fat which it contains is not found exclusively within the cells, but is likewise deposited in their interstices.

The mass of cholesteatoma, which the author has seen eight times, is soft,

semi-transparent, of the colour of white wax, but glistening, like mother-of-pearl. When dried it shrinks much, and becomes yellow. Its laminae are usually not thicker than the finest paper, and in most cases are arranged concentrically, and are easily separable. The tumors are generally more or less round or oval, with small nodules on their surface.

With the microscope the finer elements of cholesteatoma are found to be a cellular tissue composed of irregular polyedrical cells, like pigment cells, which constitute the laminae, and a crystalline fat deposited in the interspaces between those laminae. The cellular tissue is somewhat similar to the polyedrous cellular tissue of the fat of the sheep; they are easily separated, and when isolated are very transparent and pale, not containing either nuclei or granules: their basis is formed by an animal matter quite distinct from fat, and not at all soluble in either alcohol or ether.

The crystals between the layers of cells are of two kinds, tabular and lamellar; the former are most numerous, and they vary considerably in both length and breadth; they probably consist of pure cholesterine. The others are collected into little bundles of lamellae, like aciculae of stearine, but their real form is that of lamellae.

All parts of the body appear to be liable to cholesteatoma; it has been found in the bones, in the brain, between the uterus and rectum, in the mammary gland, and in subcutaneous cysts. It is most frequent in the brain; it occurs either in cysts, usually formed of very fine fibrous membrane, or on the surface of ulcers, as in urinary fistulae, in which it was twice found by M. Dupuytren.

Cholesteatoma is destitute of blood-vessels, and its increase probably takes place by the deposit of successive lamellae, as cuticle and the yolk-cells in the yolk-bag do. It is by no means a malignant disease, nor attended with fatal consequences, save in some cases in which its presence in the brain has caused death by pressure.

The last section of the work is on compound cystoid and cysto-sarcomatous growths. On the former the author says, that although he cannot coincide with Dr. Hodgkin in his attempt to extend the principle of the formation of com-

pound serous cysts to explain the structure of sarcomatous and carcinomatous tumors, yet in regard to the formation of the compound cysts which occur in the internal generative organs of the female, his observations perfectly coincide with those of our esteemed countryman. On this subject, therefore, we need make no abstract of Müller's observations; on the next subject also, of cysto-sarcomatous growths, we doubt whether the remarks of Müller will not be in some measure modified when he sees those of Sir Benjamin Brodie, which were lately published in this journal, in an admirable lecture on sero-cystic sarcoma.

Müller applies the name of cysto-sarcoma to such tumors as, while they are principally composed of a more or less firm, fibrous, and vascular mass, are yet invariably found to contain solitary cysts in their substance. They are most frequent in the generative organs; either in the ovaries or near them, in the testicle, and in the female breast. He notices three forms—the simple cysto-sarcoma, *C. proliferum*, and cysto-sarcoma with foliated warty excrescences from its cysts. In the first, the cysts have each their distinct membrane, the inner wall of which is simple and smooth: to this belong several cases described by Sir A. Cooper as hydatid tumors of the female breast. In the second, the sarcomatous mass is the same fibrous texture, but the cysts within it contain younger cysts in their interior, which are attached to their walls by pedicles; a form of morbid growth which may be regarded as a repetition of the *cystis proliferata*, but imbedded in a sarcomatous mass, which constitutes the chief part of the tumor.

The third form, *C. phyllodes*, differs greatly from the other two. The tumor forms a large firm mass, with a more or less uneven surface. The fibrous substance of which it is chiefly composed is greyish-white, and very hard. Large portions of the tumor are made up entirely of this mass, but in some parts are cavities or clefts not lined with a distinct membrane. These cavities contain but little fluid; for either their hard and polished parietes are in close apposition, or a number of firm irregular laminae sprout from the mass, and form the walls of the fissures, or excrescences of a foliated or wart-like form sprout from the bottom and fill up their inte-

rior. The excrescences are perfectly smooth, and never contain cysts or cells. Sometimes they are broad, sessile, and much indented; others have a more slender base, and somewhat resemble cauliflower condylomata. They are always formed of the same firm, apparently fibro-cartilaginous matter, as the non-hydrated portion of the tumor.

The firm mass of the tumor has an indistinctly fibrous structure, but contains neither cells nor cartilage-corpuscles. It is albuminous, and firmer than any other tumor of the same constitution. Such tumors attain sometimes an enormous size, but they are decidedly innocent; they occur earlier than it is usual for cancer to develop itself, and have little tendency to become adherent. They are not disposed to soften internally, but continue to grow, till, having attained an enormous size, they burst, and an ill-looking suppurating fungus forms upon their surface.

Such are the chief contents of this first portion of Professor Müller's work. As the first fruits of the new mode of investigating this most intricate subject, the results must be acceptable to all; and all will grant that, if the results are not such as to have exhausted the greater part of the questions respecting the nature of morbid growths, the fault lies in the difficulty of the inquiries rather than in the incompetency of the observer, who, if it had been in the power of any man living, would have unravelled the whole subject.

We cannot conclude without confirming the praise which has been generally awarded to Dr. West for the excellence of his translation; and we sincerely hope that the abstract we have given will tempt many of our readers to make themselves masters of the whole work.

MEDICAL GAZETTE.

publicum sit, dicendi periculum non recuso."
CICERO.

MANAGEMENT OF THE POOR IN SCOTLAND.

In our number of the 17th of July, we noticed the appearance of a second

edition of Dr. Alison's admirable essay on the management of the poor in Scotland. He has also published another pamphlet, in the shape of a reply to a defender of the present system, where he again advocates the cause of the poor, and shows that it is identical with the true interests of the rich*.

When Dr. Alison undertook the task of convincing the people of Scotland that their national system of charity is essentially defective, and as inconsistent with religion and reason as it is repugnant to the more generous instincts of our nature, he expected to meet with a vigorous opposition; and his expectations were, of course, fulfilled. It is satisfactory, however, to find that the enemies of the proposed improvement have not been able to hit upon any new sophisms with which to perplex the minds of the public; no brilliant economist has arisen, amidst the strife of words, to demonstrate by some fresh argument that private beneficence is very bad, and public charity worse still. In fact, Malthus's hypothesis, that the English Poor Laws were a bounty on population, was so remarkably at variance with facts, that its own parent was obliged to give it up. The other fears of the economists are more easily assuaged; and, as they have not been able to discover any new grounds for apprehension, it is to be hoped that the common sense and good feeling of mankind will obtain fair play in Scotland. One fear, indeed, of your more trembling utilitarian has been knocked on the head by a Poor Law Commissioner, and an Assistant ditto. The apprehension has been insinuated, that if workhouses are made too comfortable, there might be a run upon them; and the practical deduction is, find out the minimum of

* Reply to the pamphlet entitled "Proposed alteration of the Scottish Poor Law considered and commented on; by David Monypenny, Esq., of Pitmilny." By William Pulteney Alison, M.D. F.R.S.E., &c.

food on which the poorest cottager exists, and let the workhouse diet be less. To this Mr. Nicholls answers, that though the inmates of our workhouses are generally better fed than labourers, the irksomeness of the discipline, and confinement, produces such a disinclination to enter them, that nothing short of absolute necessity can compel able-bodied labourers to take refuge there. Mr. Revans goes much farther. He found a workhouse in Nottinghamshire, where the inmates lived in luxury, yet able-bodied persons very rarely applied for admission. How was this? Let the master answer the question. "Oh, sir," said he, "*I keep the key of the door*, and I very seldom allow the able-bodied people to go out, which they don't like; so if they can possibly live out they won't come in." This is exactly what every man of sense would have expected; there never was, and never can be, a run upon the workhouses, and destitution alone drives the poor into these receptacles; yet the half-starvation, and the mean haggling about the little comforts due to age and infirmity, to be found in too many of them, evidently rest on the false assumption, that for the sake of a few ounces of food the poor will voluntarily enter a prison.

When the reasoners of Scotland are convinced that Poor Laws are not a bounty on population, and that workhouses are not dangerously attractive, two great obstacles to the cause of humanity will have been removed;—our neighbours will cease to pride themselves on the smallness of the allowances they grant the poor; and workhouses and compulsory assessments will be seen throughout Scotland.

Whether this salutary change should be effected by a formal extension of the English system to Scotland, or by an improved administration of the Scottish law, Dr. Alison does not profess himself able to determine. The form does not

seem to us of much importance; for even the Scottish system, cold and lifeless as it seems, contains within it the germ of a better method—the statue is in the block, and wants but a Phidias to draw it out.*

It is clear, that, substantially, any real and great improvement must approximate the Scottish system very closely to the English one. Such a change could not be adopted without reluctance by those who have been taught that to drive misery out of sight is a good substitute for relieving it. The Laputan Professor would not willingly have renounced his scheme of extracting sun-beams from cucumbers; and your economist would not easily give up the hope of deriving happiness from Malthusianism. When introducing the poor-law, it would not be necessary to bring in with it any of the uncommendable parts of the old system in England, such as the paying wages out of the rates, or the complex law of settlement, with its attendant litigation. But granting that the abuses were introduced with the uses, what humane man would not prefer the English Poor Law, as formerly managed in the worst parish, to a system which permits aged and disabled persons of good character to linger on through a life of protracted starvation? Mr. R. Chambers, quoted by Dr. Alison, says, "One or two slender meals of porridge or potatoes, with occasionally a little tea, or a bowl of thin broth, form the diet of a day with most of these people. It appears to be a system of protracted starvation." Again, "The female field-labourers get ten-pence a day, which barely suffices to support and clothe them during the time when they have work. In winter, when there is no work, they have no resource but charity. But for

* By the decision of the Court of Session in 1804, the able-bodied poor in Scotland might be relieved by assessment; but this judgment is not acted upon.

the broth pots of their neighbours, they would starve outright."

"Such is the state of the poor in a small rural town in Scotland, under a system of management, which has been often represented as peculiarly calculated to *keep down pauperism*, and, in contrast with which, the English system is believed to be only a monstrous abuse*."

It would be curious to persons not accustomed to economic ways of thinking, to learn that the report on pauperism in Scotland lately made to the General Assembly, though it contains minute details as to the funds raised for the relief of the poor, and the modes of applying them, "does not contain one syllable of information as to the *condition*—as to the habits, sufferings, or privations, either of those who are relieved, or of that large class of equally indigent persons in Scotland [who are excluded from participating in them.]" Pauperism, too, is represented in this report as a disease; and when it amounts to 3 or 4 per cent. of the population, it is called an intolerable burden. It appears, however, from the statement by Mr. R. Chambers quoted above, that, in the small town he describes, during a severe winter, 25 per cent. of the population are obliged to depend on the charity of their neighbours; but the report to the General Assembly means, of course, by paupers, those only who cannot be thrust out of sight. Our own answer to this excessive clamour about pauperism would be a simple one. The wages of labour, according to the economists, are settled by the haggling of the market; but agricultural labourers have no solid protection against the parsimonious offers of their employers, save public opinion; and this is so scanty a shield, that their wages are insufficient to do more than provide for the pressing wants of the

passing day. Hence, they need the occasional assistance of the charitable to supply the deficiency of their income; and fortunate is it for the community, where benevolence forms part of the law, and the indigent can claim the succour which they require. But, whether the aid is privately or publicly given, the rich have little reason to repine; for the total remuneration given to the agricultural labourer in the shape of medical advice, extra food, &c., added to his wages, is so small, that, in equity, it cannot be considered as more than a fraction of his deserts.

The authors of such reports evidently suppose, as Dr. Alison observes, that the poor are to "cease out of the land;" but all that severity can do is to sweep indigence from the streets, and drive it to its unseen hovel!

Mr. Monypenny does not support Malthus's original theory that the Poor Laws are a premium on population; indeed, it was time to abandon a theory which its author could no longer defend. But, though Dr. Alison has shown by the evidence of facts that the poorest people marry the earliest, his antagonist answers by something which Dr. Chalmers is "inclined to think." But facts are stubborn things; and if you dread early marriages so amazingly, you should recollect that the poor of Edinburgh and Glasgow, the *Chiffonniers* of Paris, and the *Lazzaroni* of Naples, marry earlier than the well-fed artisans of England and Holland. Nevertheless, Mr. Monypenny, though not a defender of Malthus's erroneous theory, reminds us of Lord Brougham's opinion, that the old Poor Laws of England afforded "the greatest stimulus to population which the art of man could devise," &c. &c. — which is exactly Malthus's mistake in other words.

We are surprised, however, that Dr. Alison does not advert to the immorality and misery produced by the discourage-

* Alison, Reply, &c. p. 22 and 23.

ment of marriage. Horace mentions among the duties of a legislator in early times

Concubitu prohibere vago, dare jura maritis;

and we should relapse into more than pristine barbarism, if the community at large adopted the counsels of our modern sages, and deferred marriage till it was quite prudent in a pecuniary view. How can the marriages of the labouring classes be any thing but improvident, in the economist sense of the word? Hodge takes Andrey to wife, in the hope that the labour of his hands will maintain her and their six children. It usually does so; if it does not, the community bears the burden, to the sore grief of the utilitarian. But does not the coldest calculator see, that if labourers were to agree, in his cant phrase, not to overstock the labour market, his selfish views would be more utterly defeated than by all the surplus population in the world? In other words, the rise in the price of labour would be so great, as to outweigh all the money saved in payments to widows and orphans. "By Day and Night! they were indeed irresistible so; not to be compelled by law or war; might make their own terms with the richer classes, and defy the world*!" Before taking leave of the subject for the present occasion, we must express our satisfaction at finding that Dr. Alison's exertions have awakened a kindred spirit,—that the seed which he has sown has fallen on no barren ground. Many correspondents have informed him that their opinions have been changed or fixed by his statements and reasonings. The extracts from some of their letters which he gives are couched in an admirable tone.

We are highly gratified also by his appreciation of our labours in a good cause; it is a pleasant thing *laudari à laudato viro†*.

MEDICAL REFORM.

AFTER allowing the Session of Parliament (by no means a short one) to pass away without any step being taken towards the much-talked-of medical reform, the 10th of August saw no less than two grandiloquent notices:—

No. 1.—"Medical Profession Bill for the Registration of Medical Practitioners, and for the establishment of a College of Medicine, and for enabling the Fellows of the College to practise Medicine in all or any of its branches, and hold any medical appointments whatsoever, in any part whatsoever of the United Kingdom. Ordered to be brought in by Mr. Warburton, Mr. Wakley, and Mr. Hawes."

No. 2.—"Bill for the Establishment of a National Faculty of Medicine, comprising its executive departments, one for England, the second for Ireland, and the third for Scotland; the senates, or governing bodies, to be elected, in the first instance, by those members of the existing Medical Colleges and Universities who may become assenting parties to the new institution, and afterwards the elections to be confined to persons who may possess the diplomas or degrees of the National Faculty.

Of these we shall only say, that, allowing the whole session to pass without bringing in one bill, and then on the last day, when nothing could be done, giving notice of two, looks very like humbug. There are various things in our profession that we should like to see altered; but, with our experience of the past, we have no confidence whatever in any thing either Mr. Warburton or Mr. Wakley are likely to do. The feelings of both are too much involved to admit of their legislating on sound principles.

who have made comparative observations and reflected on this subject, as to the general question of a fixed, legal, and liberal provision for the poor, we have, I believe, a very fair exponent in the leading articles of the *MEDICAL GAZETTE*, a journal which all my medical readers will know to be patronized and supported by a large proportion of the most respectable medical practitioners, both in London and in the provincial towns of England."

* Carlyle's *Chartism*, p. 110.

† Alison, *Reply, &c.*, pp. 44, 45, 47. At p. 44, he says, "Of the general opinion of those medical men

DEATH OF DR. TODD, OF BRIGHTON.

DIED, on the 4th of August, Dr. Todd of Brighton, at the neighbouring village of Hurst, after having been confined to his bed for six months. He was 50 years of age, and had long been in delicate health. Dr. Todd was a most skilful physician, and an ardent cultivator of physiology. He had long been engaged in an extensive series of microscopical observations on the subject of his favourite science; and had he lived a few years longer, there is little doubt that he would have been able to explain and illustrate some of the most minute processes employed by nature in the regeneration of wounded parts.

Dr. Todd was one of the few men who are in advance of the age in which they live, and, consequently, his loss to the profession is not easy to be repaired.

OF THE CEREBELLUM.

DR. GREENE brought forward the case of a young man, æt. 20, in whom one bone of the cerebellum was deficient; the individual was deaf and dumb from his birth. He died upon the twelfth day, of fever, in the Hardwicke Hospital; he was a well made, muscular young man, with perfect use of his limbs; the genital organs were well developed, and cicatrices of ulcers existed in each groin. The left lobe of the cerebellum was altogether deficient; the right lobe and corresponding crus cerebelli were healthy, but the left crus consisted merely of a small tubercle connected with the pons. The crus cerebri of the left side was smaller than that of the right, and the annular protuberance, owing to the different development of its left side, was irregular in its form, and placed obliquely; its longest diameter being from behind forwards and to the right side. The origins of the nerves were normal; the right occipital fossa was remarkably shallow, and the foramen magnum was placed obliquely, its antero-posterior diameter being thrown towards the right side. Dr. Greene alluded to two cases recorded by Cruveilhier, of deficiency of both lobes of the cerebellum, in each of which there was loss of the power of motion in the lower limbs. (Museum, Richmond Hospital.)

SUNFLOWERS IN RUSSIA.

WHEN fertile spots occur, every garden is filled with strong beds of the sunflower; and on inquiring into the use made of this plant, we are given to understand that it is here raised chiefly for the oil expressed from it. But it is also of use for many other purposes. In the market-places of the larger towns we often found the people

eating the seeds, which, when boiled in water, taste not unlike the Indian corn eaten by the Turks. In some districts of Russia the seeds are employed with great success in fattening poultry; they are also said to increase the number of eggs more than any other kind of grain. Pheasants and partridges eat them with great avidity, and find the same effects from them as other birds. The dried leaves are given to cattle in place of straw, and the withered stalks are said to produce a considerable quantity of alkali. With so many valuable properties, it did not surprise us to see the sunflower cultivated in every cottage garden. We found it throughout the whole of the centre and south of Russia.—*Bremner's Excursions in the Interior of Russia.*

RECEIVED FOR REVIEW.

Practical Observations on the Causes and Treatment of Curvatures of the Spine, &c. By Samuel Hare, surgeon, London and Leeds. 8vo. pp. 151, with 11 plates. (The title-page has no date, but the preface is dated 29th September, 1838.)

An Atlas of Plates illustrative of the Principles and Practice of Obstetric Medicine and Surgery, with descriptive letterpress, by F. Ramsbotham, M.D. Nos. 4, 5, 6, and 7. Churchill, 1840.

Trifles from my Portfolio, or Recollections of Scenes and Small Adventures during Twenty-nine Years' Military Service, &c. &c. By a Staff-surgeon. Vols. 1 and 2. Quebec, Neilson, 1839.

An Address upon Laying the Foundation Stone of the Queen's Hospital, Birmingham, June 18, 1840, &c. &c. By Vaughan Thomas, B.D. Vicar of Stonleigh, &c. &c. Oxford, Baxter, 1840.

The Horley Green Mineral Water; its new Chemical Analysis and Medicinal Uses. By W. Alexander, M.D. &c. &c. London, Longman, 1840.

ROYAL COLLEGE OF SURGEONS IN LONDON.

LIST OF GENTLEMEN ADMITTED MEMBERS

Friday, August 7, 1840.

T. B. Johnstone.—J. S. Mansford.—R. James
—A. Dyer.—H. A. Ash.—J. Mahaffy.—H. N. Elton.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Aug. 13.

B. Kirby, Banbury.—W. Way, Tonbridge Wells.
—E. Jones, Pailen, Warwick.—F. H. Woodforde,
Ansford, Somerset.—E. A. Parkes.—F. Williams,
Bristol.

NOTICE.

We have not received the other paper alluded to by Mr. J. A.

WILSON & OGILVY, 57, Skinner Street, London.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

INJURIES OF THE HEAD, *consequences of.*
ABSCESS OF THE LIVER—HERNIA OF
THE BRAIN—FUNGUS OF THE DURA
MATER.

DISEASES AND INJURIES OF THE SPINE—
SPINA BIFIDA. DISLOCATIONS *from violence.*—Occiput on the atlas: Atlas upon the axis—*Their Nature and Treatment.*

ABSCESS OF THE LIVER, CONSEQUENT
UPON INJURIES OF THE BRAIN.

A CONDITION which is not unfrequently a concomitant of injuries of the head is abscess of the liver. In many of these cases there is no sign of direct injury to that viscus, and it has been usual to refer it to general concussion, or some inexplicable sympathy. Of late it has been observed that it occurs most commonly when there is a suppurating wound, and this circumstance induced Dance to maintain that it was a consequence of phlebitis; and as the disease occurs from wounds of other organs, without concussion, he was still more fortified in his opinion. But I must guard you against the adoption of an exclusive opinion, by stating, at the same time, that abscess of the liver has often been seen as a consequence of disease of the brain and its membranes, even when there was no violence, or phlebitis. In some cases you may observe a contusion over the liver, and then it is fair to assume that the direct injury has excited inflammation and abscess: in other cases, the tension, the re-

sistance, the painful condition of the right hypochondrium, and the bilious vomiting, would fairly lead to the conclusion, that although there may be no direct injury, the organ must have suffered from general concussion, during which, the liver, from its great bulk and mobility, has, more than any other organ, been injured. The older surgeons had a different mode of explaining this coexistence: Bertrandi supposed that after every violent concussion of the brain the blood flowed in increased quantity towards that organ, and returned in greater quantity through the jugular veins towards the heart, so that the superior cava, by bringing a larger column of blood towards the heart, physically opposed the return of blood through the inferior cava. There is, therefore, a reflux towards the hepatic veins; the stagnation thus produced occasions inflammation, which terminates in suppuration or gangrene. Pouteau objected to this theory, that there was no proof that a greater quantity of blood was directed towards the brain, or by the superior cava towards the heart. He maintained that as a consequence of concussion the blood found its way less easily into the brain; that the carotids and vertebrals become distended; that the blood finding an obstacle in the branches of the ascending aorta, passes on in an increased quantity to the descending aorta, and to the organs supplied by it: that the liver being one of the first of these, it becomes gorged or congested, and inflammation ending in suppuration may be the result. Although in each explanation the ultimate result is nearly the same, congestion of the liver—in the one case by the arterial, in the other by the venous blood, yet absolute proof is as much wanting in one as the other; and to my mind both explanations are unsatisfactory. As to Bertrandi's statement, that at the confluence of the cavae there is not the smallest angle, (*ne quidem ipsarum venarum minimus angulus*), it is totally in-

correct. We know that the orifices of those two veins are not directly opposed to each other, and that the columns of blood do not form mutual obstacles. Desault, who long studied this subject, rejected both explanations; but I cannot help saying that the explanation he has left is also unsatisfactory: he says, "that an unknown real relation exists between the brain and the liver, a more intimate relation than exists between other viscera; that by this means, an affection of the first almost always determines in the functions of the second an alteration, which may, in the dead body, be demonstrated by traces of engorgement, of inflammation, of abscess; in the living body by nausea, bilious vomiting, &c." All practitioners, says he, do not equally admit the immediate connexion of the two viscera, and the affection of the liver in wounds of the head does not seem to them to be more than the effect of a general shock; but then why does the general shock affect a particular organ? why do not other organs suffer? By this simple question he conceived all difficulty removed; and concluded that the nervous system is the principal agent of communication, upon which the circulation exercises only an indirect influence.

I believe that most commonly the affection of the liver is a consequence of general concussion; that it is in the disposition and structure of the organ that we should seek for an explanation of the relation which exists between its affections and those of the brain, instead of adopting hydraulic reasons deduced from an imaginary derangement of the circulation. Of the three cases of the kind which I have seen, in two there was absolute destruction of the tissue of the liver; and certainly a very large majority of cases of concussion or other injury of the brain have no hepatic disease.

After what has been said, you are, I trust, convinced that these affections of the liver may be consequent upon direct contusion, upon general concussion, upon phlebitis, and possibly upon an inexplicable sympathy, such as described by Desault. These abscesses are developed sometimes in an insensible manner, sometimes they occasion more or less marked inflammatory symptoms, sometimes the purulent collections are superficial, but in the greater number of cases they are deep-seated, in some pervading much, in others little of the organ. They may form in the hepatic region, causing a fluctuating external tumor, which may open outwardly; it may open into the abdominal cavity, the stomach, the intestinal tube, or even the thoracic cavity.

The first object of treatment is to prevent the development of these abscesses, but that is frequently impossible, because

of their latent progress. When symptoms of inflammation are developed in the region of the liver, bleeding and mild purgatives should be used; if the abscess be presented externally, it should be opened; not with a lancet or bistoury, lest there should be no adhesion between the peritoneal surface of the liver and that of the abdomen, in which case the purulent matter might escape into the abdominal cavity, and excite a fatal peritonitis, but with caustic potash, which would excite as much inflammatory action as might be necessary to cause adhesion, when, if necessary, a bistoury might be plunged into it. If the pus be healthy, the chances of the case doing well are much greater than when it is brown. Sometimes the discharge continues long, and exhausts the patient; sometimes it lessens quickly; but even in fortunate cases a fistulous canal is established, and long maintained.

ENCEPHALOCELE,

Or hernia of the brain, is a term which has been applied to tumors formed by a protrusion of a portion of that organ. The protrusion may occur under two different circumstances, constituting two species or varieties; the first occurs commonly in young children, before ossification of the cranium is completed, and is often congenital; the second is often a consequence of injury, the trepan, caries, necrosis, or any thing capable of producing a loss of bony matter; and has been already spoken of. The first is usually seen at the region of the sutures and fontanelles, especially in the occipital region; the second may occur at almost any point of the cranium.

In the greater number of cases the tumor is covered by the dura mater and common integuments; sometimes these coverings are wanting. The tumor so formed is not usually large, seldom exceeding the size of a pigeon's egg, though it may acquire a much greater bulk. I recollect a case in which a large portion of the brain escaped through the posterior fontanel, and constituted a large tumor, which rested on the back of the neck; and there is a cast of a case, in the Museum of the Faculty at Paris, where the entire brain is said to have escaped through the same fontanel; the child lived fifteen hours, and executed its functions like a well-formed child.

It is ordinarily presented in the form of a rounded tumor; soft, without any change of colour of the skin, with very little pain, having pulsations isochronous with those of the pulse. It may be lessened in bulk, and may sometimes completely disappear under pressure. It may be greatly increased under any effort; and this is par-

ticularly seen during crying, struggling, and sneezing or coughing. In some cases, when pressure is made suddenly upon these tumors, nervous symptoms are developed which indicate a suppression of cerebral action; there is loss of the intellectual faculties, momentary paralysis of certain parts, and loss of consciousness; but when the pressure is removed, it resumes its former bulk, and the functions, before deranged, are restored. If we pass the fingers carefully around the base, we can generally make out the edges of the cranial opening through which it has passed. If encephalocele were always simple, the diagnosis would be easy; but, in many cases, it is complicated with hydrocephalus: the tumor may then be semi-transparent, and the motion communicated to the brain, by the pulsation of the arteries at its base, may no longer be perceptible to the touch. But the chances of mistake in diagnosis are increased by a certain similarity which these tumors bear to certain bloody tumors presented in the scalp. Ledran clearly fell into this error; but if you bear in mind that these bloody tumors are not reducible, that pressure upon them excites no cerebral disturbance, and that if we press strongly we feel the bone continuous underneath, there will be little probability of your falling into this error.

So able a surgeon as Boyer maintained that there was nothing mortal about this disease, provided the indolence of the child did not prevent the employment of proper means of protecting the tumor from injury, and causing it to disappear. My experience, though limited, produces in my mind a very different impression; if the tumor be large, the greater number of patients perish. A small tumor is certainly less dangerous than a large one; in the latter a larger quantity of the brain is implicated—a larger sac is exposed to inflammation; the more, therefore, is the probability of its being exposed to external injury, and the greater the difficulty of protecting and containing it. A large tumor we can scarcely hope to cure, because without complete reduction it cannot happen, and we cannot venture to force into the cranium so large a mass as may be presented, because the cavity of the cranium is not dilatable.

Treatment.—When these tumors are covered by the integuments of the cranium, it has been recommended that gentle equable pressure should be applied upon them; and many cases are recorded of the success of this plan of treatment when the tumor is not very large. Salleneuve used sheet-lead for the purpose, and found that the tumor, gradually and constantly compressed by this agent, lessened, and ulti-

mately completely disappeared, so as to allow of ossification being perfected at the point. Whether the cases of success said to be obtained, by this plan, by Salleneuve and Callisen were really encephalocele, or bloody tumors, may admit of some question. The little experience I have had of this plan of treatment, extending to only two cases, where the tumor was small, induces me to entertain considerable doubts of the cases above mentioned, for in neither of my cases could the compression be borne. When the tumor is very large, most surgeons agree in opinion that pressure is perfectly useless, and may have the most serious inconvenience. In such cases, to contain, to sustain, and properly to protect the tumor from injury, is the extent of justifiable treatment. If the protrusion be complicated with hydrocephalus, it has been proposed, first to puncture the tumor, for the purpose of evacuating the fluid it may contain, and afterwards to use compression. Adams mentions five of these cases, of which two were cured by puncture without compression. In one the operation was repeated seven times, the quantity of fluid being less on each successive puncture. Very few men have followed the example of Adams, spite of this apparent success, because such punctures are not made with impunity either in hydrocephalus or spina bifida.

Even when there was no fluid in the sac of these tumors, there have not been wanting persons who have employed, not only puncture, but the ligature; in some of these cases this was evidently done from an erroneous impression, that the tumor did not communicate with the brain; in others it was done advisedly; but the operations have been almost uniformly unsuccessful. Forest (Obs. Chirurg. lib. 3, obs. 7,) operated in this way in a case which he believed to be encephalocele, but which bears strong marks of having been hydrocephalus. The tumor was transparent, and he says, "if hydrocephalus could form a globular tumor it might have been considered a case of this kind." A surgeon who consulted with him mentioned many cases in which the ligature had succeeded, and he employed it. During the first few days the case seemed to go on well, but at the end of a fortnight a slough formed at the summit of the tumor; it was thrown off, and a limpid fluid escaped. From that time the infant began to refuse the breast, and soon died. In 1781 Schneider tied a true encephalocele, with fluid in the sac; the tumor was large and pediculated. At the moment when the ligature was tightened the child cried, but soon became quiet. On the eleventh day the child was observed to be very weak, and in the evening became convulsed, and

in a few hours died. The examination after death proved that a considerable portion of the brain was included in the ligature. The operation of laying open the sac, and endeavouring to reduce or extirpate the protruded portion of brain, has been little more successful. In the thesis of Held is a case of the kind; the patient was a woman of 18; she had in front of the head a tumor of the size of a small hen's egg; it yielded a little on pressure: it was mistaken for a melicerie tumor, and upon the first incision being made for its extirpation, it was discovered that it was formed by a portion of brain which had escaped through the anterior fontanel, together with a couple of ounces of fluid which gushed out. The wound was closed, dressed simply, slight pressure was applied, the brain was reduced, the opening in the cranium completely closed, in the same way as it is accomplished after the application of the trepan. But this single successful case cannot be opposed to the many failures which seem to me decisive as to the operation. The patient had lived 18 years before the operation had been performed, the knife was only used in ignorance, and was laid aside as soon as the nature of the disease was discovered: happily the tumor afterwards bore compression, which has rarely been the case, and all did well; but then, might it not have done as well by simple compression, without incision? Puncture is certainly more rational, for if cautiously made with a small trocar, at a transparent, fluctuating point, the tumor may bear equable pressure, and get well.

Whatever be the operation, or the means of treatment employed, a radical cure is a rare circumstance in congenital encephalocele, which is a malconformation affecting not only the cranium, but probably the brain. Supposing it be thought advisable to abstain from pressure or puncture, and to use only a sustaining and protecting plan, there are certain things to be avoided, especially carrying burdens on the head. In Bennett's case the patient died suddenly whilst carrying a bucket of water on the head.

When the tumor is very large, partially or completely deprived of integument, and the absence of ossification is extensive, the patient is, I think, beyond the resources of our art; either the child is still-born, or dies soon after birth. In those cases a large portion of the brain is found in the distended membranes; the teguments either do not exist, or are extremely thin and deprived of hair, forming a soft, reddish, semi-transparent membrane, which easily gives way.

Hernia of the Cerebellum.—If the portion of the cerebral mass escaping through an

opening, so constituted, be the cerebellum, it has been termed a *parencephalocele*; it is much more rare than the former kind of hernia. A tumor of the size of the fist presented itself at the occiput in a case seen by Isenflamm, which turned out to be the cerebellum, which had escaped through the great occipital foramen. In 1813 a case was presented to Lallement, which he mistook for a fatty tumor; the patient was a robust idiot of the age of 23. The tumor had been long increasing, and was, at the time Lallement examined it, of the size of a hen's egg. He proceeded to extirpate it by circumscribing its base with a circular incision, and then dissecting it away, but suspended the operation in consequence of coming upon the glistening dura mater: the lips of the wound were immediately brought together: the patient was put to bed, and died on the eighth day. It was ascertained that there was a small opening in the occipital bone, through which the dura mater and a portion of both lobes of the cerebellum protruded. Not long after, a case happened to Balfes, but he, recollecting Lallement's case, did not operate; the patient died, and upon examination the case was found to be similar to the preceding. The case mentioned by Bennett is a striking example of the same kind. The treatment of hernia of the cerebellum should be in all respects similar to that of the cerebrum.

FUNGUS TUMORS OF THE DURA MATER.

With hernia of the brain the tumors we are about to consider have not unfrequently been confounded. Louis devoted himself to the study of this subject, and produced a memoir of singular ability, which is contained in the *Memoirs of the Academy of Surgery*. The fault of that memoir is, to have included too many dissimilar productions in one description.

In some of these cases the dura mater alone is the seat of disease, in others the cranium is particularly affected, in others the brain participates. Siebold, resting on a case he had observed, and Graefe on another case, maintained that the disease described by Louis as fungus of the dura mater was, in reality, fungus of the cranial bones, originating in the diploë, extending to both tables, and from thence to the dura mater and the pericranium. Walther based, upon two observations, his belief that fungus of the dura mater was the result of a simultaneous affection of the pericranium, diploë, and meninges. Both Siebold and Walther's descriptions undoubtedly apply to a certain number of cases; the bones may unquestionably be affected independently of the dura mater and the pericranium; still the facts detailed by Louis, by Wenzel, and others,

clearly show that there is a true fungus of the dura mater. In Wenzel's case, in those of Abercrombie, that of Louis, of Chelius, Jauchius, Berard, the tumor was not even adherent to the bone; in that of Hebraard, and in three of Cruveilhier's, the tumor arose from the inner surface of the dura mater. In the plates of Cruveilhier, the tumor of the dura mater may be seen making its way through the cranium. It is unfortunate that the greater number of authors who have written on the subject have based their description on a single case, by which they have fallen into that vice of reasoning so fatal to science, of framing a general law from a particular case. The only person who, for a long period, fairly considered the subject, was Ebermayer.

The disease we are considering is, ordinarily, cancerous; in Rey's case the patient had at the same time cancer of the thigh. In that of Chelius the substance of the tumor was medullary. Cruveilhier delineates six cases, all of which were encephaloid.

There is no particular point of the dura mater for which these productions manifest any decided predilection. Velpeau collected fifty cases for the purpose of exemplifying this: thirteen arose from the parietal (the comparative frequency in this situation has been referred to the glands of Pacchioni), eight from the temporal, seven from the frontal, seven from the orbito-nasal, seven from the occipital region; five from the vertex, three from the vicinity of the petrous portion of the temporal bone, and one from the midst of the falx cerebri. He also shows that it is not peculiar to any age: of forty cases it occurred six times from birth to the tenth year; from twenty to thirty, seven times; from thirty to forty, nine times; from fifty to sixty, five times; and from sixty to eighty, three times. From this it follows that between thirty and fifty it is more frequent than at any other similar period of life: as to sex, of forty-four cases twenty-three were men, and twenty-one women.

Causes.—How these tumors arise it is impossible to say; in many cases they have succeeded to a fall or a blow: these may have been causes of irritation, under the influence of which the disease was developed; but any other kind of irritation, whether of caries, necrosis, or other cause, may equally excite irritation, from which this disease may result.

Symptoms.—The symptoms by which they manifest themselves are more or less equivocal. In a first period there may be no symptoms—at least this is the case in the greater number of persons; some chance circumstances may, however, reveal their existence. The truth is, when

a compressing agent acts very slowly and gradually upon the brain, this organ becomes accustomed to the compression; the compressed portion may be atrophied; and if this portion be not indispensable to the free exercise either of the sensorial or locomotive functions, or the intellectual faculties, the patient and his medical attendant may remain ignorant of the existence of a morbid product in the brain. But sooner or later the compression exercised on the brain becomes a cause of irritation either to the brain itself or its membranes, and then marked symptoms may gradually or suddenly supervene: nothing is more common, in these cases, than to see hemiplegia supervene as instantaneously as in a case of apoplexy. A man of 60, returning home, suddenly fell down, insensible, upon the road; when consciousness returned he found the right side of his body paralysed. He was treated for three months, during which no other symptom was manifested than hemiplegia, without rigidity: during the next fortnight his temper was insufferable, he swore unceasingly; but otherwise his intellectual faculties were acute enough: at the end of that time he died. At the sides of the falx, corresponding to the middle lobe, attached to the inner surface of the dura mater, was an enormous cancerous tumor. It is scarcely possible to conceive that this tumor commenced its development at or after the moment of the accident; it is easier to believe that the brain had long borne an increasing compression, but that exceeding a certain point, the equilibrium was disturbed, and the symptoms of compression manifested. In the greater number of cases, and especially when the tumor occupies the base, the signs of compression come on gradually; sensation and motion are diminished, and at last extinguished, in the limbs corresponding to the part of the brain which is compressed; the intellectual faculties are blunted: it may end in imbecility and hemiplegia. This gradual and progressive course of the signs of cerebral compression usually enables us to distinguish between cancerous and apoplectic compression; but there are cases in which error in diagnosis as to the cause of compression is almost inevitable. Still it is necessary for us to point out what are the ordinary symptoms of this disease: head-ache and lancinating pain, which often precede its external manifestation, are too vague to be of much assistance in diagnosis; they are often wanting when the disease exists, they often occur when it does not; the other symptoms are equally vague: in fact, until an inequality appears under the scalp, it is scarcely possible to make out its existence: then the tumor, some-

times rounded and firm, more frequently irregular, sometimes soft and fungous, immovable, though not adherent to the skin, may be the seat of pulsation. If suddenly compressed, it more or less completely disappears, but at the same moment may produce paralysis. Usually on slight pressure it yields a sort of crepitating sensation, and is the seat of a pricking or pungent pain, which is often very distressing. When all these characters are present, it is not easy to mistake the disease; but it is rare that they are. The pulsations are often absent, and often exist in erectile tumors and encephalocele; and if a hernial tumor be returned suddenly into the cranial cavity, it occasions paralysis: but then a hernia of the brain is most commonly seen in infants, and erectile tumors do not often exceed a certain size. When the fungus makes its way into the orbit, as it did in Petit's case, or into the nose, as in those of Berard and Rostan, an error may easily happen.

Prognosis.—Cancerous tumors of the dura mater, are, at present, regarded as incurable; but the bloody tumors, mentioned by Camerarius and Abernethy, may be cured, so may those which are syphilitic; still, in many cases, several years pass before they approach a fatal termination. In Graefe's case the disease had existed thirty-seven years; in Schneider's five years; in Robins's forty years; in Voisin's case more than thirty years; in Thibault's ten, and in Bisset's fifteen years; and when it terminates in death, it is less by its pressure than by lighting up irritation or inflammation in the brain, which may give rise to apoplexy.

Treatment.—As to treatment, we can do nothing if the tumor be under the dura mater, because in the first period no signs manifest its existence; in the second, if there be any, they are equivocal, and, because if we ascertained their existence, we have nothing to oppose to them. They have never disappeared by resolution, by suppuration, or by compression. Caustics and ligature, or excision, are the only means which we shall examine. Five of the six treated by caustics died, (Ebermayer) and Eck's case, if cured at all, was certainly an equivocal one: Ficker's case, in which the ligature was used, was a doubtful one. Extirpation has had partial but scarcely any complete success, and always aggravates the patient's suffering. The tendency to reproduction appears to be quite as decided as in cancer of other parts, and when we associate with this the great dangers attending the operation, we cannot wonder that it is rarely attempted. If it be done, the incisions should include not only the diseased but a portion of the healthy structures. If it occupy only the bone, the diseased parts must be removed with a trepan

or saw, or both. If we have excised a portion of the dura mater, it is very important to support the brain with a piece of soft lint. In Berard's case, so soon as the pressure made by the fungus was removed the patient became insensible, and was only restored by making pressure anew. Indeed, many cases testify that the sudden removal of an agent which has long compressed the brain is not borne by that organ with impunity. Under all circumstances we cannot hesitate to say that there are few or no diseases over which our art exercises less influence, than over the one we are considering.

INJURIES AND DISEASES OF THE SPINE.

Experience has long established the axiom, that in proportion as an organ is more frequently employed, is it more subject to disease. If we contemplate in man the different parts of the nervous system, it becomes evident that the brain is the part of that system whose acts are most frequently repeated; whether we regard it in relation to the influence which it continually exercises upon the operations which contribute to the preservation of life, or its direct action in the production of the intellectual functions. It is hardly necessary to point out how great is the difference in this respect between man and the lower animals; in which the spinal system takes precedence over that of the brain. The difference observed in the frequency of diseases of the brain, as compared with those of the cord in man, appears to me to result very naturally from the physiological condition in which those organs are placed. In horses, and other animals, on the contrary, I am assured that softening of the spinal marrow is much more frequent than a similar condition of the brain. In man the occurrence of extravasation of blood in this organ, except as a consequence of direct or indirect violence, is unfrequent; whilst in beasts of burden we are informed by Dupuy that it is much more frequent. The examples of disease of the spinal cord, collected up to the present moment, are not sufficiently numerous to enable us to appreciate the influence which age or sex may exercise on their development.

The greater number of the injuries of the spine, and the accidents which occasioned them, were known to Hippocrates; to Celsus, who says, when the injury affects the superior cervical portion, death is rapid; to Aretæus, who says, that when paralysis is caused by disease of the cord, it is always on the same side as the disease; to Galen, who particularizes the symptoms consequent upon disease of particular regions of the spine; and the moderns have not gone much farther.

We must first consider certain vices of conformation of the spine, to which the attention of the surgeon is often called: before I do so, it may be as well barely to mention that there may be total absence of the whole of the central nervous system. Clarke's case, in the *Philosophical Transactions* for 1793, proves this. So do those of Morgagni, *Epist.* 12, and others. The many cases on record contain no example of the presence of the brain in the absence of the spinal cord, except those of Rayger, which are of doubtful authority; but they contain examples of presence of the spinal cord with absence of the brain.

SPINA BIFIDA.

We will first consider spina bifida, which is a comparatively frequent disease. Of 132 infants possessing some defect 22 presented this disease. In Chaussier's report we see that, after club-foot, it has been the most frequent congenital malformation. In a single year Billard saw seven cases at the *Hospice des Enfants-Trouvés*.

It is characterized by one or more tumors situated along the course of the spine; sometimes limited to particular points; sometimes comprehending the greater part of its extent. There are, it is true, certain instances in which such tumors have been developed some years after birth; but then they seem to have been consecutive to a pre-existing hydro-rachitic tumor. Genga's case, mentioned by Morgagni (*Epist.* 12, sect. 3.) is so clearly detailed that it is impossible to deny that it was such a case. The tumor in spina bifida is usually rounded; sometimes it presents a broad base; at others, it is more or less pyriform; or it may be lobulated, as in the case mentioned in the 68th Number of the *Edin. Journal*; it may be more or less completely oval, depending upon the character and extent of the opening in the spinal column; it may extend, as in Fiehlitz's case (*Richter, Chir. Bib.*), from the occiput to the sacrum; and in these cases we may feel two hard longitudinal undulating lines formed by the projecting points of the vertebræ. In a few cases the tumor is transparent; generally, however, it is opaque and resistant. When the tumor is very small, in some cases the integument is unchanged; but when it is of a certain bulk, we almost always find it thin, and of a violet or reddish colour at the centre. Occasionally they are wrinkled, irregularly depressed, and present the appearance of a depressed cicatrix, as shewn in Cruveilhier's plates, instead of a prominent tumor. Most frequently the tumor is seated in the loins; less frequently in the back; still less in the neck. Although many authors

deny it, it is occasionally seen at the sacrum.

When there are several tumors, we may shew their common connection by pressing on one; for we render the others tense. The tumor changes in character as we change the position of the child: if it be vertical, it is usually tense and resistant; if horizontal, it is often soft. Again, the action of respiration exercises considerable influence over it; during expiration it becomes tense; during inspiration it subsides.

Since I have been attached to the Marylebone Infirmary, I have had opportunities of examining four cases of spina bifida; and in none of these did the skin seem to contribute a covering to the tumor. Meckel, Beclard, and others, maintain that it generally does; that it is sometimes very thin and transparent; at other times thick, presenting violet or brownish mottling. That it occasionally fails I am satisfied; and then the dura mater, the arachnoid, and the pia mater, are the only coverings; and sometimes the dura mater is wanting.

In my own observations the imperfection in the vertebræ was very similar; but it may vary. Fleischmann (*Vitiis Congenitis, &c.*) pointed out three principal varieties; first, a complete division of the whole vertebra, including its body; second, absence of a portion of the lateral arch; third, a want of union in a well-developed arch. The first variety is very rare. Besides the cases described by Tulpus (*Obs. Med.*) and Malacarne (*Oggetti, &c.*) I know of no complete example. Zwinger's case (*Eph. N.C., Cent. 7, Obs. 29.*) was not so. The second variety is commonly seen; but the third is much less frequent.

The fluid contained in these tumors is like that of serous dropsies generally; hydrocephalus, for instance. The quantity of this fluid is as variable as the size of the tumor. Siebold has seen more than a pound; Vogel two pounds; Jukes (*Lond. Med. and Surg. Journal, Feb. 1822.*) seven pints. If the patient continues to live, the tumor generally continues to enlarge, and the quantity of fluid to increase. In many cases the fluid is limpid; in some it is straw colour; in some floeculent; in some darkish or sanguinolent. After puncture it may become much darker; in Henry's case it became purulent and foetid. Bostock, Marcet, and Lassaigñé, analysed this fluid, and shewed that, like that of hydrocephalus, it was more aqueous, and contained less albumen than in cases of ordinary dropsy. Bostock's analysis is as follows:—Water 97·8, muriate of soda 1, albumen 0·5, mucus 0·5, gelatine 0·2, with traces of lime. This fluid is usually continuous with the cavity of the cranium.

In these cases certain imperfections of

the spinal marrow are commonly seen; In some instances a central canal has been observed; in others it has been more or less completely bifid; but in my cases the alterations in the spinal cord were trifling.

It is not rare in these cases to find other vices of conformation—an extroverted bladder, an imperforate anus, the absence of a kidney or testicle, sometimes club-foot, and frequently hydrocephalus. In the cases I have observed the children were otherwise well conformed; all possessed the locomotive powers intact. In neither was there atrophy of the bladder, imperforation of the anus, or any defect in the lower limbs. The disease does not appear to interfere with foetal life; but, after birth, it causes death, in most cases, more or less promptly. As a general rule, the higher and larger the tumor, the more rapidly life is destroyed. When the patient continues to live, in some cases it may continue active and healthy, but usually it soon begins to languish and become emaciated. Some are paralysed from birth. There are, however, on record, many cases in which the disease has not been incompatible with the integrity of all the functions and the best health (Morgagni, Paletta, Fleischmann, Cooper, Jukes, &c.) Ordinarily the tumor gradually increases, unless, as is sometimes the case, it present a fistulous opening, from which the fluid continues to flow. Of Cruveilhier's five cases two were perforated from the moment of birth; but he conceived they bore marks of having been probably ruptured during parturition; but certainly in many cases old cicatrices are apparent, and therefore we are bound to believe that they may be ruptured in utero without destroying the life of the foetus.

In the vast majority of cases, when, after birth, the tumor has ruptured spontaneously, death in the midst of general convulsions soon follows. Terris' case is an exception.

However grave this disease may be, it is not necessarily mortal. I had a patient some months ago, a girl of 13, in whom the disease had been cured by the development of a plate of cartilaginous matter around the tumor. In Bonn's case the child lived ten years, in Warner's twenty, and in Camper's twenty-eight years. There is, or was, ten years ago, in London, a woman of nineteen, who was born with spina bifida. The tumor was ultimately large, but it was perforated, and there was a constant oozing; (the case was described by C. Hutchison.) Swagermann's patient lived to the age of fifty.

In the cases which were under my care, the tumor was fluctuating and semi-transparent; slight gradual pressure seemed to give no inconvenience; sudden pressure seemed to give pain. So long as the tu-

mor was not opened the health was very good, but no sooner were they opened than grave symptoms were developed. The time, however, was variable: in one case it was almost immediate, but in another they were not developed till the sixth day, and the fatal termination soon followed.

The symptoms announcing the approach of death are pretty constant. If there be a fistulous communication, the fluid escaping becomes changed, and more or less purulent and fetid; at the same time convulsive action comes on, consequent upon meningeal inflammation. The respiration becomes more difficult, and the child dies convulsed.

Many persons are of opinion that spina bifida is always a consequence of hydrocephalus. This is incorrect, for it has been seen in a brainless foetus (Littre). Obersteuffer says he has never observed a case of spina bifida with hydrocephalus. Ruysch's opinion, that it was always a consequence of a lesion of the spinal cord, is equally untenable; so also is the opinion that it is a consequence of the absence of the posterior portion of the vertebral rings, the cord wanting its proper support.

Treatment.—The fatal consequences of the rupture of the coverings in these tumors, whether spontaneous or accidental, and the no less fatal consequences of ordinary puncture, should be sufficient to proscrib[e] that mode of treatment in spina bifida. I do not mean by this to say that the rupture of the coverings has always proved fatal, for Maur and Hoffman, Camper, Genga, and Terris, give cases in which the patient survived it. The contradictory facts of Sir Astley Cooper, who succeeded twice, and Robert, who obtained a cure by repeated punctures with a needle, associated with compression, can only be considered as happy exceptions. In other hands, with the exception of a single case described by Otto, in which there was partial success, it has been eminently unsuccessful. Certainly the result, though it may justify it, is too little auspicious to induce a prudent practitioner to determine, without much reserve, to practise an operation which has almost always accelerated the fatal termination. The seton, proposed by Desault, and the ligature, by Forestus and B. Bell, have had equally unhappy results. I have seen good effects to follow compression methodically applied: Stueber, Sir A. Cooper, Abernethy, and others, have succeeded by this means when the tumor was not large. It facilitates absorption, and allows of the tissues covering the tumor resuming something of their former condition; increases their power of resistance; lessens the chances of rupture; and gives the vertebræ a better chance of development. The only compression which I have found

available was obtained by placing over the tumor a piece of oiled silk, and strapping it down by adhesive straps. Sir A. Cooper made a plaster cast which, in his hands, succeeded well; as the tumor lessened, portions of lint or cotton were placed in the cast. If we do not adopt either of these plans we must endeavour to protect it, because in itself it is not a mortal disease, but becomes so by rupture, and the penetration of air into an irritated serous cavity.

DISLOCATIONS OF THE SPINE.

In the absence of fracture of the vertebrae, the spinal cord may be wounded by a cutting or puncturing instrument. It is a very rare circumstance, however, to see such divisions as occur in the soft parts elsewhere; and as we usually see injuries of the spinal cord as consequences of fracture or displacement of one or more vertebrae, we shall not here treat of these wounds separately, but at once proceed to treat of dislocations.

The different pieces composing the spine are united by such extensive surfaces, and such powerful ligaments, that from the time of Hippocrates an opinion has generally prevailed, that without fracture dislocation was impossible. Indeed, when we consider the strength and number of its ligaments and muscles, the extent of articulating surfaces, and the small quantity of motion of each of its parts, when concurring in an extended general movement, we must be convinced that simple and complete dislocation—that is to say, a state in which the bodies and articular processes have at the same time abandoned their ordinary relations—must be almost impossible without fracture. These reflections apply especially to injuries of the articulations, in the dorsal and lumbar regions, because the bodies of the vertebrae in these regions are larger, and their articular processes vertically more elongated than those of the cervical region; and this is in the sense of the greatest extent of motion: we are, therefore, disposed to doubt whether the cases recorded as examples of dislocation of these bones, and characterized by a sudden and permanent angle of the dorsal or lumbar region, with or without paralysis, occurring after a fall, and from which no other bad consequence has resulted than the curvature, were cases of dislocation or fracture. For some time, however, surgeons have sought to infirm the dictum of Hippocrates, and to prove that dislocation may happen in any region of the spine: if we carefully examine those cases, we shall be nearer a safer conclusion if we assume that they were cases of fracture of the posterior laminae of the vertebrae. But if simple dislocation of the bodies

of the vertebrae be almost impossible, it is not so with the articular apophyses. Very authentic observations prove that this kind of displacement may occur in the cervical region, and is rendered more easy by the great latitude of motion necessary for the varied movements of the neck, but I know no clear case of even such a dislocation in the dorsal or lumbar region.

OCCIPITO-ATLOIDAL ARTICULATION.

The articulation of the atlas with the occiput is rendered so solid, by ligaments, muscles, and the nature of the articulation, that it is scarcely possible that a luxation produced by violence can happen there. The only case I know of is that of Lassus. A truss of hay fell from a height of fifteen or sixteen feet upon the back of a man's neck, whose head was inclined forward. He fell down insensible, the head inclined forward and a little to the left, the mouth half open, the jaw immovable, the upper extremities convulsed: he died in five or six hours. The right vertebral artery was ruptured, and the occipital condyles were removed three or four lines from the corresponding surfaces of the atlas. In Sir Charles Bell's case there was displacement, but then there was fracture of the borders of the occipital foramen. In Cline's case the patient lived twelve months; after death, he ascertained that the atlas was fractured transversely.

ATLOIDO-AXOIDAL ARTICULATION.

The greater number of movements of the head are operated at the articulation of the atlas with the second vertebra, the head and the atlas moving around the odontoid process as a common axis; and it is at this point that displacements, consequent upon violence, most frequently occur. The most common displacement is that which results from a forced rotation of the head: in this case the articular surface of the atlas is left in front of that of the axis on one side, and in the opposite condition on the other. The face is turned towards the shoulder; and on the opposite side, at the superior and lateral portion of the neck, a projection is formed by the apophysis of the axis. The odontoid ligaments and the articular surfaces are distended or destroyed, and the odontoid process may be unrestrained. The articular surfaces may also be deranged, in consequence of the destruction of the perpendicular or transverse ligament of the odontoid process. In the first case the process may slip out of its proper place, and compress the cord and destroy life; and this as much easier in children, that the process is shorter, and the perpendicular ligament longer and less resistant. Thus, if a child

be supported by the head, one hand supporting the chin, the other the occiput, and he struggle much, this dislocation may happen, and death follow, as in Petit's case. This dislocation of the odontoid process, without rupture of the transverse ligament, may happen in the adult under a violent muscular effort, the face inclining downward, as in Sir Charles Bell's case, where the odontoid process pierced the cord and destroyed life instantaneously.

Of all the cases of this kind of injury on record, the most extraordinary is that which I communicated to the Medico-Chirurgical Society. A man fell from a hay-rick, pitched on the back of the neck, was stunned, got up soon, was bled and purged: all the inconvenience which resulted to him during the eleven months he lived, was an inability to rotate the head. After death the following appearance was presented:—

The atlas had been fractured through the ring, leaving the articulation with the occiput intact. That portion, by the violence of the injury, was driven down between the pharynx and the axis, and carrying with it the odontoid process; when it arrived on the same plane with the axis, it became attached to it by perfect bony union. The lateral displacement of the atlas upon the axis is not necessarily mortal. Many cases show, that even successful reduction is possible: but it is probable that, in these cases, the odontoid ligaments were not destroyed. Where, however, the dislocation is accompanied by a displacement or fracture of the odontoid process, all authorities agree in believing that the accident is immediately mortal. My case, however, is a happy exception to that law. The sudden death in these cases is caused by the compression of the cord. The accident has occurred by falling on the head from a height; from a violent blow on the back of the neck; a fall on the chin; a sudden and violent shock on the head; an exaggerated rotation of the head. Some

circumstances would lead to the idea that it may happen by hanging. Louis ascertained that in those cases where the executioner drags the legs violently downwards, or jumps upon the back, it generally happens.

Treatment.—The majority of surgeons have advised that no attempts at reduction should be practised, because, say they, the deformity is better than the risk of sudden death, which attends all efforts to reduce the displacement. Still, as many cases have yielded to those attempts, we have no right to proscribe them. In a child whose head had been rotated until the chin rested over the right shoulder, Desault informed the mother of the dangers which attended the attempts to reduce the displacement: those dangers she was content to incur. He proceeded to fix the shoulders firmly, gradually raised the head, and restored it to its proper position: the pain ceased, and the child moved his head naturally. Ehrlich (*Chirurg. Beobacht*) mentions the following as a case of dislocation of the atlas upon the axis, successfully treated: A lad of sixteen fell from a ladder under a bag of flour—his head violently pushed forward by the load. He was insensible; the surface pale, the eyes fixed, tongue hanging out, respiration slow and intermittent, pulse scarcely perceptible, limbs motionless, involuntary evacuation of *fæces* and urine; the head very moveable, and resting on the right shoulder, but when placed upright fell indifferently on either shoulder: the articular apophysis of the axis projected on the left side. Ehrlich pursued the same plan with Desault; and, after many attempts, it was reduced with a snap, and gradually all the bad symptoms disappeared. I think, therefore, that such attempts are justifiable; but not without apprising the patient, or his friends, of the risk which is run.

REMARKS
ON THE
PATHOLOGY OF ACUTE HYDRO-
CEPHALUS*.

BY WILLIAM LUMSDEN, M.D.

[For the Medical Gazette.]

UNTIL the appearance, in 1768, of Whytt's "*Observations on Dropsy of the Brain*," acute hydrocephalus was either confounded with apoplexy, or de-

* Read before the Parisian Medical Society, 15th June, 1840.

scribed as fever with determination to the brain. Its resemblance to acute dropsical diseases was the principal feature which attracted Dr. Whytt's attention, and he accordingly ascribed the symptoms to effusion arising from laxity of the exhalants, or from a watery state of the blood. This opinion was generally received, until Quin, in 1779, drawing his reasons from pathological anatomy, shewed a closer alliance to inflammation; and in this he was supported by the concurrent testimony of Rush and Withering, and by the later researches of Garnett, Gölis, Martinet and Parent-Duchatelet, Lallemand, Abercrombie, and others. The idea of dropsy was now almost driven from the field, and the inflammatory nature of the disease all but universally admitted, diversity of opinion existing only as to the seat of the inflammatory action; some maintaining that the arachnoid of the ventricles and base of the brain were the parts most generally, if not always affected, and others insisting on the central portion of the cerebral substance itself being considered as the seat of morbid action. Of late the French pathologists have introduced a new element into the discussion: the labours of Guersent, Gherard, Rufz, Piet, Bequerel, &c. demonstrating the almost universal existence of granulations of a tubercular nature on the under surface of the cerebral layer of the arachnoid coat, have led to the hydrocephalic symptoms being attributed to the irritation produced by these as foreign bodies, and have proved the influence of the strumous diathesis on the production of this fatal disease.

In the few remarks about to follow on the nature of hydrocephalus, all reference to symptomatology has been purposely avoided, under the belief that pathological anatomy is the true basis upon which we ought to raise our theories of disease, and that symptoms ought never to be appealed to for more than slight collateral evidence, except in those cases where, from our ignorance of the physiology and ultimate structure of organs, the scalpel is powerless.

After thus slightly glancing at the literary history of acute hydrocephalus, the three doctrines as to its nature present themselves to our notice; and, proceeding chronologically, the first question to be taken into consideration is, "Is acute hydrocephalus a dropsy of

the brain?" In other words, "is it a disease having for its essential character an effusion of serum into the cavity of the arachnoid, the cells of the pia mater, the ventricles, or between the fibres of the cerebral substance itself?" This, the oldest opinion held by pathologists, has, since the labours of Quin and others already mentioned, been almost entirely driven from the field, yielding step by step to the growing influence of the inflammatory theory; and noticing it at all but in a cursory manner would have been an unwarrantable waste of time, did not the recent experiments of Magendie and Guillot, on the state of the ventricles during life, and the hygrometric properties of the brain, modify the appeal to post-mortem appearances.

The opinions of the older pathologists were founded chiefly on the observation of symptoms, supported by occasional autopsies; imperfect, of course, in the infancy of pathological anatomy. The progress of the disease, the gradual extinction of the senses and intelligence, and the comatose state accompanying and characterizing the later stages, led them to the conclusion that compression of the brain existed; and they were confirmed in this opinion by occasionally finding effusion in the ventricles, while the idea of inflammation seemed inconsistent with the frequently slow and insidious nature of the attack, and with the absence of quick, irritated pulse, heat of skin, and other febrile symptoms. As pathological anatomy became an object of greater attention, numerous cases were found in which the effusion was either entirely wanting, or too much in quantity to account for the symptoms; and the numerical method of our days proves that effusion is even less frequent than is generally supposed. In one series of twenty-seven cases observed by Bequerel, eighteen did not present the slightest trace of an anormal quantity of fluid; and in another of ten cases, effusion existed only four times. But it will be found immediately that this evidence is insufficient, and that the mere absence of effusion at the examination of the body by no means leads to the conclusion that none existed during life.

Magendie was the first who observed and insisted upon the hygrometric properties of the cerebral substance. He shewed that, in order to find the cerebro-spinal ventricular fluid, the animals

upon which he made his experiments must be examined immediately after death, otherwise absorption took place, the fluid disappearing among the fibres of the nervous tissue. Guillot has carried out these observations, and arrived at some curious and important results. Numerous experiments on animals have proved to him—

1st, That in the normal state, and during life, the cerebral ventricles are filled, and even distended, by serosity.

2d, That the quantity of this fluid diminishes in proportion to the length of time after death at which these cavities are examined.

3d, That the fluid which has thus disappeared is to be found in the cerebral substance.

4th, That the brain is endowed with hygrometric properties to such an extent, that a piece taken from the cerebrum of a dog immediately on being killed, and plunged into water or serum, possesses the power of absorbing its own weight of these fluids; and,

5th, That differences exist in different animals, and in the same animal, according to the age, and the shorter or longer period of time allowed to elapse between death and the dissection.

The importance of these observations will be easily understood. They bring a new element into the field of discussion, and diminish, if not destroy, the weight of the arguments founded on the existence or non-existence of effusion after death.

It very rarely happens that an autopsy is made sooner than twelve hours after death, and by far the greater number take place at a still later period. From this it follows that, in those cases in which effusion is found after death, unless it is in such quantity as to distend abnormally the ventricles, we are not bound to conclude that there existed during life morbid effusion. Why may not a change have taken place in the physical properties of the nervous tissue? Why may not its hygrometric power have been diminished, thus leaving the normal quantity of serum in the cavities unabsorbed? There is certainly nothing against this supposition, as it is not unfrequently the case that we find a firmer state of the brain than natural accompanying the existence of serous fluid in the ventricles. On the other hand, in those cases in which no effusion is found, the conclusion is not by

any means necessary that no abnormally large quantity of serum existed during life. An opposite change to that just alluded to may have taken place in the minute structure of the cerebral mass, endowing it with increased absorbing power, by which the fluid present before death may have been removed from our sight. Neither is this supposition improbable, as we frequently find the brain soft, and as if infiltrated, the septum lucidum and other central parts fragile and disorganised,—a change most commonly ascribed to inflammation, but certainly on insufficient and feeble grounds, as it is frequently observed in cases in which no symptoms of lesion of the nervous centres existed during life. Maceration and infiltration are far more probable causes.

It is evident, then, that in our post-mortem examinations the quantity of fluid in the brain cannot be estimated by merely measuring what we find in the ventricles, or in the cells of the sub-arachnoid cellular tissue. That existing in the cerebral substance itself must be also taken into account. When we find, therefore, effusion in the ventricles, accompanied by a soft infiltrated state of the brain, as in a case mentioned by Gölis, in which this viscus, considerably increased in size, yielded upon pressure a large quantity of fluid, which oozed out as if from a sponge, all doubt is at an end, and the evidence of the existence of dropsical effusion is irrefragable. But in acute hydrocephalus this is a lesion seldom to be met with, and where it occurs must be considered as merely accidental. An opposite state is much more frequent. In the eighteen cases reported by Bequerel, in which no effusion existed, it is distinctly stated that the brain presented a healthy appearance, was of good consistence, and that the septum lucidum and the walls of the ventricles were not in the slightest degree altered. Thus, even with the modifications which the researches of Magendie and Guillot have introduced into the question, the conclusion is evident that hydrocephalus is not essentially an acute dropsy of the brain.

The theory which comes next in order is that in which the protean power, inflammation, is made to play the chief part. It is a matter of great importance in a therapeutical point of view, more particularly because it has been the prevailing opinion all over Europe for the

last fifty years. Before, however, commencing the inquiry into the truth of this doctrine, a most indispensable consideration presents itself to our notice. As pathological anatomy is the foundation upon which these remarks have been raised, it is of the utmost importance to have a clear understanding about the signs which we are warranted in admitting as evidence of the existence of inflammation. On this subject there exists among professional men great looseness, it can scarcely be called diversity, of opinion, as few have a distinct idea of what they mean when making use of the term inflammation. This evidence may be derived from two sources — symptomatology and pathological anatomy. The former has, for reasons already stated, been excluded from this paper, and may be dismissed here with the simple remark, that the literary history of hydrocephalus shews distinctly the weakness of evidence drawn from this source. It is not to be supposed that the Whytts, Cullens, and Pinels, those laborious observers and faithful delineators of disease, could have introduced such terms into their nosological system as “apoplexia hydrocephalica,” and “febris cerebialis,” if the evidence of inflammatory action had been convincing. Turning, then, to pathological anatomy, and inquiring what is the evidence furnished by it for the existence of inflammation, it will be found that the only undeniable signs are, active capillary congestion and modification of nutrition, such as softening, induration, secretion of pus, lymph, and the like. These are witnesses whose testimony cannot be called in question. It now remains to be seen whether they speak in favour of the theory of hydrocephalus at present under consideration. In authors an almost perfect unanimity exists on one point — that the appearances are not constant. One says they are generally met with; another that they are frequently seen; and a third that they are often to be found — all agreeing that they are sometimes absent, and that the hydrocephalic symptoms may exist without them.

In the first form of the disease, according to Copland, and it is certainly by far the most frequent one, the appearances on dissection are described to be the following:—Venous congestion in the membranes, inflammatory ap-

pearances in the longitudinal sinus, (it is not, however, stated what these are, and great reliance cannot be placed upon post mortem inspections in which such vague phrases occur as “marks of inflammation,” “inflammatory appearances,” and the like,) an effusion of limpid serum, varying in quantity from two to six or eight ounces; the substance of the brain soft and blanched, especially towards the centre, the fornix and septum lucidum being more or less disorganized, and soft like curd; slight watery infiltration of the cerebral substance, and a few other lesions less constant and of less moment. It must strike every one that these appearances cannot be received as marks of inflammation; the congestion is venous, not arterial, the effused serum is limpid, and can scarcely be admitted to be the product of inflammation, particularly as Baillie and Marcet have both shown that it is coagulated neither by acids nor heat, and the analysis of the latter proves that the quantity of albumen is very small. The state of the central parts is easily and more satisfactorily accounted for by the observation of Gaillot, mentioned above, than by calling in the assistance of inflammation.

Parent Duchatelet, and Martinet, have represented the disease in question as an arachnitis of the base of the brain and ventricles; but although occasionally occurring, this is by no means constant. Within the last two months I have seen seven autopsies of acute hydrocephalus, and in only one of them was there any mark of arachnitis; there was a deposition of lymph on the surface of the pons varolii, and opposite the base of the third ventricle. That true inflammation occurs, and that not unfrequently, I do not intend to deny; I have seen pus infiltrated in the cells of the pia mater, adhesion of the two layers of the arachnoid, sero-purulent effusion in the ventricles, and dotted extravasation of blood in the substance of the brain, but without being induced to regard them in any other light than complications. Hydrocephalic symptoms terminate frequently in death, without leaving a trace behind which can be referred to inflammation: the conclusion, therefore, cannot be avoided, that acute hydrocephalus is not essentially an inflammatory disease.

The most recent doctrine on the subject is that which has arisen within the

last fifteen or twenty years, from the careful and laborious researches of the French pathologists. According to it, hydrocephalus is a scrofulous affection, and depends immediately upon a deposition of tubercular granulations in the pia mater.

The eminent writers who, in the latter half of last century, first insisted upon the inflammatory nature of the affection, and called the attention of the profession to the fact, that effusion within the cranium is neither constant nor necessary to the production of the symptoms, have, with few exceptions, allowed the influence of an hereditary taint. Gölis, in his animated and, if I may be allowed the expression, picturesque history of hydrocephalus, quotes, on this subject, Quin, Odier, Cheyne, Peter Frank, Portenschlag the elder, and other labourers in the same field who had preceded him, and bears ample testimony to the truth of their observations. Its frequent occurrence in children of precocious intellect has often been observed, and we know that precocity of intellect is not an unfrequent attendant on the strumous diathesis. Sauvages observes, in speaking of eclampsia from hydrocephalus, "*Elle attaque les enfans surtout lorsqu'ils ont un vice scrofuleux dans le sang, et le mesentère rempli de glandes squirrhenses.*" Coindet remarks, "*les scrophules sont une des causes predisposantes;*" and Cheyne holds that scrofula and hydrocephalus are frequently convertible into each other. The coincidence between the periods of life subject to these diseases has been adduced as an illustration, at least, if not a proof, of their intimate connexion. Hydrocephalus attacks all ages, but all are not equally exposed to it. Rare in early infancy before dentition, it rages with its greatest violence during the period of childhood, and disappears after puberty, to be met with afterwards only in an exceptional manner.

Guersent, in a table of eighty cases from the age of six weeks to sixty-eight years, shows that the period of greatest frequency is between the third and fourteenth years, and Piet finds, in a series of ninety observations, in which the youngest is eleven months and the oldest fifteen years, that the sixth, seventh, and eighth years present the greatest proportion of cases, the numbers at each of these ages being four-

teen. But leaving reasoning from analogy and collateral evidence, it will be found that direct testimony is not wanting in favour of this view of the subject.

Laennec is quoted as the first who drew the attention of the profession to the frequent occurrence of small greyish granulations on the surface of the cerebral hemispheres in cases of acute hydrocephalus. The existence of these granulations was denied altogether by some, and by others stated to occur only rarely. I find them in the article Hydrocephalus, of the *Cyclopædia of Practical Medicine*, mentioned as things "of casual occurrence;" and Copland merely remarks, "tubercular formations have been found in various situations within the cranium." Gölis says distinctly he never saw them, but adds, with the greatest and most praiseworthy candour, that he never gave himself much trouble in looking for them. About eight or ten years ago the subject was taken up by Guersent, Gherard, Ruz, and Piet, and to them we are indebted for a most minute and accurate description of the morbid appearances found in acute hydrocephalus, called by them "*Meningite Tuberculeuse.*" Their observations have been confirmed by Lediberder, Valleix, Green, and Bequerel, the two former having extended their researches into the period of manhood. There results, from the labours of these diligent observers, a weight of evidence in favour of the scrofulous nature of the disease, extremely difficult to be got rid of. We have no longer mere analogy for our guide. We have direct, and it might almost be said, demonstrative facts, were not demonstration unfortunately a thing scarcely known in medicine. Piet, in his thesis of 1836, gives the details of twenty-three cases, of which eleven were actually phthisical, and four had tubercles in other parts of the body. In another series of eighty-seven cases mentioned by him, sixty-three presented tubercles in various organs. Guersent has only seen one case in which no tubercles at all could be found; in all the others either the lungs or bronchial glands were affected with tubercular deposit. Of one series of twenty cases mentioned by Bequerel one only presented neither granulations nor tubercles; in the remaining nineteen the pia mater was studded with granulations, and the lungs were phthisical.

Another series of ten cases furnished similar results. During the last three months I have observed attentively seven examples, in all of which granulations were found in the cerebral membranes, in two instances co-existing with regularly formed tubercles, both in the centre and periphery of the brain, and, in all, with tubercles in the lungs and other viscera; the liver, spleen, and intestines, being most frequently affected. Some doubts have been cast upon the tuberculous nature of these granulations; Senn, Charpentier, and Cruveilhier, considering them as false membranes, and Berton holding their identity with the glands of Pacchioni in a state of enlargement. The last opinion being absurd, to use the mildest term, it is the most easily set aside. A simple inspection of the seat of the granulations is sufficient to prove it erroneous. In place of occurring in the greatest quantity on the upper surface of the hemispheres, which would be the case if the glands of Pacchioni were the seat of the lesion, their most frequent seat is in the fissures of Sylvius, and along the sides and base of the brain.

With regard to the other opinion, direct demonstration is wanting to prove it false, from the difficulty of examining either chemically or anatomically such small bodies. Pelouze, it is true, has analysed the granulations, and has found them to be identical in composition with crude tubercles; and I have examined them, with great care, under the microscope, and compared them with tuberculous matter from all parts of the body, without being able to detect the slightest difference of structure. But, after all, little weight is to be laid upon either the chemical or microscopical examination, since the composition of those textures of the human body, whether normal or abnormal, which are rich in albumen, is pretty nearly the same, the difference between them depending chiefly upon their physical organization—a difference which, in the present state of science, it is always difficult and often impossible to appreciate, and because, under the microscope, substances not manifestly organised present very much the same appearance when viewed by transmitted light. Evidence from this source, then, only derives importance from its connexion with that of an indirect nature, which will now be briefly gone over. These granulations

are never met with, except in scrofulous subjects, in whom regularly formed tubercles exist in other organs, and they are often found in the pia mater, mixed with and evidently passing into tubercles, presenting the cheesy structure. I saw, just the other day, a case of this kind, in which granulations, about the size of a pin's head, and tubercles of all sizes under that of a pea, were intermixed promiscuously together, and evidently passing into each other; they are clearly analogous to the grey granulations of Bayle, the tubercular nature of which is now beyond all doubt. Besides, were they formed of coagulable lymph, we should expect to find them only in organs in a state of inflammation; but this is far from being the case, as they are met with in scrofulous subjects along with tubercles in almost every organ of the body, and totally unconnected with any marks indicating inflammatory action. They are most common under the pleura and peritoneum, and I have met with them in the liver, spleen, and kidneys. Thus, then, if circumstantial evidence is to be admitted at all, it is impossible to avoid concluding that the granulations in question are merely small tubercles.

On glancing back over this short examination of the modern French doctrine, it will be found that the constant occurrence of the signs of scrofula with hydrocephalus has been completely proved; but that the disease depends essentially upon the irritation caused by the presence of granulations in the pia mater cannot be admitted, as these bodies are sometimes entirely absent, and when present their number bears no proportion to the severity of the symptoms.*

Notwithstanding the cursory and imperfect view which has been taken of the pathological lesions in acute hydrocephalus, the conclusion is evident that they are very varied in their number and nature. They may, for greater clearness, be arranged into four groups, sufficiently distinct from each other to admit of separation.

1st, Those cases in which no lesion whatever can be detected.

2d, Those in which there is only

* I recollect one case which went through all the stages of hydrocephalus to a fatal termination, and presented on inspection no other lesion than three small granulations on the upper surface of the cerebellum.

slightly increased vascularity, and increase in the quantity of cerebral fluid.

3d, Those in which evident traces of inflammation are discovered, such as sero-purulent effusion, coagulable lymph, pus, and hæmorrhage.

4th, Those in which tubercular granulations are formed on the under surface of the visceral arachnoid.

The three last may be variously combined with each other; a certain degree of effusion frequently existing along with the granulations, and their presence sometimes giving rise to inflammatory action.

On considering these facts, we cannot help exclaiming, how is it possible that one effect can proceed from such a variety of causes so different in their nature? How are we to explain the existence of a train of symptoms, which are pretty regular in their course, by the presence of organic lesions so dissimilar? There must be something more in hydrocephalus than effusion, inflammation, or tubercular deposit; but the difficulty is, to know where this something is to be looked for. Are we to search for it in the other organs? Are we to find this cause in functional derangement of the brain, from diseases existing in a distant part, as affections of the liver, irritation from worms, and the like? Certainly not. These, when they do exist, are merely concomitant, depending upon the general diathesis, and produced immediately, in the great majority of cases, by the deposition of tubercular matter, causing ulceration of the mucous membrane of the intestines, obstruction of the mesenteric glands, or chronic inflammation of the peritoneum. Acute hydrocephalus is essentially a derangement of the nervous influence; we must therefore look for its immediate cause in the nervous system itself. But, unfortunately, in the present state of science, our endeavours will be futile. Until we know more about the ultimate structure of the brain and spinal cord, in their normal state, we cannot hope to acquire any knowledge of the changes which occur in these structures from disease. But it is to be hoped that the ardour which has been shewn of late in the study of minute anatomy, and of the phenomena of the formation of living structures, will lead to a more careful study of minute pathology, by which the causes of morbid action will be investigated, and not merely the results of that action de-

scribed. Then, and not till then, may we look for a solution of many of those difficulties which are at present stumbling-blocks in the way of the healing art, and for some insight into the nature of a class of diseases to which it may possibly be afterwards shewn that hydrocephalus is nearly allied—diseases looked upon as the opprobria of medicine—chorea, hysteria, and epilepsy, bidding defiance to the pathologist; and tetanus, and hydrophobia, resisting the utmost efforts of therapeutics.

I shall now conclude, by again remarking that we must not look for the cause of acute hydrocephalus in the many and dissimilar lesions described by pathological anatomists, but in some peculiar change in the ultimate structure of the brain, possibly analogous to what we may suppose to exist in the neuroses, depending upon a scrofulous constitution, and frequently, but not necessarily, complicated with dropsical effusion and inflammation.

CASE OF ASCITES.

To the Editor of the Medical Gazette.

SIR,

I INCLOSE you the particulars of the case of ascites, the fluid of which I described in a former number of your journal, and from the chemical constitution of it some physiological deductions were drawn.—I am, sir,

Your obedient servant,

PHILIP B. AYRES, M.R.C.S.

Thame, August 17th, 1840.

M. L., æt. 46, a strong-built woman, accustomed to hard field labour, rather emaciated, with a pinched countenance, applied to me in February last, complaining of enlargement of the abdomen, which had gradually increased for several months, following suppression of the menstrual flux. I examined her, and found a considerable quantity of fluid in the abdominal cavity; so much, indeed, as to preclude all attempts to ascertain the state of the liver, and other abdominal viscera, on disease of some one of which the ascites evidently depended. Her pulse was small and rather accelerated, skin harsh, urine scanty, high coloured, and depositing a pinkish sediment, and her cheeks striated with minute red vessels which so fre-

quently indicates abdominal organic disease, particularly that of the liver.

As the fluid continued to increase, notwithstanding the use of diuretics and purgatives, I advised her to be tapped, partly with a view of obtaining a more satisfactory examination of the abdominal viscera, and also thinking that by removing the collection of fluid I might prevent its return by appropriate treatment. I should mention that, prior to the operation, she complained of little or no pain, and what little existed was referred to the back, neither was there much tenderness, as the manual examination did not seem to annoy her. After the paracentesis the fluid did not re-collect, but the abdomen was shrunk, hard, and air gurgled through the colon when pressure was made on the abdomen. Neither could I detect any enlargement of the liver. The pulse was generally from 90 to 100, small and weak; the appetite remained pretty good; but she suffered from frequent vomiting; at first of greenish mucus, and afterwards of the food itself. The bowels were generally relaxed, and the motions rather deficient in bile. She gradually became more and more emaciated; œdema of the right ankle, and, towards the termination of the case, of the left also, made its appearance; and, a few days before her death, the skin and conjunctiva became yellow. She died on the 10th of June.

Post-mortem Examination twenty-four hours after death.—The body extremely emaciated, so that, on cutting through the integuments, every trace of adipose tissue has disappeared. *Thorax*:—The lungs perfectly sound; no trace of tubercles; but cellular bands, of ancient date, connected the pleura pulmonalis with its costal prolongation. The heart very small and flabby, with extremely thin walls. Those of the left ventricle scarcely a quarter of an inch in thickness. *Abdomen*:—The whole of the abdominal viscera glued together by fibrinous exudation (coagulable lymph), in the midst of which the omentum was imbedded, so that they were separated with the greatest difficulty. The liver, somewhat larger than natural, was mottled, presenting the appearance usually called gin-liver. In the gall-bladder, 45 calculi, averaging the size of a common nut-kernel, were found, consisting of cholesterine and biliary matter.

The kidneys presented a healthy appearance, except that they were slightly flabby. Spleen natural.

REFLECTIONS.—It is sufficiently evident that this was a case of ascites dependent on disease of the liver, although we must, at the same time, admit some degree of inflammatory action in the peritoneum. It is manifest, from the history of the case, that she could not have suffered from acute peritonitis, since there was little tenderness or pain in the abdomen from the commencement of the disease; indeed, the symptoms (save the abdominal enlargement) were so slight that she did not apply for medical advice until the size of the abdomen, and the debility dependent on the progress of the disease, precluded laborious occupation. It is well known that chronic peritonitis is so insidious in its approach and progress, as in some instances scarcely to be observed, save from the constitutional symptoms and some abdominal disorder, which, together, yield a very doubtful diagnosis: but here we have sufficient disease of the liver to give rise to the effusion. It will be found on reference to my detail on the chemico-physical properties of the fluid, that it contained fibrine in solution, which coagulated in a few minutes after it was removed from the body. This shews that the abdominal cavity was free from adhesions until after the fluid was removed, for had adhesions existed the abdomen could not have been emptied of the fluid which was most easily and completely effected. Now, as the fibrine was in solution in the fluid, and as the fluid had been gradually collecting for several months, some unknown cause must have preserved it in solution, until its relations with the vital energies were disturbed by the evacuation of a portion of it; and in this particular it differs from common acute or chronic peritonitis, in which coagulation of the coagulable lymph takes place in a very short time after the effusion, so that fibrous bands, &c., are found in cases which have lasted only a few days or weeks. The symptoms after the operation did not indicate an attack of acute peritonitis, so that in all probability the fibrine was deposited from what fluid remained in the abdomen after the operation, or some small quantity secreted immediately after, which, by gluing the viscera together, and to the reflected peritoneum, obliterated the cavity, and

prevented further effusion, as in the radical cure of hydrocele. At all events, the post-mortem examination goes to establish the deductions I drew from the chemical constitution of the liquid, in my former paper.

OPERATION FOR STRABISMUS.

THE BLUNT HOOK.

To the Editor of the Medical Gazette.

SIR,

THAT you may render a service to the profession, and a relief to the sufferings of many afflicted with obliquity of vision, I beg an early insertion of an improved blunt hook, which I have recently employed in many cases with perfect success.

The shape and size of the instrument, (which was made by Mr. Weiss,) are accurately indicated by the annexed figure.

Being formed with a view to its turning freely in a small deep space, its object is to pass beneath the rectus muscle at its narrowest part, in such a manner as to inclose all the fibres of the latter at once, and bring the muscle perfectly into view, without causing it to be violently stretched, or the globe pulled from its socket—a process which causes intense pain to the patient when a straight or slightly curved director is used to separate the muscle from the sclerotic.

Its advantages to the surgeon are, that he can readily secure the whole muscle, and separate it to any extent he pleases, without using more force than necessary to separate the cellular tissue between the muscle and the globe; also, should any fibres remain undivided, he can, in consequence of the free motion which the peculiar curve of the hook allows, readily

find them: it likewise enables him to make an even division of the fibres of the muscle, which (without the use of the director or hook) cannot be done.

To the patient the advantages of this

hook over the common director are inestimable, as it saves all the pain caused by the stretching of the nerves, and of the parts which attach the eye to the orbit.

Its advantage over the scissors (when used without a director or hook) is, that it allows of an even division of the muscle close to its insertion, for in many cases, where the muscle is *not* cleanly and closely divided to its insertion, the irregular fibres swell, become inflamed, and granulate, so as to require several applications of caustic or sulphate of copper during two or three weeks after operation. In no case where I have employed the hook, and divided the muscle evenly, and close to its insertion, has the application of any caustic been required.—I am, sir,

Your most obedient servant,

JAMES A. ADAMS.

27, New Broad Street, City,
August 3d.*

P.S. My friend Mr. Mackmurdo has requested me to say that he has found very considerable advantage in the use of the above-mentioned instrument.

INSTRUMENT FOR TREATMENT OF MYOPIA.

To the Editor of the Medical Gazette.

SIR,

IN reliance upon your well-known desire to promote the interests of the profession, in receiving all communications offering advantage to the public, I beg leave to present to you, for an early insertion in your valuable journal, an account of a new method of curing shortsightedness.

I am, sir,

Your obedient servant.

AUG. FRANZ, M.D.

19, Golden Square, August 18, 1840.

In reading the *Allgemeine Zeitung* of May the 7th, I first became acquainted with a new method of treating myopia by means of an apparatus invented by Dr. Berthold, professor at the University of Göttingen. To receive more explicit information on a subject of so much importance as this discovery appeared to me, I placed myself in direct correspondence with Professor

* By some mistake this paper did not reach us till the 23d.—ED. GAZ.

Berthold, and to his kindness I am indebted for the means of laying this report before the profession, as he not only sent me several communications by letter, but also the paper read by him before the Royal Society of Sciences at Göttingen, accompanied with a drawing of the apparatus. On the leading points I give short extracts from his paper and from his letters.

"In any attempt to cure myopia," says Professor Berthold, "our attention must first be directed to the *mutationes oculi internæ*, or the faculty inherent in the eye, of accommodating itself to the various distance of objects from the eye. Of the existence of this faculty in the eye there can be no doubt, but in what this power of adjustment consists is a question upon which a great diversity of opinion yet prevails. At all events it is subject to the will. According to the calculations of Olbers, the proportion of this power of adjustment in the human eye is such, that if the distance of the crystalline lens from the retina could be altered to one line, we should be enabled to see objects with equal distinctness, from a distance of four inches to the utmost extent of human vision. The same effect would result from a displacement of the lens to a distance of one-half of a line only, provided the radius of the cornea could be altered to about two-fifths of a line.

"The chief indication in the cure of myopia is to accommodate the above-mentioned vital power of adjustment to the physical power of refraction in the transparent parts of the eye; and to the attainment of this end, generally speaking, no obstacle exists. To regulate this power of adjustment so as to effect a permanent cure, or at least a diminution of myopia, we must proceed upon the principle, that, like every other voluntary motion of the body, it can be increased by continued and proper exercise, and by, at the same time, carefully obviating whatever might interfere with the advantages gained by it. With a view to attain this object, an apparatus, called the *myopodiorthoticon**, has been invented, which serves for the purposes of reading and writing; these being the means best adapted for the cure of myopia as intended by this instrument.

"This apparatus consists of a desk to be placed upon a table. The desk is articulated anteriorly with a board or pedestal of equal size by means of hinges, with a view of regulating and adjusting it to a proper position, in which it may be retained by a support. From the posterior part of the desk two screws rise vertically, one at either side. These screws pass through a cross-bar, which may be moved upwards or downwards by means of a mother-screw situated below it, and retained in this position by a second mother-screw situated above it. Through the centre of the cross-bar a graduated rest passes, in a horizontal direction, for the support of the head, which rest, being moveable, is held in position by a screw. By the motion of the desk upon its pedestal the cross-bar on the lateral screw, and the rest in the cross-bar, the apparatus may be so regulated, that a book to be read may be brought in the position best adapted to the situation of the eyes, and the power of sight. Parallel to one of the lateral screws of the desk a scale passes upwards through the cross-bar. This scale is graduated like the above-mentioned rest, that the gradual diminution of the nearsightedness may be accurately ascertained, but more especially that the apparatus may be adjusted to the difference in the print of the books read."

The rules to be observed in the employment of this instrument are, according to Professor B., chiefly these:—

"1. The apparatus must be so regulated that the person using it can read large print with ease, whilst leaning with the upper part of the root of the nose against the free extremity of the rest, previously brought in such a position as to place the eyes as accurately as possible opposite the centre of the book upon the desk. Care must be taken, at the same time, that the one-half of the book containing a smaller number of leaves have its deficiency compensated by suitable support, so that both halves may always form a horizontal plane.

"2. In moving the cross-bar upwards, by turning the mother-screws on the lateral screws, the distance from the free extremity of the rest to the book, or the distance of distinct vision, is to be increased every second, third, or fourth day, according to the scale, about one-half or a whole line, but never to a

* Derived from *μυωψ*, a near-sighted person, and *διορθωτικόν*, something apt or fitted to improve.

point where the print can no longer be read with facility, and where, therefore, reading would become an exertion to the eyes. A rapid increase of distance must be especially avoided, as the power of adjustment in the eye increases but slowly, and would not be able to follow; and, moreover, too great an exertion of this power can even become hurtful to the organ.

“3. For reading with the apparatus, a book must be chosen of a clear and large print, and, if possible, with the same-sized type throughout, not interspersed with italics, &c. The same print must be read as long as possible; a work containing a large number of volumes is, therefore, preferable. Should a change of book, or of the type, become necessary, the distance of the rest from the book must be regulated again to that point where the print can be read with ease, and the increase of distance gradually conducted in the manner above mentioned. For writing, the distance of the rest from the paper placed upon the desk may be somewhat more ample than for reading, if the patient observes that general rule for myopic persons, viz., to write a large hand.”

4. “During the progress of the treatment, all occupations requiring close or irregular approximation of the eyes to the object, such as sewing, knitting, embroidering, drawing, &c., must be avoided. At times, when the patient is not using the apparatus, he should practise looking at distant objects only, take frequent exercise in the open air, and view distant trees, green fields, and hills. A proper diet should be observed, and all heating food and liquors abstained from; a cooling aperient is to be taken now and then, and habitual congestion of the head or eyes suitably counteracted.”

Professor Berthold states in one of his letters to me, that in Göttingen, as well as in several other parts of Germany, this instrument is already much in use for the treatment of myopia, and that its effect has surpassed his expectation, even in the most severe cases. Of the numerous cases under his treatment he relates one of a student, who was very anxious to be cured of his myopia, or to have his sight at least improved. This young man, aged 26, enjoyed very good sight from his birth, but during his education at school this had gradually di-

minished until a confirmed myopia established itself. When the patient placed himself under the Professor's care the degree of nearsightedness was such, that he could only read a common print at a distance of four inches: he suffered at the same time from a congested state of the vessels in the conjunctiva and eyelids, the margins of which were rather swollen, and easily reddened by the stimulus of light and air. A few leeches were applied in the neighbourhood of the eyes, and occasionally repeated. Sulphur. cremor tartari, and pulvis rhei, ordered to be taken internally, so as to ensure two or three loose motions daily, and a strict diet recommended. After the continuation of this treatment for a short time the myopodiorthoticon was brought into use: by its use the distance of vision became gradually increased in the manner above described, so that the patient now, after the lapse of scarcely four months, can read with facility and distinctness, at a distance of eleven inches and one-third, a print which formerly he could only read at four inches distance. He also sees distant objects in the open air far better than before. The use of the apparatus is still continued, and he is not content with the distance of eleven inches and one-third, but purposes extending his sight to sixteen or eighteen inches. When the patient commenced the use of the apparatus he had made rapid progress in increasing the distance of vision, by which he had certainly gained great practice in the power of adjustment of the eyes, but this organ having been over-exerted became easily fatigued, so that it was considered necessary to begin the use of the instrument again from the commencement. Prof. B. lays it down as a rule never to be deviated from, that a slow and steady progressive increasing of the distance of vision, especially in the beginning of the treatment, is the chief condition upon which a safe and perfect removal of myopia by this apparatus depends. He farther remarks, that in early life a more rapid cure may be expected than in mature age; and that the time of duration of the treatment with the apparatus is exactly proportioned to the degree of myopia.

I have been informed by several of my friends in Germany, that the Royal Society of Sciences of Göttingen has highly commended the ingenious construction of the myopodiorthoticon, and

expressed their approbation of this new method of treating nearsightedness; and that much attention and interest have been excited, not only at Göttingen, but also in several other towns of Germany, by this invention. If we attentively consider the principles upon which the construction of this instrument rests, we shall find that they are theoretically perfectly correct, and therefore, in my opinion, its practical worth can hardly be doubted, the less as its inventor has already succeeded in curing a number of cases of myopia. There appears even every reason to believe that a judicious use of this instrument will prove effective not only in myopia, but also in cases where presbyopia exists in young persons, or where one eye is near and the other farsighted—an ophthalmic defect which is not very rare.

As this instrument is very simple in its construction, any writing-desk used in colleges, offices, &c. may be easily furnished with its more essential parts, and thus students, clerks, &c. afflicted with nearsightedness, which in these persons is always brought on by their daily occupation of reading and writing, may make the cause of their affection the means of cure. Proper attention must of course be paid to the medical and general rules laid down for this method of treating myopia. This instrument may, farther, be a means of preventing myopia, when used at an early period of life, especially by those children in whose eyes an hereditary predisposition for myopia may exist, which generally shows itself after the commencement of instruction. For this purpose the apparatus might be introduced into schools and other public institutions for education on a large scale, viz. by converting a whole school-table into a common myopodiorthoticon, which is regulated according to the distance of vision of each individual, chiefly by means of a somewhat different rest for the support of the head. The introduction into public institutions of the myopodiorthoticon thus contrived would moreover prove advantageous in several other respects, inasmuch as the use of this apparatus would oblige the children to sit in an upright position, and to hold their heads erect, and thus prevent curvatures of the spine, complaints of the chest, congestions of the head, and other diseases, which are apt to appear in children of a weakly constitution, after

an habitually improper position of the upper part of the body during reading and writing.

I have now a myopodiorthoticon in my possession, which I had made according to Professor Berthold's drawing, with the exception only, that instead of one graduated scale, I ordered two to be made, one at each side of the desk, in order to be enabled to regulate the cross-bar with greater precision. The pedestal I have also altered, and it is now so contrived that, while the whole instrument remains upon the table, the desk may be raised to a height suitable for a person whilst sitting or standing. With this instrument I have written and read myself during the last four weeks, merely to ascertain whether its use is attended with inconvenience or restraint; but I find that, on the contrary, when once habituated to it, much comfort and support are derived from its employment.

As perhaps mine is the only instrument of this description in this country, I shall feel great pleasure in affording to those who may be interested in this method of treating nearsightedness, the opportunity of examining the mechanical contrivance upon which this method is based.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Acute Hydrocephalus; or, Water in the Head an Inflammatory Disease, and curable equally and by the same means with other Diseases of Inflammation. By DAVID D. DAVIS, M.D., &c. London, 1840. 8vo. pp. 309.

It has long been the established opinion that the effusion of water in acute hydrocephalus is the consequence of inflammation of the brain. After narrating some cases of the disease, Dr. Abercrombie says—“From a fair and candid review of the whole subject, I think we can have but little hesitation in concluding, that this is the ordinary form of the disease which is commonly called acute hydrocephalus; that it is originally an inflammatory affection, chiefly seated in the substance of the central parts of the brain; that it gene-

rally terminates by ramollissement of these parts, combined with serous effusion in the ventricles, &c.*

Dr. John Clarke, in his *Commentaries on the Diseases of Children*, treats of hydrocephalus under the head of phrenitis, or inflammation of the brain, and recommends bleeding from the external jugular vein in children above a year old.

Underwood says, "Whatever may be supposed the immediate cause of hydrocephalus, practitioners seem chiefly to have depended on repeated bleedings, purges with jalap or calomel, blisters to the neck or head, diuretic medicines, and the external use of mercurial ointment. A large bleeding early in the disease I have thought very beneficial, especially in children of a robust habit*."

Yet in spite of the opinions of such eminent physicians, the majority of practitioners do not bleed largely in hydrocephalus; whether from a natural distrust of their own diagnosis, or from the fear of the remedy proving as fatal as the disease. Dr. Davis, indeed, doubts whether even the theory is generally received. He says, "A notion of this kind somewhat doubtfully exists among some members of the profession. But the impression in question does not amount to a living practical faith in this country; if, indeed, we may venture to presume that it even approximates to a general opinion." (p. 165.) Our author accordingly shows from dissections (chiefly those in Gölis's work), that hydrocephalus is an inflammatory disease; he gives the diagnosis of its several stages, and discusses its treatment at length. The account of the first stage extends to eleven pages; but we do not see in it any symptoms so eminently characteristic as to enable the practitioner to adopt without hesitation the extremely vigorous treatment recommended by our author. A couple of diagnostic signs, if they could be found, would be more satisfactory than this long discussion.

In the treatment, the most important point, says Dr. Davis, is bleeding; which is to be carried to "full fainting." It is not a state of faintness that is wanted: it is full and decided fainting." (p. 241.) In children from a

month to a year old, the quantity of blood taken should be from three to five ounces. When the blood cannot be obtained from the arm, cupping is to be adopted in preference to leeching; or the jugular vein is to be opened.

When the child has recovered from the fainting, an emetic is to be administered. An infant six months old is to take a quarter or a fifth of a grain of tartar emetic, with five grains of ipecacuanha. The parents are not to have any confidence "in certain alarming and otherwise uncalled for observations of druggists' apprentices, and other young gentlemen occupied in shops of pharmacy, about the magnitude of doses of medicines intended for young children."

The third indication is to diminish the morbid heat of the head by cold applications. The best is some iced fluid in one of Mackintosh's water-cushions; and the fluid must be changed every half-hour, as long as it is agreeable to the child. Blisters, if applied before blood has been abstracted, often aggravate the symptoms. Calomel is useful; and Dr. Davis commonly recommends a purge consisting of two or three grains of calomel (or sometimes twice that quantity), with six, eight, or twelve grains of jalap, according to the age of the patient, after the operation of the emetic is over. Calomel may also be exhibited to resolve the inflammatory action; but this must be done with discretion, as in full and frequent doses it has sometimes destroyed the patient. It has occasionally, though rarely, cured acute hydrocephalus, without bleeding. Dr. Davis never depends upon it, but uses it only as an auxiliary to the lancet, or in cases where bleeding would be too late.

We next come to an alarmist manifesto, which does not please us; it is entitled "Circumstances indicative of danger of acute hydrocephalus, which should operate as a warning to parents and guardians to take the advice of their medical friends in good time." It is divided into thirteen paragraphs, containing occasions for alarm; and these sections are so sweepingly comprehensive, that half the children in the kingdom would be thought in danger of hydrocephalus by their anxious parents.

The work concludes with the details of six cases of acute hydrocephalus

* Abercrombie on Diseases of the Brain, 2nd Edition, 1829, p. 143.

† On the Diseases of Children, 8th edit. p. 349.

treated by our author at University College Hospital. The treatment, which was successful in every instance, consisted of the vigorous measures already mentioned; but the water-pillow was used only once. He has been equally fortunate in private practice under similar circumstances; that is, when he has seen the patient soon enough. Whether this active treatment will be generally attended with the success which Dr. Davis supposes, must, of course, be left to time to determine. His work is replete with valuable information; as, independently of his own experience, it contains an abstract of the best treatises which have appeared in English on acute hydrocephalus.

Cursory Notes on the Morbid Eye. By ROBERT HULL, Extra-licentiate of the Royal College of Physicians, &c, London and Norwich, 1840. 8vo. pp. xx. and 249.

THIS work is divided into ten chapters, which respectively touch on the diseases of the conjunctiva; the sclerotic; the iris; the choroid; the retina; the cornea; the membrane of the aqueous humour; the corpus ciliare; the vitreous humour; and the optic nerve. It is a useful and curious book; useful in substance, and very singular in style. Dr. Hull, who is now physician to the Norfolk and Norwich Hospital, was formerly surgeon to the Ophthalmic Dispensary in the same town; and these notes deliver the result of his own experience, as well as his commentaries on the practice of others.

The style is often humorous, and sometimes witty; and though it is certain that quaint phrases and sportive sallies are alien to the genius of a scientific work, candour obliges us to confess that we have been amused by these agreeable eccentricities.

Dr. Hull has found the oil of turpentine useful in strumous ophthalmia, and inflammation of the cornea, as well as in iritis.

Apropos to rheumatic iritis, he mentions that he has used the artichoke with success, both in the hot and cold forms of ordinary rheumatism. The dose is a drachm of a tincture three times a day, with ten grains of an extractum cyuaræ. In treating of *hemipia*, or half-sight, Dr. Hull observes that this

is of two kinds; the one, where a man sees things with half an eye; the other, when only one-half of a given object can be seen. "Dr. Wollaston was an illustration of both sorts of hemipia. As a philosopher, he saw things with half an eye; as a patient, with cerebral disorganization, he was the victim of this singular disorder in each organ of sight." (p. 216.)

Those who purpose to study diseases of the eye with the deep attention which they deserve, will do well to read Dr. Hull's ingenious work; for, independently of containing many instructive cases, it supplies the reader with materials for thinking.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

MANAGEMENT OF THE POOR IN SCOTLAND.

IF an Englishman, discontented with the mode of relieving the poor in his native island, were to turn his eyes to the continent, in the hope of finding some abler system of management, the kingdom of Holland would be among the first to attract his attention. If the Dutch erred, he would be pretty sure that it could not be on the side of incautious liberality. Their excessive sobriety and prudence have been proverbial for ages; and it might be supposed that they would be the last to forgive any pecuniary indiscretion. "When a man happens to break in Holland, they say of him, that *he has not kept true accounts*. This phrase, perhaps, among us, would appear a soft or humorous way of speaking, but, with that exact nation, it bears the highest reproach*." It might have been conjectured, therefore, that so rigorous a nation would have been as indisposed to

* Spectator, No. 174

pardon a pauper-labourer as a bankrupt merchant; and that, in the true spirit of Malthus, they would have expected the ploughman to make a provision for old age out of his scanty earnings. But how stands the fact?

Mr. Nicholls, in his Report to Lord John Russell, "on the condition of the labouring classes, and the provision for the poor, in Holland," speaks of the scrupulous economy and cautious foresight of the people in terms as strong as those employed by Steele in the quotation we have just given. "To spend their full annual income is accounted a species of crime." Nevertheless, "the institutions for the relief of indigence are numerous in Holland, and consist of *hospices* for the aged and infirm, orphan-houses, workhouses of towns, *dépôts de mendicité*, or district workhouses, the poor colonies, and private charitable institutions. * * * Many of these institutions, in their structure and appearance, rather resemble palaces than poor-houses, and they form one of the most prominent characteristics of the great towns."

To this Dr. Alison adds, what Mr. Nicholls has omitted to observe, that there is in Holland an extensive system of out-door relief, authorized and enforced by law. The fund for the relief of the poor is derived partly from endowments and voluntary contributions, as well as from the direct tax; but Dr. Alison justly observes that the effects of a fixed and uniform provision depend on the certainty with which it can be expected, and "not on the source from which it comes, which is very often unknown to the receiver." The sum expended on the poor in these establishments is 4s. 4d. a head on the whole population of Holland: this is nearly four times the amount of the Poor's Fund in Scotland, while the value of money is higher in the former. "And what is the consequence of all this?" asks

some Englishman slightly tinged with Malthusianism, but not yet in a hopeless state of mental delusion. "I suppose the Dutch must have lost all their antique virtues, and have become a huge mob of paupers: each labourer struggling to obtain the largest share from the national broth-pot, until every man has devoured every one else, like the Kilkenny cats in the story!"

Let Mr. Nicholls answer the question. "Nothing can exceed the cleanliness, the personal propriety, and the apparent comfort of the people of Holland." He saw only two beggars, and not a single ragged, dirty, or drunken person. These facts, and plenty more like them, given in Dr. Alison's former pamphlet, have convinced many of those who were led astray by the sophisms of the economists, and did not know the facts of the case. It appears from the clearest evidence, that in those countries where there is only a scanty provision for the poor, such as France, Italy, and Spain, the indigent are far more miserable, and absolute destitution is far more common, than in the North of Europe, where relief by law is administered.

Dr. De Vitré, writing to Dr. Alison, scouts, as he well might do, the visionary idea that charity is paralysed by the Poor Laws in England. The man who first put forth this fancy must have had a marked preference for solving problems on paper, to looking at facts in the scene before his eyes. In no country is private charity so munificent as in England; and the Poor Laws, far from drying up the fountain, have merely been one of the channels through which it flows. Indeed, the Poor Laws, by raising the standard of comfort due to the indigent, have given private charity a higher mark to aim at. The obvious truth is, that the Poor Law, and, what is of more importance, its liberal interpretation for ages, were not forced by a benevolent despot upon a reluctant people, but

were the natural offspring of English feelings; and to suppose that the same people who disgusted our scribbling Harpagoes by the comforts lavished on the workhouses, steeled their hearts against misery in all other shapes, is an absurdity that could only have proceeded from the skull of an economist.

It is curious that Dr. Alison's antagonist, Mr. Monypenny, admits, in its fullest extent, the existence of very great and appalling distress in Edinburgh and Glasgow; and allows that the arguments by which Dr. Alison has enforced the necessity of a cure for this serious evil are powerful and resistless. But while he admits the flagrantcy of the evil, he denies the expediency of the remedy proposed by Dr. Alison, and, instead of an additional assessment, recommends another voluntary subscription. But, unfortunately, the unanswerable reply is, that a subscription of this kind does not flourish in Edinburgh. Last winter the destitution of the poor was a pretty general subject of discussion there; only £600, however, could be raised in several weeks; and as additional funds could not be procured, the relief abruptly stopped, "when so far from the destitution being adequately relieved, many very destitute families had not even heard of the subscription*."

The scantiness of the collection is certainly surprising; or, at least, would be so, if we did not recollect that poor-rates and subscriptions come from the same purses, ruled by the same wills; and as we have above observed that large poor-rates do not dry up the sources of charity, so small ones do not render them more copious. We are to recollect, too, that not the poor of Edinburgh alone, but those of Glasgow, Paisley, Greenock, Perth, Dundee, and Aberdeen, are in the same precarious condition; liable to the sweeping attacks

of unrelieved distress, with starvation and fever in its train. The smaller towns are nearly on the same footing; and 200,000 of the population of the Highlands and Islands are even worse off. Dr. Alison comes to the painful, but, we fear, too accurate conclusion, that "*the lowest class of society, in more than one-half of the population of Scotland, during at least a part of the year, is in a state of lamentable destitution, for which there is no adequate provision.*"

With this general destitution, and the example of the failure at Edinburgh before us, it would be vain to hope for voluntary subscriptions. A writer in the Ayr Observer prefers the voluntary to the compulsory system, but says, oddly enough, "The excellence of the Scottish system is generally acknowledged. But in what does this excellence consist? Simply in giving a penny-farthing a day instead of sixpence." It seems that in certain districts this frugal allowance is the *το καλον*, or charity in its ideal beauty. "Most of the managers of the poor in landward parishes, with whom the penny-farthing a day is the maximum, are so tied down to the imagined excellence of giving this miserable pittance, that *they never feel any compunctions on refusal, however painful may be the distress*.*"

The assessment, too, must be universal, and the law of settlement must be altered, or the poor will continue to flock into Edinburgh as they do now.

The most plausible argument urged by Mr. Monypenny is, that in the Parliamentary proceedings of 1834, the Scotch system was held up as a model of imitation. The plain fact was, that in the talk of the more vehement economists, the Scottish system was called better than the English, simply because

* Alison, Reply, p. 20.

* Alison, Reply, p. 22, from Ayr Observer, May 5, 1840.

it gave less relief. Its details were not known; for if the terrible facts brought to light by Dr. Alison had been then published in England, the most icy prater about surplus population would have been ashamed to praise the five farthings a-day system.

Moreover, since 1834, several official reports have been published on the condition of the poor in Ireland; and the details of unutterable misery endured by the unrelieved poor of that country have done much to wean all reasonable persons from Malthusian whims. The Poor-Law Commissioners, too, have been chastised into a greater semblance of decency: so that Mr. Monypenny is clearly wrong when he supposes that the public estimation of the Scottish system has undergone no change in England since 1834.

We do not altogether agree with Dr. Alison in his approbation of the workhouse system as now carried on in England. It is clear that harshness too often gives the tone to their internal administration; and it must demand the nicest tact on the part of the master, to steer his course, guided by the rigorous injunctions of the Commissioners on the one hand, and any remains of humanity which may linger in his breast on the other. To be kind to the wretched inmates of the house would be to disobey the rule that workhouses are to be eminently distasteful—in short, “tests of destitution;” and if he carries the spirit of the regulations into execution too actively, he is liable to be hauled over the coals by their authors; to be disowned, in fact, like the imprudent emissary of a crafty minister. Hence such scenes as those which have taken place in the Bath Union Workhouse. The Rev. C. Fowell Watts, late chaplain to the establishment, informs us that a woman who had been made to pick oakum in a cold out-house till disease was produced, and who had given evi-

dence in the course of the investigation by the Assistant Commissioner, said to him: “Oh, sir, I am determined, as long as I stay in the house, never to tell any thing again, so great has been the persecution and ill usage I have received since I gave evidence.” Among other instances of oppression, Mr. Watts gives the case of a child, four years old, looking the picture of wretchedness and sickness, who was taken out of the house by its mother, after its back had been covered with wheals and bruises as the punishment for wetting its bed. In another case, a child, eight or nine years old, was flogged most cruelly, three days running, for complaining to the guardians of having been beaten unjustly. The bread has several times been shewn Mr. Watts at the time of receiving it, not half the proper size. In a word, the poor, generally speaking, are “very unhappy in the house*.”

The reader cannot suppose that the instances of ill-usage in workhouses, which from time to time force their way into the newspapers, are the only cases that occur. Would that they were! Those under whose sanction, or by whose instigation, the severities are exercised, are “respectable” persons; they keep gigs, nay, tandems and barchouches; they hang together; and even those whose approbation of union matters is gradually waxing cold, do not like to denounce their comrades. The poor themselves have scarcely any access to the press. Is anybody so simple as to imagine that of the atrocities committed at our public schools, under the name of fagging, one tithe has ever come to light? No! it is enough that the practice is winked at, if not sanctioned, by the masters; cruelty remains uncensured within the iron limits of the white slave-gang; and it must be some extraordinary fact indeed, which

* Times, Tuesday, Aug. 25, 1840.

is enabled to burst its unhallowed ceremonies, and affright the uninitiated public!

Again we part from Dr. Alison with the deepest admiration and esteem; and we fully join with him in the observation which he quotes from Dr. Johnson, that "a fixed and decent provision for the poor is the true test of civilization."

CANCERUM ORIS.

To the Editor of the Medical Gazette.

SIR,

As the following case of "cancerum oris," in which it was deemed expedient to institute a medico legal inquiry, must necessarily be interesting to your numerous readers, I have taken the liberty to send it for insertion in your valuable journal. The Morning Advertiser, of Thursday, Aug. 20, contained the most correct account of the proceedings. I have, therefore, transcribed them from that journal, and have added some further remarks which were accidentally omitted.

I am, sir,

Your most obedient servant,
EDWARD AUGUSTUS CORY, M.D.

Canon Street Road, Aug. 21st, 1840.

Extraordinary Investigation: Medical Practice.—Yesterday evening an important inquiry took place, before Mr. Baker, touching the death of a child, four years of age, the daughter of Mr. Clark, a carpenter, and dealer in coals and vegetables, residing in the New Road, who, it was alleged, came by her death in consequence of mercury having been improperly administered to her by a medical gentleman named Cory. The affair excited considerable interest in the neighbourhood, owing to the very high professional reputation of Dr. Cory, and the inquest-room was crowded to excess. There were not less than twelve of the leading practitioners of the district present, amongst whom were Mr. Adams and Mr. Curling, two of the surgeons and lecturers at the London Hospital; Messrs. Tripe, Major, Garrett (parochial surgeon), Gurney, and others. Several gentlemen from St. Thomas's and Guy's Hospitals also attended. The jury, having been sworn, proceeded to view the body, which presented a most horrible spectacle. It was very much emaciated, and one side of the face was completely eaten away.—Mary Ann Clark, the mother of the child, stated that the deceased was taken ill about seven weeks ago. Previous

to that time the child had had good health. The complaint was whooping-cough, accompanied by spitting of blood; and she called on Dr. Cory, of Cannon Street Road, who saw her until the following Monday, in all five days. On the fourth day after his attendance the child complained of soreness of the mouth, and her teeth were very loose, and came out. The next thing she noticed was the child's tongue and the inner part of her cheek. Both were much swollen and risen in white blisters, so much so that her side and double teeth became imbedded in the side of the cheek.

Dr. Cory, when she first consulted him, recommended her to send the child into the country for the benefit of the fresh air, as the best method of getting rid of the whooping-cough; but she would not agree to this, as she was dissatisfied with Dr. Cory's carelessness about the case, and sent for Mr. Rutherford, a surgeon, of Ratcliff Highway, who, when he saw the child, stated that the patient ought not to be removed into the country, and that he thought it ridiculous for any medical man to advise such a thing. Mr. Rutherford advised that the child should be kept warm; but Dr. Cory had ordered her to give it all the fresh air she could, although she told him when she did so that the child always fainted away. [The child was kept closely confined in a little back apartment, in immediate approximation with coals and vegetable matter in a state of decomposition.—E.A.C.] "Mr. Rutherford declined to interfere in the case, when he found that Dr. Cory had attended the child. The child got gradually worse, and she took it to Mr. Curling, who operated on the cheek. On the following day she again took the child to Mr. Curling at the London Hospital, but he gave no hopes of recovery, as mortification had commenced.

A medical gentleman on the spot attended the deceased after this until her death, which took place on Monday morning. She called several times on Dr. Cory as she came from the hospital, but never could see him. She left word for him to call at her house, but, instead of doing so, he sent the following note:—

"Dr. Cory sends his respects to Mrs. Clark and begs to decline attending the child, and recommends Mrs. Clark to those (if she can find them) who will do more for its benefit, and pay more attention. Mrs. Clark will be so good as to remember that in the first instance Dr. Cory told her that medicine would not do the child much good, and the only chance of its recovery would be in the removal of it into the country for a time. If Mrs. Clark had thought proper to comply with this recommendation the child would have had a

very good chance of getting well. The idea of the child having had mercury is too ridiculous to be noticed, and Dr. Cory is surprised that a person of Mrs. Clark's apparent good sense should entertain for a moment such an absurd opinion. Dr. Cory has the honour to attend nearly all the most respectable inhabitants of the neighbourhood, and he is too much occupied and too independent to put up with any nonsense from any of his patients.

"Cannon Street Road, August 10, 1840."

The coroner having read the letter aloud put some questions to the witness, who said that Dr. Cory had told her that the complaint of the child was hooping-cough. He also gave it (the malignant disease) another name which she could not recollect.—Dr. Cory—I told you the deceased was affected with cancerum oris, which means canker of the mouth; did I not? Mrs. Clark—Yes, that was the term. Mrs. Clark continued—There were no symptoms beyond hooping-cough and spitting of blood until the child had been four days under Dr. Cory's treatment, when small blisters showed themselves in the mouth, and the teeth became loosened. [The whole evidence of the woman was of the most rambling and exaggerated description. There were not the slightest symptoms of any affection of the mouth the last time I saw the child, which was five days after I first prescribed for it. It was stated that an illegal practitioner in the neighbourhood had insinuated to the mother that the child had been improperly mercurialized.—E. A. C.] Coroner—Who wished an inquest to be held on the deceased? Witness—Both my husband and myself, sir, as we were dissatisfied with Dr. Cory's treatment of the child. [The beadle was perfectly aware that the first proposition of an inquiry emanated from me. This was mentioned at the time, but has not been noticed by the reporter.—E. A. C.] Cross examined by Dr. Cory.—You did not say in my hearing that medicine would not do my child any good. All that I know is, that you gave orders to your assistant not to supply me with medicine unless I paid for it. Dr. Cory said he was willing to allow his book, in which was written every thing he had prescribed for the child, to be examined by the medical gentlemen present, who would find that he had not sanctioned the administration of a single grain of mercury; indeed, he should hardly have advised the removal of the child into the country, if he had thought it necessary to put it under the influence of mercury. Dr. Cory here read an extract from Professor Cooper's Surgical Dictionary, descriptive of the disease, termed cancerum oris, with which

disease the child was affected. The symptoms of this disease exactly corresponded with those described by the mother of the child. The disease was one that seldom or ever affected adults. Several of the medical gentlemen present stated that they had examined Dr. Cory's book, containing the prescriptions administered to the child, and could not find that any mercury had been given. They considered the treatment quite proper.

Mr. Blizzard Curling, nephew of the late Sir W. Blizzard, Surgeon to the London Hospital, deposed that the child was brought to him a fortnight ago. There was a large spot of mortification on the left cheek. The disease was of such a decided character that he told the mother and her friends it could not recover. He gave it a ticket for the hospital, and prescribed the usual remedies. He asked if the child had been taking mercury, and was shown a powder, which he did not test, but advised that it should not be given to the deceased. The disease was a very singular one, and in the incipient stages white livid spots would arise, the teeth become loose, and other symptoms exhibit themselves, which will often arise when not one grain of mercury has been administered. Cleanliness and fresh air were very essential in curing the disease called cancerum oris. Persons afflicted with it would stand very little chance of recovering in such a confined and densely populated neighbourhood as St. George's in the East.—A juror asked Mr. Curling why he advised the friends of the deceased to discontinue the powders? Mr. Curling said his only motive was that he was not then aware of what the powders might be composed. A juror—Is the disease contagious? Mr. Curling said it was difficult to say, but he was inclined to think it was: it principally affected children between the ages of eighteen months and seven years. [Mr. Tripe, a most respectable practitioner of twenty-two years standing, had had two cases of cancerum oris lately in his own practice. He had not given them any calomel, or other preparation of mercury. Mr. Major had also had a similar case.] Mr. Garrett, the parish surgeon of St. George's in the East, said he was decidedly of opinion that the disorder in question was a kind of epidemic, principally confined to densely populated districts, where the ventilation was defective. If all the metropolitan thoroughfares inhabited by the lower classes of the community had a free current of air through them, the health of the people would be greatly improved. Thousands of the poor, especially in the East end of London, never got a mouthful of pure atmospheric air for months together;

indeed, a gleam of sunshine was quite a treat to them. The coroner said there could be no doubt that the mortality of the metropolis was greatly increased by the lack of fresh air. Mrs. Clark said her child had not suffered from any want of cleanliness; and should never be convinced that it was not killed by mercury. The coroner said that the feelings of the mother under the circumstances were very natural, but it was quite evident she was in error. The jury and the medical gentlemen present had had an opportunity of examining Dr. Cory's book, from which it had appeared that not a single grain of mercury had been administered to the deceased; still, he would repeat that the conduct of the mother was very natural, though she was evidently labouring under a gross mistake relative to Dr. Cory's treatment of the child. A juror—I consider the case one of great importance to the public generally. We are all occasionally in the hands of medical men, and it is necessary a strict watch should be kept upon them, in order to prevent improper medicines from being administered, from which the most lamentable consequences have but too often ensued; but in the present instance no blame appears to be attributed to the surgeon. The coroner, in summing up the evidence, remarked that in a case like the present an inquiry was of the utmost importance, not only for the satisfaction of the friends of the deceased, but also in justice to the medical attendant, who might do all in his power to conquer a disease without success. Dr. Cory was a gentleman in great practice, and he had never heard any complaint of his treatment. It appeared from the testimony of the numerous medical men present that the treatment of the child was perfectly correct; and it is probable that had his advice been taken, and the child sent into the country for the benefit of the fresh air, it would have been alive at that moment: the benefit of a pure atmosphere in such cases was incalculable. The late Sir William Blizard, the principal surgeon of the London Hospital, some years ago, discovered that the cure of surgical patients was from some cause greatly retarded.

After speculating upon the cause for some time, he found out that the common sewer flowed close to the walls of the hospital, and he conjectured that the effluvia arising therefrom affected the health of the patients. He therefore got the sewer walled over, and a vast difference was soon perceptible among the patients. He mentioned this to shew the jury the effects of an impure and close atmosphere in such cases.

"The jury expressed themselves perfectly satisfied, and returned a verdict of "Natural

death from cancerum oris, and that death was in no way accelerated by the medical treatment of the child."

MILITARY HOSPITAL, EDINBURGH.

Case of Comminuted Compound Fracture of os frontis, extending to os ethmoides, os sphenoides, os nasi, and nasal plate of superior maxillary bone on the left side, accompanied by continual loss of cerebral substance, in which the patient lived twelve days, retaining his senses with very little exception till his death.

JULY STR.—Private —, 29th regiment, ætat. 29, a stout, robust man, 9½ years service, of which 5½ years were in the Mauritius, was assisting in pulling a rope upon the fore-castle this morning, when the rope, which passed through a large block, gave way, and the block flew upwards and struck him on the forehead. He was seen at five minutes past six, when the following was his state. An enormous swelling of the integuments covering the os frontis, with three lacerated wounds upon it, from the centre of which about a teaspoonful of cerebral substance, broken down, was protruding. On examination, a probe passed into the cavity of the head; no depression existed, nor did the constitutional symptoms indicate any such. The pulse was 86, and full. The pupil of the right eye contracted; that of the left could not be seen, from the swelling. Pulse fell to 70 on bleeding. He is quite sensible, and complains much.

R Pulv. Jalap., gr. xxx.; Calomel, gr. viiss.; Aquæ, ʒiiss. M. V.S. ad. ʒxvi.; Appl. Lintæum Vulneri.

Quarter to 7 A.M.—Has just vomited some cocoa he had taken last night, and afterwards some blood, from the exertion of vomiting; portions of brain are protruding from all the wounds. He is becoming drowsy, but when aroused is very fretful and irritable. Half-past 8. He took the draught; the portions of brain were gently wiped away. 9 o'clock. More brain has presented itself at each of the wounds. He has slept for a quarter of an hour; his respiration was slow and gentle; he is now awake, and very irritable, attempting to tear off the lint; pulse 76, and soft; is perfectly sensible. Half-past 12. Remains in the same state: bowels not moved.

R Pulv. Jalap. gr. xx; Ol. Croton, mʒj. M. Passed the catheter, and drew off ʒiv. of urine.

3 P.M.—No change; is very irritable when aroused; soft brain and blood oozing from

the wounds; bowels unmoved. 7 P.M. Bowels confined; pulse 80, and full; pulse fell to 70; brain exuding from the wound: has taken a few teaspoonsful of tea.

V.S. ad. $\frac{3}{4}$ x. R. Ol. Croton, $\frac{mij}{j}$; Ol. Ricini, $\frac{3jss}{j}$. M.

July 9th, 8 A.M.—Has slept tolerably during the night. About 10 P.M. he passed his urine freely; there has been no motion of the bowels; talks at times incoherently, but is not in such a state of stupor as yesterday; pulse 76; tongue brown; the wounds are filled with cerebral matter and blood. Medicine operated three times.

R. Ol. Croton, $\frac{gtt}{ij}$; Ol. Ricini, $\frac{3jss}{j}$.

9 A.M. was removed from H.M.S. Vesuvius to Edinburgh Castle.

10th, 8 A.M.—Has had a good night; bowels open once, passed his urine twice; head somewhat easier, and wounds not so foul as yesterday; cerebral matter, however, still exuding from them.

Appl. Lotio Frigid. Capiti.

11th.—Complains much of pain in his head. The wounds have the same appearance. The swelling of the integuments having diminished, a crepitus has been discovered over the left external angle of the os frontis, by staff-surgeon Dr. Robertson; has taken tea and bread; pulse 74; bowels open twice since he has been on shore.

12th.—Has had a good night: a probe passed through a small opening in the central wound, two inches inwards into the cavity of the head. There is still cerebral matter, mixed with bloody serous discharge; is quite sensible; bowels confined; pulse 74; tongue cleaner; appetite tolerable.

R. Ol. Ricini, $\frac{3i}{j}$.

13th.—No change.

14th.—Complains much of want of sleep; has been incoherent last night; tongue foul; bowels open twice by the oil; pulse 76, and small; very distinct crepitus on left side of frontal bone.

R. Morph. Acet., gr. 1-3; Acid. Acet., $\frac{gtt}{iv}$; Aq. distill., $\frac{3i}{j}$. M. hor. som.

15th.—Has slept well; crepitus and fluctuation, or rather an undulating sensation as though no resistance was offered by bone, very distinct over the left eye; tongue foul; pulse 74; bowels confined.

Ol. Ricini, $\frac{3ss}{j}$; Rep. Haustus, hor. som. Hab. Mixt. Diaphoret. ter in die.

16th.—Rather feverish; pulse 80, and hard; much discharge from wound; is not altogether so well.

Cont. Omni.

17th.—Pulse 76; tongue foul; opened a collection of matter in left eyelid.

18th.—Has been incoherent all the night. The orderly reports, a portion of brain came away this morning the size of a hazel-nut; pulse 90, and hard; is quite sensible; pupil of right eye much contracted; is in a profuse perspiration; brain and blood exuding from the opening.

19th, half-past 3 A.M.—Died.

Sectio Cadaveris, before Dr. Myham, 29th regiment, staff-surgeon Dr. Robertson, and Sir George Ballingall, thirty-two hours after death.—*External appearance:* Body muscular, and well formed; ecchymosis of depending parts of body; a deep semi-circular depression, three inches long, extending from highest part of forehead straight down to the left orbit: this was not visible during life, owing to the extensive swelling. On removing the scalp, the whole of the left side of frontal bone was found smashed; one irregular piece of bone, three inches long, was isolated, as well as several smaller pieces; the fracture extended to the orbital plates of the frontal and sphenoid bones, the os planum of the æthmoid bone, and also the os nasi and nasal plate of superior maxillary bone, and the crista galli was loose. The anterior lobe of the brain, corresponding to the wound, was completely disorganized and infiltrated with pus. The pericranium was in a high state of ecchymosis; but, singularly, the dura mater, as well as the rest of the brain not immediately implicated in the injury, was in a normal condition, which accounts for the absence of constitutional symptoms in this melancholy case.

It is due to state that when on board H.M.S. Vesuvius, every possible kind attention conducive to the comfort of the patient was afforded by Lieut. Blount, commanding, to whom, as well as to Dr. Incedon, surgeon, R.N., of that ship, for his kindness and co-operation, I beg to offer my sincerest thanks.

GEORGE ALEX. COWPER,

M.D., M.R.C.S.L., Assist.-Surg. 29th reg.

Edinburgh Castle,
Aug. 10th, 1840.

NEW OPERATION FOR THE CURE OF PROLAPSUS RECTI.

By M. ROBERT.

THE surgical operations now performed for prolapsus recti are ineffective when the disease has arrived at its worst form. Incision, excision, and cauterization, affect only the mucous membrane, and make it adhere to the sphincter, which, after the cicatrization, remains as relaxed as before.

These considerations induced M. Robert to shorten the muscle in proportion to the degree of its relaxation, and made him hope that the cut extremities of the muscle would form, by their union, a narrow ring, and thus prevent the prolapsus of the mucous membrane. This operation was performed with success in June 1839, on a washer-woman, aged 33, in St. John's ward, at La Pitié. The woman, when pregnant for the third time, had a prolapsus recti which was but temporary, and only occasioned a supportable degree of discomfort. Her fourth pregnancy brought on a prolapsus of the uterus, a permanent and very considerable prolapsus of the rectum, and a relaxation of the parietes of the abdomen. M. Roux now excised a prominent portion of the mucous membrane of the rectum. This somewhat relieved her; but the prolapsus soon increased; the fæces came away involuntarily, and she had pains in the loins, and the upper part of the thighs. This combination of symptoms confined the patient to her bed, and in June 1839 she was admitted into the Pitié. At that time the sphincter was so relaxed that four fingers could be easily introduced. The patient having been prepared by a progressive diminution of diet, and the use of opium, so as to produce as long a constipation as possible, M. Robert proceeded to operate in the following manner:—He made an incision on each side of the anus, beginning several millimetres from the middle of the aperture, and directed backwards to the point of the coccyx. The flap of skin between the two incisions was removed, together with the portion of the sphincter which it covered; and half the length of the muscle was thus removed. The two sides of the wound were united by three stitches of the twisted suture.

On the sixth day after the operation the ligature came away, and union was almost complete. Nevertheless, there remained a fistulous passage from the anus to the coccyx.

On the fifteenth day no stool had been passed; and, therefore, on the following morning, the want being felt, the fæces were removed with the curette, to prevent the straining of defecation, which must have been injurious.

On the forty-first day, the patient, who previously to the operation had not been able to retain her stools, kept a clyster for a whole day. There was no longer any prolapsus, and the aperture was of the normal diameter; only, when a finger was introduced, it was not pressed with all the force of the sphincter in its natural condition. In the course of the month of August the patient walked, and passed her stools voluntarily; but a small *bourette* of the mucous membrane had already pro-

truded, and though, twice touched with the actual cautery, was not destroyed.

The cure has been a lasting one, in spite of the protrusion of the mucous membrane.

MM. Gerdy and Bérard were appointed to draw up a report on his paper.—(*Gazette Médicale* of June 20th, in its report of the sitting of the Academy of Medicine on June 16th.)

HOW TO KEEP COOL IN INDIA.

JUNE 9th.—The thermometer at 112 all day in our tents, notwithstanding tatties, [blinds], phernanticlotes, and every possible invention that was likely to lessen the stifling heat. Runjeet Sing sent us word that he could not stand the heat any longer, and was going off at once to Lahore, which he did, taking his whole camp and about five thousand troops with him; he marched upwards of fifty miles that night.

The thermometer after ten o'clock A.M. at 113. All sorts of experiments to keep themselves cool are tried by the different unhappy individuals in camp; I think mine the most successful. Dig a large hole in the ground, in the centre of your tent, and then place your table over it to form a sort of inner roof, and prevent the sun from shining down upon you. Make your cheestie water the whole floor of the hut, and then hang a wet sheet over the hole, like a hammock; pegged to the ground on the edges of the pit, to prevent its touching the bottom; take off all your clothes, and get into it, and by having a skin of water thrown over you every ten minutes, you may perhaps get the thermometer down to 100, which would be a perfect heaven to what we are now enduring. * * * *

JUNE 17th.—Hard at work all day endeavouring to make ourselves cool and comfortable in our new quarters—a work of considerable difficulty and trouble. I succeeded tolerably well by pitching a tent about twelve feet square, made entirely of the fresh cuscus grass, and lined with yellow muslin, very thin, to prevent the water from the outside wetting the furniture, and yet sufficiently fine to allow of a free current of air. This I have pitched in the middle of the large marble hall in the centre of the gardens, the roof of which prevents the sun from striking down, and all four sides being open, the hot wind is able to blow freely through it, which, by keeping the tent constantly wet on the outside, is converted from something resembling the blast of a furnace into a cool and refreshing, though damp breeze, and the thermometer brought down to 84.”—*The Court and Camp of Runjeet Sing, by the Hon. W. G. Osborne.*

PHTHISIS PULMONALIS.

To the Editor of the Medical Gazette.

SIR,

I HAVE been looking into the work of Mr. Bodington, on Phthisis Pulmonalis, recently noticed in your valuable journal, and the practice therein recommended, of allowing to consumptive patients a glass or two of Sherry, brought to my recollection a somewhat stronger remedy for the same intractable disease, given in a much older and more ponderous publication: I mean Salmon's *Botanologia*. At p. 1234 of that work, edit. 1711, Salmon states, "that Diatessaron or Punch, a mixture of four things, has cured such as have been in deep consumption, by drinking it daily for about five, six, or seven months together. Half a pint every morning fasting, eating with it a white ship-biscuit toasted, and soaked in the same; half a pint half an hour after dinner; half a pint about five in the afternoon; and half a pint at going to bed. This quantity may be well enough for men, but the female sex may (if they please) a little diminish the dose, as their reason and experience shall direct them." The author directs the Diatessaron to be made of the following ingredients; viz.

Water, one quart; Brandy, do.; Pure Lime Juice, one pint; Double refined Sugar, one pound. M.

I remain, sir,
Your obedient servant,

LECTOR.

London, Aug. 18, 1840.

RUSSIAN PRACTICE.

Displacement of the Heart, by Jerkoffski, director of St. Peter's and St. Paul's Hospital, at Petersburg.—In consequence of hydrothorax, the heart had been pushed quite to the right side; but as soon as the appropriate remedies had removed the water, the heart returned to its place, as was easily ascertained by the stethoscope, and the patient was discharged cured.

Galvanism in Disease, by Dr. Pehtnikoff, of Bobruisk.—The author employed galvanism in three different ways. 1. Simple galvanism applied by means of one copper and one zinc plate, to spots deprived of their cuticle, by a blister. 2. Compound galvanism or the galvanic-voltaic pile, either vertical or horizontal, consisting of from 30 to 50 plates. 3. Acupuncture, or galvanopuncture.

Paralysis of nearly the whole body, cured by the Extract of the Rhus Toxicodendron. From the *Collectan. Acad. Med.-Chir. Vilnensis*.—A man, aged twenty-seven, took the extract, beginning with three grains a day, and improved as the dose was increased; all

other remedies had been of no avail. When the quantity had been increased to thirty-four grains a day, it was again gradually diminished. The patient was perfectly cured.

LEECH-GATHERING IN RUSSIA.

ONE of the branches of industry prosecuted here is singular enough; it is the gathering of leeches for the Hamburg dealers. When talking with a person connected with this trade, we thought of Wordsworth's friend, of leech-gathering fame; but the collectors of the Ukraine do their work in such a wholesale, unpoetic way, that Wordsworth would not soil his verses with them. Having exhausted all the lakes of Silesia, Bohemia, and other more frequented parts of Europe, the buyers are now rolling gradually and implacably eastward, carrying death and desolation among the leeches in their course; sweeping all before them, till now they have got as far as Pultavia, the pools and swamps of which are yielding them great captures. Here a thousand leeches are sold for four roubles (3s. 4d.); at Hamburg, before reaching which one-half die, the same number is sold for 120 roubles (near £5); and in England the country apothecary pays £9 and £12. 10s. for the quantity which originally cost only 3s. 4d. But of every thousand at least seven hundred die before reaching England.—*Bremner's Excursions in the Interior of Russia.*

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Aug. 20.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

INJURIES AND DISEASES OF THE SPINE,
continued.—SPONTANEOUS DISLOCATION
of Atlas and Axis.—DISLOCATION of Cervical, Dorsal, and Lumbar Vertebrae.—
FRACTURE, CONCUSSION, COMPRESSION,
and INFLAMMATION OF CORD.—CARIES
OF THE VERTEBRÆ.—*Their Nature and
Treatment.*

SPONTANEOUS DISLOCATION OF ATLAS AND AXIS.

SPONTANEOUS dislocation of these articulations is not a rare disease; it has been confounded in more than one instance with wry neck; in several with rheumatism. This affection is spoken of by Hippocrates and Galen, by Ætius, by Van Swieten, who, however, doubts whether it occurs at the occipito atloidal articulation, without direct violence. A case is detailed by Mauchart, in Haller's thesis; another by J. P. Frank; Reil mentions examples; so does Richter; and there are several specimens in Sandifort's museum. Anchylosis at both these points is described by Bertin, Duverney, Sabatier, Sandifort. Boyer believed that we are not at present in a condition to describe this disease; and it was not until Schupke collected and arranged the cases to which I have referred, that a different opinion prevailed: his thesis was succeeded by the treatise on luxations of his master, Rust, who gave a digest of thirteen cases which he had observed.

The affection is distinguished by pain, at first trifling, but afterwards deep and

fixed, at the back of the neck, accompanied by difficulty or inability to move the head: these symptoms may appear to be stationary for weeks or months, increasing however at night; pressure upon the point increases the pain; deglutition is difficult, although, when looking into the fauces, no reason for it can be seen: at this time any movements, either in turning, inspiration, or deglutition, exasperate the patient's suffering; the muscles become permanently contracted, and the head fixed, and the physiognomy assumes a peculiar appearance; there is permanent tumefaction, and the pain extends to the head. All these symptoms indicate the existence of simple inflammation of the articular surfaces and their ligaments: at this period the disease is curable. Soon the inclination of the head to the shoulder increases, the rigidity augments, difficulty of deglutition is greater, respiration is impeded, the voice is hoarse, the least motion is insupportable, and the displacement may than be considerable. The head is most frequently directed to the right; Rust saw it so seven times out of nine; Ollivier twice out of three times: when both sides are affected, Rust says the head is pushed forward. The disease may be limited to the destruction of the odontoid apophysis and its ligaments, as was the case two or three years ago at the Westminster Hospital, and as was observed in a case by Ollivier. In these cases no attempts should be made to right the head, for the pain will be excessive.

When the disease has continued long, symptoms of compression are usually manifested, and these may exist for weeks for months, the atlas being so displaced as to occupy a third, half, or two-thirds of the canal; however, in the progress of the disease the dentatus becomes pushed backwards—an effect of the destruction of the bony support by caries. The pain now becomes intolerable, the patient cannot lie on the sound side, nor for more than a

few minutes on the other; sleeplessness is almost habitual; no movement of the body is made without characteristic precautions on the part of the patient; the opening of the mouth is limited; deglutition is more difficult, and sometimes at this period a soft fluctuating tumor behind the *vclum palati* may sometimes be seen: this is an abscess in front of the bodies of the vertebrae, which has twice been seen to open into the pharynx, leaving a fistulous communication.—(Rust, Schupke.) All the symptoms are now aggravated; those of compression and irritation of the cord are more distressing; and at this time the symptoms of phthisis may be manifested, the cough accompanying which is a dreadful aggravation; the dyspnœa augments, and the patient seems to be asphyxiated. Sometimes death suddenly follows some movement, and it has then been found that the odontoid process has been let loose, and has wounded the medulla.

The progress of this disease is not rapid: in any of the cases to which I have referred life was not destroyed in less than seven months, except by accident; and where proper means have been used in an early stage, the symptoms have been subdued, and the disease cured, in a few months; but in these cases there has been inability to move the head, in consequence of true or false ankylosis. This termination is rare, but it may occur even at a later period of the disease, as in a case mentioned by Rust, and another by Ollivier: ordinarily, however, it is not so: the disease proceeds through months or years, though usually the duration does not exceed twelve months: still there are cases enough on record where ankylosis has occurred, to induce us to persevere in our endeavours to arrest its progress.

In the examination of persons who have been the victims of this disease in an advanced state, we find the condyloid cartilages, the lateral masses of the atlas, those of the corresponding portions of the atlas and the axis, partially or totally destroyed, their circumference presenting osseous spiculae, the osseous tissue carious and excavated, the ring of the atlas broken down into several portions, the odontoid process and its ligaments more or less completely broken down, the dura mater softened, or thickened and rugous, or pus is effused in its cavity. The relation of the occipital bone with the atlas is changed, and the spinal canal is interfered with. Often, in the midst of these changes, the medulla spinalis is comparatively unaffected, and this is especially evident when death is suddenly produced; but more frequently its tissue is softened; sometimes it is converted into pulsatous diffuent matter, its membranes thickened and vascular; sometimes a clot of blood is found at the softened part;

Rust found the vertebral artery ulcerated, and an extravasation of blood into the spinal canal.

Opposed to those alterations we may place the following, which demonstrate the curability of this disease. Riolan states that he saw union of the first two vertebrae without interference with the motion of the head; this fact is repeated by Palfyn and others. Duverney saw a case in which there was ankylosis of the first six vertebrae; the atlas and axis, however were so displaced, that the odontoid process was only two lines removed from the posterior arch of the axis. A case much resembling this occurred to Mr. Lawrence, and the specimen is, or was, in Mr. Langstaff's museum. Hunauld had a specimen of ankylosis of the occipital bone with the atlas, and with it a displacement so considerable that the posterior arch of the vertebrae corresponds to the middle of the occipital foramen: analogous cases are described by Meckel, Frank, Colombo. Van der Wypersse mentions six cases; Sandifort has described and figured six (*Mus. Anat.*); other cases, not less curious, are mentioned by Goetz, Dubreuil. A very singular case was presented to the Académie Royale de Méd. by M. J. Cloquet: union of the axis with the occiput; the anterior arch of the atlas was completely destroyed, and the body of the axis became firmly united with the occiput, so that the odontoid process passed into the occipital foramen. Wigan's case, considering the age of the patient, is not less remarkable. Unquestionably ankylosis may occasionally happen without so much mischief as we have described; such, I apprehend, is a case mentioned by Morgagni (*De Sed. et Caus. Morb. Ep. 62, sect. 11.*)

As a correct diagnosis is here so important, we may consider shortly those affections with which it may be confounded. Rheumatism of the muscles at the back of the neck, and wry neck, have been mistaken for it, and *vice versâ*; but as in rheumatism the whole of the back or the neck is painful, and the pain is not more increased by pressing laterally than posteriorly; and as in spontaneous luxation the pain is circumscribed, and when pressure is made at the point it is greatly aggravated, and also does not present periods of quiet and exacerbation, and does not arrive quickly to a high degree of intensity, a mistake should not often happen. It is not often that the disease can be confounded with wry neck: in the luxation local pain has preceded the twist; in wry neck it is not usually the case. Again, certain conditions of the ligaments of the spine succeeding to rheumatism may produce wry neck, so may inflammatory action of the cellular tissue in the vicinity of the tonsils in scarlet fever, but these can

scarcely be confounded with the affection we are considering.

The disease is most frequently seen in young persons, rarely in old; there is one case, in Graefe's Journal, where the patient was sixty. Scrofulous persons are commonly affected. Some persons have expressed an opinion that the little covering used upon the neck was a cause of the affection, but in that case females would be more exposed to it than males, and this is not found to be the case. That an accidental cold may excite inflammatory action at these points is possible. Some persons have believed syphilis to be an exciting cause, others have suggested rheumatism and gout: to those general causes we may add local agents: a sudden revolution of the head, a fall on the head or neck, or a blow, the habit of carrying burdens upon the head, fractures, spiculæ of bone piercing the articulation from the pharynx, are occasional causes.

Treatment.—Though many general causes may predispose to this affection, we must not rely on general means for its cure; we must resort to energetic local treatment: large numbers of leeches should be applied so long as there is heat at the part, followed by emollient cataplasms, from which patients often derive great comfort. Rust thought otherwise. When the arthritic pain is subdued and only rigidity remains, frictions, by means of stimulating liniments, mercurial ointment, or acetum cantaridis, will be found efficacious. Unless from these means decided good is experienced, they must not be persisted in, for the disease is probably stationary only in appearance, but we must recur to issues applied near the part. Rust prefers the red-hot iron, which he passes over the skin backwards and forwards from the diseased point to the fifth or sixth cervical vertebra. I am quite willing to admit the great value of the actual cautery, but I think Professor Rust's advocacy of it too exclusive. The experience of our countrymen in the treatment of similar affections lower down in the spine is rather in favour of caustic potash. Whichever means we employ, the wound should be long kept open, or what may be better, a succession of issues should be made and healed up. If, in spite of these means, an abscess should form and point in the neck, Rust thinks that the iron should be applied upon the integument over it; he thinks that the irritation so excited occasions the absorption of a certain quantity of the pus it may contain, and that the rest will find an easy vent when the slough is thrown off; he has found this method very successful when the abscess was not large, nor the patient exhausted. It is most important that the head should be kept perfectly quiet, because we may thus favour anchylosis—in

such a case a most desirable result. The necessary immobility is best attained by the use of a proper collar. Although I advise the greatest reliance to be placed on local means, I do not wish to convey an opinion that general treatment is useless; gout, rheumatism, and syphilis, supposing there be reason to apprehend that they are present, should be treated by appropriate means; so should scrofula; and whatever be the treatment employed, benefit seems to be derived from the use of laxatives, not only by rendering efforts at stool unnecessary, but by exercising a general beneficial influence upon the disease.

DISLOCATION OF THE LAST FIVE CERVICAL VETEBRÆ.

All the movements of the neck are not executed between the atlas and axis; a comparatively considerable extent of motion is possessed by the joint action of the remaining five cervical vertebrae. When the forward, backward, or lateral movements are carried too far, the articular facettes of the five oblique apophyses may lose their points of contact, and be no longer capable of resuming their proper positions. A barrister turned his head round suddenly to speak to a client who was behind him, and produced this kind of displacement: usually, indeed, it appears to be a consequence of muscular contraction. Children throwing somersets, or standing on the head, have produced it; but in all these cases it is a dislocation of one side. Walther (*Journal für Chir.*, vol. 3, cap. 11, p. 197) mentions a case where both sides were displaced. Mr. Lawrence has recorded one similar case (*Med.-Chir. Trans.* vol. 13). Mr. S. Cooper mentions another case, and Dupuytren a fourth.

A sudden acute pain is felt at the part, with a sensation of something giving way, with a noise in the posterior and lateral region of the neck, at a height varying with the point of injury. The face is turned to the side opposite to the injury, the patient being unable to redress the head. If we attentively examine the region of the spine, we easily feel the prominence of the spinous process of the dislocated vertebra, and also that the superior vertebrae are more or less deviated from the side to which the face inclines. In Walther's case, both sides being displaced, the head was inclined backwards, the neck was curved, with a decided concavity backwards, and convexity forwards; the anterior parts of the bodies were a little separated from each other, and no fatal injury was inflicted upon the cord. We might, however, reasonably suppose that compression, inflammation, or destruction of the cord, would be the common result.

When the luxation of an oblique apo-

physis is left to itself, the pain gradually ceases, and soon all that remains is the inconvenience of a vicious direction of the neck, and a change in the motions of the head. This is the reason why Boyer, Richerand, Dupuytren, and others, have recommended, as a general rule, that no efforts at reduction should be made, lest, as in the case of Petit-Radel, they should end in injury to the cord, and instant death. But these opinions rest only on single ill-described facts, whilst there are many others, like those of Seifert, in Rust's Mag. vol. 34, page 419, in which the attempts have been crowned with most complete success. Still, in spite of the suggestions as to reduction, given by Brunus, Theodorie, Lanfranc, Paré, Petit, Heister, there is a general indisposition to interfere.

If attempts be made, the patient should sit on a chair, the shoulders should be firmly fixed, the head should be held between both hands, and extended, carrying it a little in its natural direction. When there is a displacement of both sides, the observation of Walther shews that we may succeed. In his case the patient was laid on a bed, and there fixed by three assistants, one keeping the shoulders firm, another making extension upon the head, at first in the direction of the displacement, afterwards in the natural direction of the neck; then, when extension has been carried to a certain point, the head is brought, as much as possible, into its natural direction.

DORSAL AND LUMBAR VERTEBRÆ.

Simple dislocation of the oblique apophyses, and the bodies of the dorsal vertebræ, can scarcely I believe, occur, because of their large articulating surfaces, the number and strength of their ligaments, and the power of the surrounding muscles. Still Rust believes it may; and Sir Charles Bell mentions a case where the last dorsal vertebra was dislocated without fracture. The only case in which these dislocations may ordinarily exist is when there is fracture, which cannot happen without great violence; and then symptoms of concussion, compression, or destruction of the cord, are almost inevitable. Almost every recorded case of dislocation of the dorsal or lumbar vertebræ has turned out to be accompanied by fracture, and some injury of the cord. The structure of these vertebræ, and the nature of their ligaments, do not seem to allow of simple dislocation. Dupuytren described many cases of luxation with fracture; in one case there was a change in the direction of the vertebra, and only a destruction of the intervertebral cartilage, without fracture. In all the cases there was injury of the spinal cord, which caused death. After that, it is easy to determine what we ought

to think of those cases where, in consequence of injury, a projection is produced at some point of the spine, and the patient is unable to straighten himself, but is laid upon his back over a barrel, and the pretended dislocation is reduced. The vertebral ligaments may be partly or wholly destroyed without dislocation. Boyer has proved this; but such injuries may, by damaging the cord, occasion sudden death, with all the symptoms which may be presented in a case of fracture. In all such cases the proper treatment is absolute rest, the most energetic antiphlogistics, and the most powerful counter-irritants; these measures can alone prevent the development of bad consequences.

FRACTURE OF THE SPINE.

Fracture of the vertebræ is a comparatively rare affection. This is owing to their small extent, which, as in most short bones, offers little advantage to contusing bodies; to the mobility which each enjoys through the medium of the intervertebral cartilage, to their deep-seat, and the large masses of muscle which cover and protect them in the greater part of their extent. Again, the spongy nature of their substance, and the great mobility of the column itself, render almost null those forces, which, instead of acting upon a particular vertebra, act upon the whole column. In the latter case the ligaments may be distended or destroyed, but the bones are usually not fractured. Still fracture may occur, and may affect the vertebræ of either region—may implicate the vertebral ring, or only the apophyses.

A fracture may be caused by violence applied directly on the spine; if it be limited it may fracture the posterior lamina of a vertebra, or only the apophyses; but, ordinarily, fractured spine is a consequence of a fall from a height; it may be produced by a heavy body passing over or falling upon the back, by projectiles, and it has succeeded to exaggerated muscular action. Reveillon describes the case of a soldier, a good swimmer, who plunged, head foremost, into the Sambre; his comrades, after a few minutes, seeing him motionless, proceeded to his assistance, and brought him to land. It was found that there was no fracture or luxation of the limbs, but that they were paralyzed; he could not hold up his head, the skin was insensible, a severe pain was felt at the inferior and lateral part of the neck, but there was no sign of external injury; he had priapism, and frequent desire to make water. He said that, at the moment of plunging into the river, he discovered that it was not so deep as he had conceived it to be, and that he had suddenly bent his head back to

prevent its striking the bottom, and that he as suddenly lost his senses. By frictions, warm fomentations, and baths, his suffering was alleviated, the priapism ceased, the desire to make water was much less frequent, the paralysis of the limbs was less complete, but in the evening delirium came on, and during the night he died. After death it was ascertained that blood was infiltrated around the vertebral column; that the spinal canal external to the dura mater was full of blood; and that there was fracture completely through the body of the fifth cervical vertebra. A violent inflexion has, in some cases, been said to produce a like effect. But though it may occasion a great strain upon the fibrous tissues uniting the vertebrae, a prodigious force must be necessary to fracture; and if it happen, it will be complicated with some injury to the spinal cord, or to the nerves which set out from it.

Symptoms.—When the spine is fractured the patient usually cannot raise himself, or, if he does, he falls down again. He feels an acute pain at a point corresponding to the fracture—a pain which is increased by the slightest movement of flexion, extension, or rotation of the trunk; besides that, he experiences numbness, weight, or complete insensibility, with loss of motion in all parts of the body which derive their nerves from a part of the spine below the injured point. This state is dependent upon concussion or compression, by a fragment of bone or extravasated fluid. Immediately, or soon after the accident, a paralysis of all parts below the fracture usually supervenes; paralysis of the inferior extremities, the bladder, and the rectum, when the fracture is situated at the inferior part of the dorsal column; accompanied with difficult respiration and tympanitis, when the fracture is higher up in the same region. The position in bed, in consequence of the paralysis of the lower limbs, causes pressure; and gangrene at the sacrum from that cause, and from deficient nervous energy, is the common consequence. By little and little the paralysis usually extends, and the patient dies exhausted, after a period of time, variable in extent; it may be two, three, four, five, six, or even more weeks. If the fracture be situated as high as the third cervical vertebra, and be accompanied by displacement, death is usually almost immediate. If it be situated immediately below the origin of the phrenic nerve, paralysis of the arms, the viscera, and the legs, is the usual consequence. Yet this paralysis is rarely complete; sometimes one arm is more severely affected than the other. That is usually the case in oblique fractures; respiration is much disturbed, and death usually follows between the third and the seventh day (Cooper). When inflammation sets in,

delirium, agitation, and priapism, are commonly seen;—but, in Sir B. Brodie's experience, priapism does not occur in the absence of paralysis;—the patient endeavours to sit or stand, and death usually occurs about the fifth day (Bell). If the inflammation be of a chronic character, death follows later, from compression, or from some structural change in the cord. Unquestionably these signs, succeeding to a violent blow on the part, leave usually little doubt of fracture of the spine. But when the fracture is limited to detach a spinous or a transverse process, the evidence of the kind of injury is often very inconclusive; it may be very difficult to distinguish it from simple contusion of the soft parts. In some cases no crepitation can be felt, and there may be little deformity; for the tumefaction may prevent us from acting directly upon a spinous process for the purpose of ascertaining whether it be moveable, and whether a crepitation may result; and this tumefaction may mask any deformity; and the cord itself may be seriously injured, though the violence was insufficient to produce fracture. It may, in such cases, be found very difficult to distinguish fracture from concussion; but then the patient suffers no inconvenience on this account, because the same treatment is required in either case. In either case, whether concussion or compression be the consequence of the injury, they are manifested by the same symptoms—paralysis; but if we carefully examine the progress of the case, and if compression be produced, not by a fragment of bone, but by extravasated blood, we may sometimes follow the progress of the paralysis, and determine that it is owing to a still increasing extravasation, and not to a concussion, the effects of which are never more intense than at the moment of the accident. The effects of contusion are those of inflammation of the cord; they begin to manifest themselves in five or six days after the injury.

We see that fracture of the spine is a most grave injury, the gravity dependent, in most cases, more upon the accidents which follow it than upon the fracture itself; but it is almost always mortal. The rapidity with which this termination is brought about has reference to the extent of the injury, and its nearness to the superior part of the cord. Yet gun-shots have produced fracture, and the case has done well; and in my case, before alluded to, the violence attending the fracture was great, but no bad symptom was developed.

Treatment.—In the treatment of fractured spine, the course ordinarily followed is to place the patient on a bed, lying on his back; but some persons, among them Sanson, have suggested that by lying on the back certain inconveniences are neces-

sarily incurred which might be avoided by placing the patient on his belly. Among those inconveniences are the occasional aggravation of the symptoms from pressure upon the injured vertebra, the necessity for moving, if cupping, or any other applications to the part, are indicated. But then if we place the patient on his belly, it may be necessary to turn him two or three times a day to introduce the catheter, and to many people the position is a very tiresome one. Whatever the extent of injury, our first care is to anticipate, if possible, the development of inflammation of the cord; for this purpose we use, largely, antiphlogistic means, and keep the patient perfectly quiet. If, in spite of all our efforts, inflammation of the cord has been developed, and if, by the means we have used, it has abated, counter-irritants may be found useful in dissipating it; and at this period purgatives are often found very advantageous. If only concussion existed, it may, if slight, give way completely; but if, after the period when inflammation might reasonably be expected, numbness remains, blisters to the spine will occasionally dissipate it. Retention of urine, which accompanies these injuries, requires the catheter, and it should be used, at least, twice a day, and even then the urine will yield a strong ammoniacal odour. It has been recommended that a catheter should be left in the bladder; but I object to it, because it is very apt to inflame or otherwise injure that organ. Constipation will sometimes yield to mild laxatives; but, in others, the blunted sensibility of the intestines, requires energetic stimulating purgatives, such as croton oil, and terebinthinate enemata. The next thing we have especially to guard against is the occurrence of sloughs upon the sacrum, or other parts upon which the body rests; and it is worthy of remark that, when the patient has been laid on his belly, the knees have promptly suffered. If these sloughs are developed, they are very apt to be aggravated by the urine dribbling away, and the fæces passing under the patient. To lessen this, good warm poultices must be applied, and frequently renewed, until the sloughs are thrown off, or even after.

In a few cases the patient has survived; the fracture has been consolidated, but the paralysis persists: we then apply moxas or issues on each side of the fracture; and upon the limbs we use frictions, baths, douches, or any similar means of rousing the dormant energies. When they fail, and we have no reason to apprehend that inflammation exists, we may try strychnia: by some persons great eulogiums are passed on it; but I have never seen, in those cases, much benefit to accrue from it, or from any other medicinal or other agent.

Such are the principles of treatment in

these cases, but they do not in certain cases exclude the employment of other means; for instance, when a fracture affects the apophyses, or the posterior portion of the vertebral canal, and is accompanied with displacement, some persons advise that we should endeavour to restore the fragment to its proper situation. If in a case of this kind there were evident signs of compression, such a course might be justifiable; it is a species of meddling, from which good might possibly result, but the chances of increased mischief are infinitely more to be dreaded; and if the fracture did not extend beyond the apophyses, there could be no necessity for it. In Mr. Barlow's case it did not seem that much good resulted from it (*Med.-Chir. Trans.* vol. 17), nor in that of Mr. Hardwick.

When there is reason to conclude that the spinous process is depressed, and the evidence of compression by the posterior half of a vertebral ring is pretty complete, the advice has been given, and acted on, to cut down upon the part, and endeavour to relieve compression. Viguier proposed the trepan for the purpose; and Cline, Barton, Tyrrel, Edwards, Wickham, Attenburrow, and Laugier, have acted upon the suggestion. Before I record the results of the operation, I may call in question the prudence of resorting to it. The posterior laminæ of the vertebrae are too profoundly situated to allow of such an operation being lightly undertaken; the symptoms proper to point out the exact seat where it should be applied are often wanting, for experience demonstrates that they are very similar, whether there be concussion, compression by blood or bone, or even a severe strain. Take the following cases as evidence:—Unexpectedly a sack of flour, weighing nearly three hundred pounds, fell on a man's neck; an acute pain was felt at the bottom of the neck: he was carried to the hospital; the spinous process of the seventh cervical vertebra was found more prominent than natural; the limbs were paralysed; respiration was laborious; the rectum and bladder did not act; the patient died at the end of five days. After death a fracture of the posterior laminæ of the seventh cervical vertebra was discovered, together with a depression of one portion which compressed the cord. A mason fell from a height of fourteen feet, and was insensible; when he acquired consciousness, he found the lower limbs paralysed; the urine was retained, so were the fæces at first, but passed involuntarily afterwards; fever supervened; respiration became laborious; and he died on the twelfth day. Bloody serum was effused, so as to fill the canal of the dura mater, from its inferior to its middle region, and compressed the cord. A stocking-weaver fell into a ditch, injuring the loins: soon he found paralysis

of the lower limbs, the rectum, and the bladder. The disease followed the same course as in the former case, and the patient died. Neither fracture nor any other lesion of the cord or its covering, nor extravasation, was found. A man amusing himself with some friends in feats of agility, suddenly found a dragging and sharp pain along the spine; the next day the lower limbs, the bladder, and the rectum, were paralysed; the disease took its ordinary course, and he died in a few weeks. The parts upon examination appeared perfectly natural, as in the former case. In the first case it is possible that the trepan might have been useful, but the symptoms were similar in the other three; and it is clear that the trepan should not have been employed in those cases. In 1814 Mr. H. Cline resorted to the operation at St. Thomas's Hospital: the patient died on the second day. In the year 1822, in a case of fracture of the posterior laminæ of the ninth and tenth dorsal vertebræ, the patient, a man of 30, had paraplegia; the operation for the purpose of removing pressure was performed by Tyrrel; there was considerable mitigation of the symptoms, but the patient died with symptoms of peritonitis on the fifteenth day. Barton's patient died on the third day, after a momentary return of sensibility. Laugier's patient died on the third day; and Edwards's case did well; but then injury was limited to the inferior part of the lumbar region, where the cord no longer exists, but is divided into a multitude of filaments, and where pressure, to a considerable extent, is borne without bad consequences. Certainly the trepan here offers many more difficulties than in the cranium; but the facts we at present possess are insufficient to enable us to decide clearly on the occasional propriety of resorting to so grave an operation. In analogous cases it has been recommended by Sir A. Cooper, but Sir C. Bell thinks it unjustifiable.

We may now consider very shortly wounds, concussion, compression, and inflammation of the spinal cord—immediate consequences of violence.

When lesions of the spinal cord are produced by a penetrating or cutting instrument, external symptoms and the direction of the wound are usually sufficient to unmask the injury, and inform us of the probable situation of the lesion of the cord. When the accident results from a fall or blow, there may be ecchymosis, or a projecting spinous process, to point to the seat of injury; in the absence of these signs the patient may direct us to it by describing the seat of pain. Loss of sense and motion in all parts below the injury is the common sign; in some cases only one side may be affected, but gradually it extends to the other.

Concussion.—I have no power to enable you in the majority of cases to distinguish between concussion and compression; but this I regret the less, because the treatment adapted to one is, in most cases, proper to the other disease. Loss of sensation or motion, or of both at the same time, involuntary excretion or retention of fæces and urine, are the ordinary symptoms of both: there may be convulsions, as in Stoll's case, where tetanus succeeded to concussion of the spine. Sometimes the paralysis, at first limited to the legs, gradually extends upwards, and destroys life, at a time when hopes of cure were entertained. When the concussion is not very severe, the symptoms may gradually yield; sensation and motion are gradually restored, sometimes together, sometimes the sensibility first; but the excretion of urine and fæces may long continue involuntary. There may be a very sensible decline in the temperature of the paralysed part, as well as an absence of transpiration. But I know no case of erection of the penis in simple concussion: this is a very common symptom in other affections of the cord. Concussion is not so constantly fatal as compression, though it may destroy life rapidly, and leave no trace of disease of the cord; there are, however, very many examples of recovery from its effects. We must not estimate the intensity, or at least the danger, by the intensity of the immediate injury: the fall may have been from a great height, and unbroken; the immediate symptoms may have been very urgent, but the patient may get well. Whilst a man may slip down in his own room, the immediate symptoms of concussion may have been comparatively slight, but they end in death. The difference depends on this circumstance; in the one case the concussion determines the development of disease of the cord; in the other it does not. Peter Frank, when speaking of the gravity of injuries of the spinal column, relatively to their influence on the cord, mentions four cases where the patient died paralysed, from falling on the back from a high tree. The spinal cord was examined with great care, and there was no extravasation, trace of inflammation, or any other lesion of the cord or its coverings. Hippocrates was familiar with this effect; he says, "Alioqui multo plures erurum et manuum impotentia et corporis stupore afficiuntur, uniscunque supprimuntur, quibus quidem ex vertebræ gibbo neque intrâ neque extrâ excesserint, sed in directum spinæ vehementur concussi fuerint." (Lib. de Articulis.)

Treatment.—In these cases general bleeding must first be employed, and must be repeated as often as any symptom indicates the necessity. If the patient be already feeble, we must rely more on local bleeding

and counter-irritation; but even then we should commence with a general bleeding, proportioned to the patient's strength and the urgency of the symptoms. If there be retention of urine we have recourse to the catheter; if there be obstinate constipation, either enemata or mild purgatives should be administered. Dry frictions upon the paralysed parts are occasionally useful; and the diet should be spare. From strychnia I have never derived any benefit; still in other hands it has had different effects, and therefore I should say that when inflammatory symptoms have passed away, the health is good, and we have no reason to suppose that the paraplegia is consequent upon softening succeeding to compression, this medicine should be tried.

Compression.—When the disease is compression of the spinal cord, there may be loss of sensation and motion below the injured point; it may at first affect one limb, and gradually affect the other: it may indeed be confined to one, may affect more particularly the anterior or posterior portion of the column, and manifest itself by its effects, more decidedly upon sensation or motion, or *vice versa*: when one side only is affected, the same side of the cord is affected. Paralysis of the bladder always exists in lesion of the cord, and is first manifested by retention, followed by incontinence. Cases have occurred, it is true, where the functions of this organ were not deranged: Desault's case was of this nature. The paralysis of the rectum does not always exist; but we are not to assume that because there is constipation, there is not therefore paralysis, because retention of *fæces* may sometimes be owing to paralysis. Sometimes involuntary dejections immediately follow the accident; usually, however, this happens when the patient has survived the accident some time; it then succeeds to obstinate constipation. The intellectual faculties are usually undisturbed; there may be a momentary loss of consciousness, depending on slight concussion of the brain. The pulse varies according to the different complications which accompany the injury; usually it is regular. But these symptoms undergo, as we have seen, certain modifications depending upon the portion of the cord affected. Compression suddenly produced, especially by luxation or fracture, usually destroys life, sometimes very rapidly; but to this rule there are many exceptions: Ollivier's 17th case is a striking example. We may admit certainly with Caspar, that slight compression of the dorsal or lumbar region, without other complication is not absolutely mortal. But these are cases over which our art has generally little control; first, because we cannot always make out that the symptoms

satisfactorily indicate compression; and next, if they did, we have no certain means of relief. The general means of treatment are similar to those recommended in concussion; but here, of course, the question of elevating a depressed bone may arise.

Inflammation.—If the injury, without producing serious concussion or compression, have excited acute inflammatory action in the spinal cord, it is usually manifested by the followingsymptoms:—Numbness in the fingers or toes, sometimes difficulty in moving them, and a disagreeable sensation of cold. These symptoms may be successively developed in the limbs, and may extend to the trunk. Convulsions may occur from the first. At the same time, or soon after the occurrence of these symptoms, a deep and more or less acute pain is felt at a point of the spine corresponding to the seat of inflammation; it may extend along the whole spine, and may be exasperated by motion. It is not commonly increased by pressure. Khloss states that it is increased by lying on a feather bed, but not by a mattress. Usually, however, we can ascertain how far the disease extends by striking lightly upon each spinous process. Sometimes the paralysis ascends, affects the upper parts of the body, prevents respiration, and causes asphyxia. Usually the paralysis is at first manifested on one side of the body, and afterwards extends to the other. As a rule, when the inflammation is limited to the dorsal and lumbar regions, the lower limbs alone are affected, the upper when the cervical region is the seat of disease; but this is not always the case. The functions of the rectum and bladder suffer, more particularly the rectum; whence constipation. For some time the excretion of urine may be voluntary, but retention usually comes on. The pulse is ordinarily frequent, full, irregular, and sometimes tumultuous, the respiration is frequent, and sometimes laboured; in fact, fever is developed. These are the ordinary signs, but many sympathetic actions may be set up, varying with the region affected. If the *cranial* portion suffer, the intellectual functions may be troubled; there may be delirium trismus, grinding of the teeth, a red dry tongue, difficult deglutition, followed by hemiplegia and general paralysis, and articulation may be impossible. If the *cervical* portion be affected, there is severe pain in the back of the neck and rigidity of its muscles, as well as those of the arms; they may be convulsed or paralysed; the respiration is difficult and diaphragmatic; the dyspnœa increases, and the patient dies. If the *dorsal* portion suffer, there is often convulsive action of the trunk, in which the limbs do not participate; respiration is hurried, the heart's action is irregular, and there is fever. When the lum-

bar portion is inflamed, the lower limbs are paralysed, the urinary and intestinal functions are disturbed, and there is deep-seated pain in the loins.

When the disease is *chronic*, the symptoms are similar to those I have described, but they are more slowly developed. A painful state of the limb may exist long before paralysis, and when the paralysis follows, the limb may become retracted; and the contraction cannot be overcome without great force and much pain. The limbs may be agitated, as it were with galvanic shocks, if we pass the hand along the course of the nerves. There is a depression of temperature, absence of perspiration and continual exfoliation of the cuticle. If the patient can walk at all, he is bent forward, complaining of numbness or pain along the spine. We generally find the condition of the cord to exercise a very decided influence upon the heart's action; it is energetic and irregular. As to the abdominal organs, besides the changes in the urinary excretion, and the constipation, there is a cord-like tightness around the abdomen, and then the lower limbs are moved with more difficulty.

If acute, the disease usually destroys life on the third or fourth day. In Chevalier's case the patient lived a fortnight. In Maccari's eighteen days. The disease is very rapid when the dorsal portion is affected; whether this be, as was supposed by Earle, because the canal is very narrow there, I cannot say. If the disease extend beyond ten days it may be cured, or may last for months. A patient with chronic inflammation of the cord may live, (paralysed it is true) for many years, but long before that bed-sore is usually manifested. Whether, considering the obscurity of the early symptoms, and the possibility of their being mistaken for rheumatism, we are to accept these old cases as undoubted inflammation of the cord, may be a matter of question.

Treatment.—General and local bleeding, warm baths long continued, rigid diet, and laxative clysters, are the ordinary means of treatment. Cold applications have been used with bad success. When, by the means indicated, the acute symptoms are abated, much good has been derived from douches of salt water upon the spine, at a temperature of 90°. They should be directed from a height of six or eight feet; the opening of the tube should have a diameter of half an inch to an inch. At the same time a caustic issue should be made on either side of the spinous process under which the pain is most felt. If the disease be chronic, those means must be used with moderation, but they must be continued long when the pains are severe. When, however, the paralysis exists without much

pain and excitement, the time for the energetic employment of counter-irritants has arrived. In many of these cases more or less irritating purgatives seem to produce a good effect. Dry frictions must be frequently employed; and as soon as the part has been well rubbed, some persons say they have derived much benefit by placing flannel two or three times doubled along the spine, and over it oiled silk, by which a kind of continual local vapour bath is applied. Douches, such as I lately described, have also been found useful. Blisters, moxas, setons, and issues along the spine, are also indicated. The application of strychnia upon the blistered surface has also been strongly recommended. The bladder and rectum must be attended to.

CARIES OF THE SPINE.

In the whole round of our profession there is no disease a proper knowledge of which it is more important to possess than that we are about to consider, whether we regard the frequency of its occurrence, or its disastrous consequences. Much discrepancy exists in the works of different authors when treating this subject, in consequence of confounding two very dissimilar diseases in a single description. In the one case the affection is a proper caries, commencing in the superficial structures, attacking, as it were, the cortical substance of a vertebra, whilst the other portions of the bone remain unchanged; the other, often tubercular, affects the less dense inner structure of the vertebra, reducing it to a soft pulsatious mass, with tumefaction. In the first, the patient feels a fixed pain in the affected region of the spine, which is often mistaken for a rheumatic pain; it increases when he stands or walks long, but is very little increased by compression. It goes on, and rigors and slight fever indicate the formation of abscess. In the second, the change in structure is marked by a dull pain, by an uneasy sensation in the epigastric region, an uncomfortable constriction of the chest, feebleness and coldness of the legs. The change of consistency in the bodies of the vertebra renders them incapable of supporting the weight of the superincumbent parts; they give way, the spine is flexed, and a gibbous curvature takes place, whose projection is backwards. In many cases the spinal cord is compressed, and the inferior extremities are paralysed. This is the disease known as Pott's curvature. In the first case, as in the second, the matter resulting from this caries may fuse along through the surrounding cellular tissue, and form purulent collections at a distance from the diseased part.

This caries may affect any of the verte-

bræ—the first, the second, the third, or even the occipital condyles; the odontoid apophysis may be entirely separated from the body of the axis by it. But most commonly it is at the dorsal and lumbar portions of the spine that the disease is seen. I have known a spine where the angle formed at this point was 90 degrees, and the bodies of the last cervical, the first, second, third, fourth, and fifth dorsal vertebræ, were completely destroyed. Delpech mentions a case where the disease had destroyed the bodies of twelve vertebræ. The following case from Cruveilhier is a good specimen of this curvature.

Caries of the bodies of the vertebræ most commonly affects young persons, at that period of life when the symptoms of scrofula are most generally manifested. It may occur at a later period. Mr. Pott, however, never saw it in a person beyond forty. Brodie has seen it in a person of forty-five. In youth it is said to be too frequently developed as a consequence of excessive masturbation. Boyer said he had frequent opportunities of ascertaining this. Lobstein treated a patient where this was probably the case, a scrofulous young man, considerably emaciated, who had also an ulcer connected with caries of the instep. In the course of treatment he complained of a pungent pain at the right side of the chest near the spine; it yielded to a blister. The suppuration at the instep suddenly ceased, symptoms of tetanus were developed, became intense, and the patient died. The first cuneiform bone was carious; there were two lumbrici in the ileum; the vesiculæ seminales were very large, renitent, inflamed along their external surface, and full of what appeared to be healthy pus. In the vertebral canal was a tumor which lessened its diameter and slightly compressed the cord. This tumor was an abscess under the posterior ligament; it was full of a thick white plas-

ter-like pus. The body of the last dorsal vertebra was destroyed.

Caries may occur in a rheumatic patient, and it is believed is excited by it. A woman of 40, who had once borne a still-born child, but was in good health, while carrying a burden on the head wished to clear a gutter; at the moment she felt an acute pain in the right groin; from day to day it increased, and ultimately extended over the whole abdomen, which became hard, contracted, and painful. A severe pain at the epigastrium, and another still more severe in the dorsal spine, prevented the woman from lying on either side. A large bleeding relieved her, and the whole of the pains, except that in the groin were much better; that, on the contrary, became fixed above and behind the pubis, extended to the left groin, and became extremely intense. The uterus was suspected, and the suspicion was confirmed by the discovery of fissures, and great heat at its neck, and by the diminution of the pain during menstruation. The affection was conceived to be rheumatic, and the pains became agonising, extending to the sacrum and the thighs, and accompanied by difficulty in passing urine, and in respiring. Opium produced only a momentary calm; soon after the extremities became paralysed, the strength decreased hectic, with nocturnal delirium and obstinate diarrhœa, exhausted her, and she died. The peritoneum presented traces of old inflammation, the mesenteric glands were tubercular, the right side of the bodies of the lumbar vertebræ were covered by a tumor, which when cut into furnished a blackish red matter; the bodies of these vertebræ were broken down, the intervertebral substance was intact; the vertebral canal was fairly opened, but the disease did not extend further, it had not affected the membranes.

The disease may be excited by external injuries, but I apprehend a strong disposition to it already existed in these cases.

The first effect of this form of caries is, as we have seen, to soften the body of a vertebra so as to render it incapable of supporting the weight of the trunk; the vertebra above the point losing all support from the body, but sustained behind by the articular apophyses and posterior portion of the ring, which are not softened, tips forward as it were, so that its spinous process, brought into nearly a horizontal direction, projects under the skin, causing a gibbus. An angle is thus described by the spine, with a projection or apex backwards. As this condition may implicate many vertebræ, a singular change is brought about in the patient. He grows shorter, his limbs look too long for his height. He avoids all movements which flex the trunk forward; in walking, the legs are slightly

flexed, the neck extended, and the face turned up. The position of the trunk, when the patient is in bed, is very similar to that which he presents when he is up; but he can only lie on the side. If the disease affect the cervical region, the trunk is straight, but the head, deprived of support, is inclined from one side to the other.

Symptoms.—In a large number of cases, if the gibbosity be considerable, and if it have occurred suddenly, it may exercise a fatal influence on the cord or nerves: the patient complains of a sensation of pinching, or tearing, in the thighs and legs, together with convulsive twitching and numbness, and he cannot command completely all their movements; sometimes, suddenly or gradually, paraplegia comes on, with or without paralysis of the bladder and rectum, and often accompanied with rigidity of the limbs. But these effects are by no means constant, for there are a great many cases on record where the substance of the cord has been almost completely interrupted, without any difficulty of moving the limbs being experienced.

Pott says, "If the patient be a child, the account most frequently given is, that for some time previous to the incapacity of using its limbs it had been observed to be languid, listless, and very soon tired; that it was unwilling to move much or briskly; that it had been observed frequently to trip or stumble, although no impediment lay in its way; that when it moved hastily or unguardedly, its legs would cross each other involuntarily, by which it was often and suddenly thrown down; and that if it endeavoured to stand still and upright, unsupported by another person, its knees would totter and bend under it; that it could not, with any degree of precision or certainty, steadily direct either of its feet to any particular point, but that in attempting to do so, they would be suddenly and involuntarily brought across each other; that soon after this it complained of frequent pains and twitchings in its thighs, particularly when in bed, and of an uneasy sensation at the pit of the stomach; that when it sat on a chair or a stool, its legs were almost always found across each other, and drawn up under the seat; and that in a little time after these particulars had been observed, it totally lost the power of walking.

If the patient be an adult, and no violence has been committed or received, he will tell you that his first intimation was a sense of weakness in his back bone, accompanied with what he will call a heavy dull kind of pain, attended with such a degree of lassitude as rendered a small degree of exercise fatiguing; that this was soon followed by an unusual

sense of coldness in his thighs, not accountable for from the weather, and a palpable diminution of their sensibility. That in a little time more his limbs were frequently convulsed with involuntary twitchings, particularly troublesome in the night; that soon after this he not only became perfectly incapable of walking, but that his power either of retaining or discharging his urine and fæces was considerably impaired, and his penis became incapable of erection." This is a graphic description of the symptoms as they usually occur, but there is much variety in this respect; for instance, sometimes the arms are affected, and in many cases the symptoms are not confined to parts below the diseased point.

In many cases, however, with all these helps, the diagnosis is very difficult, especially in children before they can walk, when one important element is wanting. Many means have been pointed out for the purpose of overcoming these difficulties at an early period, when there is no posterior projection. Copland recommends pressure upon the part, as the diseased vertebræ are very sensible to its action. He also advises that a sponge with hot water should be passed along the spine. Wherever the vertebræ are unaffected, the patient is only sensible of the contact of warm water, but at the diseased point a burning heat is felt. Frank thinks this a good test. Wenzel conceived that the pains should increase by pressing on both scapulæ, or by employing ammoniacal frictions on the part. Stiebel believed that a hot bath, with carbonate of potash in it, left no doubt of the precise point of disease. But you will, in many cases, find all these means fail. In fact, I would engage to shew cases where the disease did not exist furnish the indications just mentioned. I regard as most important the ordinary attitude of the patient. This sign exists even before there is much feebleness of the extremities. The knees are flexed, and the head inclined backwards; in walking the arms are flexed at the elbow, which is brought close to the trunk; the patient constantly seeks a rest for the hands; he frequently rests them on the hips, and when he stoops he rests them on the thighs. In bed he does not turn himself without much difficulty. But when, in addition, the curvature exists, and abscess is developed, we are relieved of all further difficulty in diagnosis.

I had lately an opportunity of examining one of these cases after death; several vertebræ were carious, superficially, to a considerable extent. The anterior ligament was detached, and formed, with the surrounding cellular tissue, a large sac, filled with purulent matter, more con-

sistent than that which had been flowing out; a tortuous sinus established a communication between this sac and the external tumor; the bodies of two vertebræ were completely destroyed by the evolution of tubercles; the fibro-cartilages had not suffered much. In some cases the vertebral ligaments are softened, the intervertebral cartilages are destroyed, the spinal cord and its coverings may exhibit marks of irritation, or inflammation; around the carious point a large collection of purulent fluid may be found, in the midst of which a kind of stalactiform osseous production is seen, more or less completely connecting the vertebræ above and below those destroyed; and giving a beautiful example of the efforts which nature makes to repair the loss of substance which has been sustained. When the caries has been cured, we find the loss of substance surrounded by irregular ossification, by which the destroyed bone is replaced, and the cavity filled up. If we examine a number of specimens of vertebral caries, and compare them one with another, we see that the causes which produce them bring very sensible differences in their appearance. Thus, in scrofulous caries, the disease affects many vertebræ, and does not spare the intervertebral substance; while, in rheumatic caries, a contrary condition is presented. The vertebral ligaments constantly remain unaffected in the midst of the destruction of the bony tissues,

choleric temperament. I suffered in the autumn of 1810 from a protracted and violent bilio-nervous fever; at the end of that year, and until 1812, I had several quotidiens and tertians; and in 1813 I had a miliary typhus fever (*Kriegstypus*). Ever since these illnesses I perspire copiously, and from slight causes; I am also inclined to diarrhœa, but I rarely labour under it, because I avoid all such meats and drinks as would be likely to bring it on. My bowels, however, are open two or three times a day. In order to keep in very good health, I require a bit of hard work once a week or fortnight—an object which I am generally fortunate enough to obtain in the practice of midwifery." (p. 25-6.)

The ladies are described in the following manner:—Ch., a lady aged 45, of short stature and delicate constitution, but healthy, and of a sanguine temperament. L., a young lady of 18, tall and slender, of a delicate and arterial constitution, a sanguine temperament, and quite healthy. Th., a girl aged 12, of a middle-size, and stout for her age, of an arterial florid constitution, and sanguine temperament; she likewise was perfectly healthy. Both the last, adds Dr. Jörg, live with the utmost simplicity: they eat meat and vegetables, but take neither wine nor coffee, and but rarely tea; they usually drink water, milk, or a weak pale ale; and, though they work and study, do not neglect exercise in the open air.

"When we tried experiments with any remedy, we followed no other dietetic rules than those by which we had been guided previously. We lived regularly in every respect, just as a healthy man must do, who wishes to remain healthy. The students of Leipsie, though their board is quite sufficient for the purpose of nourishment, do not find the dishes too numerous, nor prepared with too much art, so that they are not likely to be hurt in this way. Many of them drink coffee, but, partly by the roasting, and partly by the boiling, this has lost its narcotic power, and hence does not exhibit those poisonous effects which the exaggerated representations of many physicians would make us believe that it produces upon the healthy. Most of the students in Leipsie take wine only on rare occasions, and though a few of them drink beer, it is, for the most part, a very weak beverage, not capable of destroying the effects of the remedies experimented on.

"But these things are of less consequence than is commonly supposed, provided the ordinary course of life is adhered to; as for myself, I lived as usual during my experiments. At 5 or 6 in the morning I took two cups of coffee with milk; at 7 or

MEDICAL EXPERIMENTS.

BY DR. J. C. G. JÖRG.

ABOUT the year 1822 a society was formed at Leipsic for the purpose of trying the effects of medicines on the healthy: it consisted of Dr. Jörg, an eminent accoucheur of that town, and twenty-six other persons, three of whom were ladies. The results of some of their experiments were published by Dr. Jörg; and the account is preceded by observations on the advantages to be derived to medical science from experiments of this kind, and by a descriptive list of the members of the club. Thus, No. 4 was Mr. Frederic Conrad Steinbach, aged 26, from Pegau, tall and stout, of robust constitution and sanguine temperament; he took his degree May 13, 1823. No. 21 was Mr. Charles Ottomar Otto, aged 22, from Weissenfels, tall and lean, of lymphatic constitution, and sanguineo-choleric temperament. No. 22 is Dr. Jörg himself, who gives the following account of his own physical conformation:—

"I am 45 years old, stout, of a middle size, robust constitution, and sanguineo-

8, generally speaking, a little white bread and butter; at 1 I dined on soup and meat, with or without vegetables, and at 8 or 9 I supped in the same style. Both at dinner and supper I have long been in the habit of taking half a bottle (or a pound) of white Würzburg, or red Assmannshäuser wine; and I continued to do so during the experiments. Had I altered my usual mode of living, had I given up wine and coffee, I should have been out of tune, and perhaps made myself half ill. The result justified my mode of proceeding; for most of the medicines had the same effect on me as on the other members of the experimental society. Nay, in many cases, it was quite clear that medicines had less effect on those individuals who drank milk, white beer, or plain water, than on me who use other beverages. If any of us slept ill at night, we intermitted the medicines, until due rest had restored our body to the proper degree of sensibility."—(p. 21-23.)

The medical substances, of which the effects are reported and commented upon, are seventeen in number; namely, nitre, cherry-laurel water, bitter almond water, Vauquelin's prussic acid, Von Ittner's prussic acid, valerian, serpentaria, the flowers of arnica, the root of arnica, camphor, castor, musk, St. Ignatius's bean, assafoetida, opium, digitalis, and tincture of iodine.

Unless the contrary is expressly asserted, it is to be understood that the dose mentioned was taken once only in the day. Although, in order to comprise this abstract within reasonable bounds, we must in general content ourselves with giving the results, and pass over the details of the experiments by which they were arrived at, we will make a single exception to our rule, and give the commencement of the numerous trials on which Dr. Jörg has founded his theory of the operation of nitre.

"On the 27th February, 1822, at nine A. M., Engler swallowed a grain of nitre, rubbed down with five grains of white sugar, but without any effect.

On the 2d of March, at the same hour, he took three grains of nitre and six of sugar, and a few hours afterwards his urine was more copious, darker, and redder. After the lapse of several hours a sediment formed, which, when the urine was shaken, rose in flocculi. On March 4th, at the same hour, Engler took four grains of nitre with the same quantity of sugar; this dose was followed by the same increased secretion of urine, and by a still more frequent desire to go to stool, without more frequent evacuations of the rectum. The same effects were produced by five grains

taken on the 5th of March, and six grains on the 6th. On the 7th of March seven grains were taken at nine in the morning, and again at five in the afternoon; on which the experimenter observed throughout the day that a pale and turbid urine was frequently discharged, and that there was repeatedly a sensation of pressure downwards to the anus, without more than the usual evacuations.

On the 8th of March he omitted the nitre; the urine was reduced to its regular quantity, and the pressure towards the anus was no longer felt. Two doses, of eight grains each, being taken on the 9th of March, at 9 A. M., and 5 P. M., the same sensations were experienced as on the preceding day, though not in a greater degree than from the smaller doses. On the 11th of March he took two doses of ten grains each, at the same hours as before, and the urine became still redder and more turbid, but was not secreted in greater quantity. Though there was repeatedly the sensation of bearing down towards the anus, the evacuation did not take place as usual in the morning, but towards evening. On the 12th of March two eleven-grain doses were taken at the same hours, and with the same results. On the 15th of March he took two fifteen-grain doses at the same hours, which were followed by an increased discharge of clear urine. The tenesmus and bearing down, however, were felt less frequently than after the earlier doses. (p. 28-9.)

The largest doses were taken by Assmann; on one occasion he took two drachms at once, and on another day two drachms at twice. These large quantities produced head-ache, violent thirst, oppression of the stomach, abdominal pain, and other distressing symptoms, so that Dr. Jörg dissuaded him from taking larger quantities. Dr. Alexander, of Edinburgh, however, whose experiments our author quotes at some length, tried the effects of nitre with much greater boldness, not to say rashness. He found that nitre is less active when it has been some time dissolved in water; when it was in this state he could take six, eight, or twelve drachms within 24 hours, without inconvenience, the only effect being an increased secretion of urine. But when he took an ounce dissolved immediately before swallowing, at the rate of a drachm every ninety minutes, in four ounces of water, the following were the effects. First, a refreshing coolness, then coldness and pain in the stomach, and at last sharp and lancinating pains, not only in the stomach, but through the whole body, which were so violent that for fifteen minutes he could not breathe without feeling the acutest pain at each

inspiration. He afterwards divided an ounce and a half of nitre into eight equal parts, and took one every ninety minutes, immediately after its solution in water; but the pain in the epigastric region and over his whole body was so great, that he was obliged to desist from his experiments. Dr. Jörg then gives at some length a case of poisoning with nitre, related by Alexander; but we will avail ourselves of the brief abstract of the same case given by our great British toxicologist:—"A woman in the second month of pregnancy, immediately after taking a handful of nitre in solution, was attacked with pain in the stomach, swelling of the whole body, and general pains; she then miscarried, and afterwards had the usual symptoms of gastritis and dysentery, united with great giddiness, ringing in the ears, general tremors, and excessive chilliness. She seems to have had a narrow escape, as for three days the discharges by stool were profuse, and composed chiefly of blood and membranous flakes." (Christison on Poisons, p. 162-3.)

From the sum total of these experiments Dr. Jörg concludes, that *nitre is a stimulus to the kidneys, the intestinal canal, and the skin*. Its action upon the kidneys, which is most to be depended on, is shown by its increasing the quantity, and altering the quality, of the urine. It acts upon the alimentary canal from its commencement, and upon the auxiliary organs which open into it, increasing the secretion of saliva, causing dryness of the mouth and the œsophagus, thirst, morbid hunger, and pain in the stomach, (the pain being like that of inflammatory irritation,) a sensation of pressure or cutting in the small intestines, with rumbling, flatulence, and relaxation of the bowels; sometimes there is constipation, when the nitre has acted more especially on the small intestines, the kidneys, or the skin. Its power over the large intestine appears from its so often causing a desire to go to stool, even when this was not followed by actual evacuations. It more rarely affects the skin. When used in moderate doses it has no after-effects, and does not attack other organs. It was only when taken in very large doses that it excited giddiness or pain, or confusion of the head. Nitre, however, has one subordinate effect, which physicians have prized too highly, and have consequently prescribed it in diseases where it was totally out of place. When taken immediately after it has been dissolved in water, it cools the mouth, the œsophagus, and sometimes the stomach, for a few minutes. This primary effect, however, is soon followed by its secondary one, that of warming, namely; and the

greater the former, the more marked is the latter. Thus the more the frequency of the pulse has been diminished by the original refrigeration caused by the medicine, the more is it increased by the subsequent reaction.

From this fact, and from its power of stimulating the skin, the kidneys, and the intestinal canal, Dr. Jörg deduces the conclusion that nitre is not an antiphlogistic remedy, but that it is to be used as a derivative in inflammation of the head, neck, and sometimes of the thoracic cavity. Moreover, as in moderate doses it does not act upon the nerves or the brain, it is well qualified to be a substitute for the mercury which is so frequently given too liberally in the phrenitis of children. In many cases, too, it must be an excellent emmenagogue. In the majority of cases the dose should be from three to five grains twice a day, though there are occasions when eight, ten, or more, should be given.

Cherry-Laurel Water.—The medicine used in Dr. Jörg's experiments was prepared in the following manner, in conformity with the prescription of the Saxon Pharmacopœia, (Dresden, 1820, p. 168.)

Take of fresh cherry-laurel leaves cut into pieces, lbj.; Alcohol, ℥j.; Common water, lb. vj. After mixing, three pounds are to be distilled over.

The doses varied from three to fifty drops; though one experimenter, Heisterbergk by name, who appears throughout as the Mithridates of the club, took, on one occasion, 112 drops, with but little effect, save that of lowering his pulse about twelve beats in a minute.

Before recapitulating the effects of cherry-laurel water, Dr. Jörg observes that many drugs are tasted or smelt long after having been swallowed; while this substance, the moment it reaches the parietes of the stomach, seems decomposed, and therefore deprived both of its taste and odour. He remarks likewise that no drug throws more difficulty in the way of the experimenter than this one; for as it begins by attacking the head, it diminishes his capability of judging of his own sensations.

The cherry-laurel water was found to cause heaviness, with oppressive and stabbing pains in the brain, especially in its anterior part, in the region of the nerves of the eye, but particularly confusion of the head, with diminished sensibility of the whole body, slowness of the pulse, weariness and inclination to sleep, sleep itself, relaxation of the whole body, but especially of the thighs, disinclination to work; and, secondarily, irritation, itching, and tickling in the larynx, as in the com-

mencement of inflammation of this part, frequent slight coughing, and increased secretion of a tough mucus in the trachea. It would appear, too, that the slowness of the pulse is more or less associated with the affections of the head.

This remedy acts as an excitant upon the brain; and, therefore, the retarding of the circulation and the diminution of the sensibility, for which physicians most frequently prescribe it, are purchased by an exaltation (though but a transient one) of nervous and cerebral life (*des Nerven- und Gehirnlbens*). Hence this medicine is ill adapted for patients suffering under inflammation or congestion of the brain, but will be advantageous in inflammation of the abdominal and genital organs, or in increased sensibility without inflammation. It must be injurious in pneumonia, as it has a tendency to inflame parts connected with the lungs, namely, the larynx and trachea, exciting cough and dryness of the mouth.

It will be particularly beneficial in diseases of the female genitals attended with increased sensibility, whether they bear an inflammatory character or not: on the other hand, it might do much harm in the first six days of scarlet fever, and in puerperal fever with a tendency of the *materia lactea** (*Milchstoff*) to the head, as in either case it might favour the metastasis to the brain.

Dr. Jörg asks whether the cherry-laurel water, from the prussic acid which it contains, may not be additionally useful in the inflammations in which he has recommended it, by rendering the blood more venous, and, therefore, less plastic, and thus, more or less, preventing the adhesion of the inflamed parts by exudation. This effect would ward off great evils in inflammation of the intestines, peritoneum, urinary bladder, and uterus.

No one, he says, who is accurately acquainted with its medicinal properties, will believe that this remedy can have been of avail in obstructions of the abdomen, in what is called an *atrabilious* state, in hemorrhoidal affections, in obstructions of the glands, in induration or carcinoma of the uterus. In these and similar diseases it can have done no real service, unless we reckon as such its depressing the sensibility of the nerves. Nor must it be used in the various spasms for which it is prescribed by physicians, without the greatest caution. Those spasms or convulsions which depend on irritation of the brain, or arise from

repletion of its vessels, and the general or partial pressure which the central organ of the nervous system thereby suffers, cannot be quieted by this remedy.

As it acts upon the healthy in very different doses, the physician must select those for the sick with the greatest care; but they will probably range from three to fifteen drops, two, three, or four times in the twenty-four hours, though in some cases they must be gradually increased. We must recollect, too, that it soon loses its strength by standing, and by frequent opening of the phials in which it is contained.

Bitter Almond Water.—The medicine used in the experiments was prepared according to the Saxon Pharmacopoeia, by mixing one pound of bitter almonds with an ounce of alcohol, and six pounds of water, and distilling over three pounds.

It appeared, from the majority of the experiments, that although this remedy tasted and smelled more strongly of bitter almonds than the cherry-laurel water, it is weaker. Its effects, too, are of the same kind, and it may, therefore, be very well dispensed with.

Vauquelin's Prussic Acid.—The doses taken by the society varied from half a drop to three drops in twenty-four hours. They also destroyed four young magpies, two young cats, two young rabbits, a guinea-pig, and two frogs, with this drug. Four drops were sufficient to kill a half-grown male cat in three or four minutes.

It appeared, from examination after death, that, when prussic acid has been taken, the blood puts on the venous character, and is accumulated in the veins and the right half of the heart. Dr. Jörg also found this effect gradually take place in a frog poisoned with five drops, and placed under the microscope.

He concludes, from his experiments on men and animals, that prussic acid acts not only with the utmost rapidity, but with the utmost violence as a stimulus to the brain and nervous system, but more rapidly and violently on the cerebral than on the ganglionic nerves. This excitement is sooner or later followed by a diminution of nervous and cerebral life, or by death itself. When death does not soon take place, an inflammatory irritation of the trachea, and especially of the larynx, is produced. It also paralyses the lungs, thus causing those dreadful sensations which arise from the non-oxygenation of the blood. Hence the advantage of taking the patient into the open air.

Dr. Jörg would wish to see this remedy expunged from the *materia medica*, on account of its dangerous strength; and we agree with him. The cherry-laurel water

* By this phrase Dr. Jörg must mean the tendency to the head of that portion of the blood which, in a healthy woman, should secrete the milk.

is far preferable. If Vauquelin's prussic acid is to be used, the dose should not exceed half a drop, or a drop, every four, six, or eight hours.

He remarks that, in all cases where the primary and secondary effects of a remedy are almost diametrically opposite, much depends on the magnitude of the doses and of the intervals between them: thus when some abdominal organ is violently inflamed, if it is desired to make the pulse slower, and the blood more venous, much larger doses of prussic acid will be required than if it is desired in a nervous disease to change the tone of the nerves.

Ittner's Prussic Acid.—The doses taken of this medicine varied from half a drop to three drops. Dr. Jörg himself took none; for Vauquelin's acid had acted so strongly upon his sensorium and common sensation, that he foresaw that Ittner's would have deprived him of his tact, both in the literal and figurative sense of the word. He found, however, from his experiments on men and animals, that this solution of prussic acid is rather stronger than the former one, and, therefore, still less deserves a place in the pharmacopœia. If ever prescribed, the dose should be from the fourth of a drop to a drop, every four, six, or eight hours.

The root of Valerian.—The society first tried an infusion; the proportions being generally from ʒij.—ʒj. to a pound of water, and the time of maceration a quarter of an hour. The dose was usually a quarter, but sometimes one half, of this infusion. Sometimes it was taken in a more concentrated form, as for instance, ʒij. of valerian infused in ʒiiss. of water.

When taken in the form of powder, the doses varied from half a drachm to two drachms and a half.

The results of the experiments show that valerian is a stimulus to the brain and the organs of digestion: when used in infusion it acts more on the head, when in powder, more on the abdomen and its organs. Dr. Jörg blames the manuals of materia medica for recommending valerian in hypochondriacal and hysterical cases. It is to be used, he says, in cases of debility, but not where there is any congestion of blood in the brain or the abdomen. The range of doses is to be from half a drachm to two drachms.

The root of Serpentina.—An infusion was first tried; the quantity infused varying from a scruple to two drachms. The society afterwards took the powder in doses varying from gr. xv. to ʒiss.

Dr. Jörg found that serpentina is a stimulus to the intestinal canal and its auxiliary organs, and that it favours con-

gestion in the abdominal viscera; but with this peculiarity, that it does not promote mucous or glandular secretions, but rather the development of air in the intestines. Sometimes it acts as a stimulus to the brain, and causes congestion in that organ; sometimes it accelerates the circulation; and occasionally it stimulates the urinary, and, probably, also the genital organs. When infused, it acts more on the head and less on the abdomen, and *vice versâ* when in powder. When taken in small doses its effects last from 8 to 12 hours; when in large, from 18 to 20. Hence it should not be given oftener than twice in twenty-four hours; and sometimes once is enough. The dose should be from a scruple to a drachm, whether infused or in powder.

Dr. Jörg thinks it probable that serpentina, from its power of checking the mucous and fluid secretions of the intestinal canal, will be found particularly useful in chronic diarrhœa without any trace of inflammation, and in diarrhœa arising from colliquation. After observing that from its power of extricating air in the intestines, it would probably be hurtful when meteorismus is already present, he concludes with a very proper saving clause: "but this last point must be learned from experience at the sick-bed." (p. 181.)

The flowers of Arnica.—This remedy was taken in infusion. The dose of the flowers varying from 1½ to 45 grains, the smallest doses being taken by Mrs. Ch. and Miss L.; the largest by Heisterbergk. It was afterwards tried in the following manner. A drachm of the flowers was infused in six ounces of water, and a table-spoonful of the filtered infusion taken every two or three hours; this being the quantity and the intervals, says Dr. Jörg, in which most writers recommend this remedy, when it is to be taken in moderate doses.

He concludes from the experiments, that arnica flowers irritate and inflame the alimentary canal throughout its whole extent; the œsophagus, however, the stomach, and the small intestines, more than the large ones; that they act more upon the muscular fibres of the intestinal canal than on its vessels, and therefore promote contraction in the several divisions of the intestines, far more than secretion or absorption. They must also act upon the urinary system, and increase the secretion of urine either in quality or quantity; nor do the brain, the circulation, the skin, the lungs, or the trachea, escape the influence of this stimulus.

The action of arnica flowers lasts much longer than is commonly supposed, as it extends to from 24 to 36 hours.

Almost any book of materia medica will serve to show that arnica flowers are pre-

scribed in doses too large, and too closely following each other.

If the patient is very irritable, a spoonful of fluid impregnated with the virtues of one or two grains of the flowers will suffice; to less sensitive persons we may give half an ounce of fluid, in which from three to five grains have been infused.

Dr. Jörg having found that arnica flowers are an external irritant, recommends them or their infusion as a mild rubefacient, and the infusion as an application to foul, malignant ulcers, which threaten sphacelus or induration.

The root of Arnica.—This drug was first tried in the form of a tincture prepared with one part of the root to six of alcohol. The doses were pushed as high as 84 drops, but the effects were very slight. It is rather to be considered a spirituous bitter, than as possessing the peculiar powers of arnica. The club then took the infusion of the root; the quantity infused varying from gr. iiss. to 3j.

Dr. Jörg states the following differences between the infusion of the root and the infusion of the flowers of arnica. 1. The former being less acrid is a lesser stimulus to the cavity of the mouth, to the œsophagus, stomach, and small intestines. 2. Its slower and milder action upon the intestinal canal affects the muscles rather than the internal mucous membrane, and therefore promotes contraction, rather than any other function. 3. In persons whose digestive organs are not very irritable, it apparently acts more upon the brain than the infusion of the flowers.

Dr. Jörg concludes by remarking that arnica has long been celebrated for its power of discussing indurated parts, and promoting the absorption of fluid effused in the brain, but that this power was not shown among the experimenters, as there was nothing to be discussed or absorbed. Still, he says, the experiments clearly prove that arnica has this power; for, whatever increases the activity of the alimentary canal, exalts the function of the lymphatics, and causes derivation from the brain. Hence arnica is similar in its effects to calomel, with the difference that the former calls forth an inflammatory diathesis, while the latter rather promotes a scorbutic relaxation.

[To be continued.]

CÆSAREAN OPERATION.

(From a Correspondent.)

This operation was performed, on the 15th inst., by Mr. Whitehead, of Manchester, in consequence of extreme deformity of the pelvis. Premature labour

had been induced in four previous pregnancies about the end of the fourth month. The usual means were employed in the present instance until the end of the seventh month, but without the desired effect. The child and placenta were extracted without any difficulty in about two minutes after the first incision was made, and the whole operation completed in the course of a quarter of an hour from the commencement. The loss of blood amounted to about ten ounces. The suffering, according to the patient's own account, was not greater than that occasioned by one or two strong labour pains. The mother and child, up to the present time (the sixteenth day after the operation), are doing well.

Owing to circumstances which it is needless to mention a detailed account cannot be furnished at present, but will be hereafter.

August 31st, 1840.

ON

SECONDARY DEPOTS OF MATTER.

HOW ARE PURULENT DEPOSITIONS OF MATTER FORMED AFTER INJURIES AND OPERATIONS IN PARTS REMOTE FROM THE ORIGINAL SEAT OF INJURY?

Illustrated by numerous Cases, &c.

By JOHN CHARLES HALL, M.D. F.L.S.

"Utendum est ætate; cito pede præterit ætas."
OVID.

WILLIAM T——N, ætat. 35, a man of very intemperate habits, was placed under the care of a surgeon, having, four hours previously, received a kick from a horse on the posterior part of the head. There was a wound, two inches in length, which separated the scalp from the cranium, the bone being denuded of its periosteum to the extent of a crown-piece. There was no appearance of fracture or depression. He stated that he was stunned by the blow for some time, but had not been sick. When first seen he was stupid and sleepy; pulse 100, strong and full.

Eighteen ounces of blood were taken away from the arm, and a purgative, composed of calomel and colocynth, administered.

6th, (noon).—Has passed a tolerably good night; not at all drowsy. Complains of a little pain in the head; bowels

have acted freely; tongue slightly furred, but moist; pulse hard, and 84; countenance flushed and anxious; skin hard and dry.

9, P.M.—Pain in the head increased. There is a slight puffiness about the edges of the wound; pulse 86, hard and wiry; bled again to ten ounces.

7th.—The blood extracted yesterday was highly inflamed. Has passed a quiet night; no pain in the head; still drowsy and inclined to sleep; pulse 84, more quiet; tongue moist; *the adhesions were broken up, and a considerable quantity of serum escaped.* Apply a poultice to the wound.

15th.—No particular change since our last report. Is now going on well; wound nearly healed. Wants to go home; and says there is nothing the matter with him.

16th.—No change.

17th.—Pain in the head to-day, relieved by purgatives.

23d.—Appears to be going on well; the bone, however, is denuded and rough.

26th.—Up to this day he remained quite well, and was allowed to walk about his room. Violent pain in the head now came on; singing in the ears; with repeated rigors alternating with the most violent perspirations.

10, A.M.—Severe pain in the head; face much flushed; skin hot; tongue loaded; pulse 120, full and sharp. Bled to twelve ounces.

3, P.M.—Pain in the head better; pulse 90; blood taken away in the morning buffed. An incision was made down to the bone, which was exposed by the accident; it felt rough, but the periosteum was spreading over it: a saline mixture was ordered. In the evening he had another rigor; pulse 120, strong but compressible; blood buffed and cupped; a blister to the head. The medicine to be omitted.

R Hydrarg. Chloridi, gr. ii. quâque 4ta. horâ sumend.

27th.—Has passed a very restless night. Had two rigors; one at evening, and the other in the morning: pain in the head; pulse 132; cough; no râle, no tenderness of the abdomen; tongue white and loaded; skin hot and dry; slight delirium.

2 o'clock, P.M.—The trephine was applied over the original seat of injury to seek for pus, but none was found; the dura mater was perfectly sound, and not

one drop of matter escaped; the wound was closed by suture. Vespere, pulse 72, quiet; no pain in the head; or, to use the poor fellow's own words, "none worth speaking of."

28th.—Has been rather restless during the night. Had a rigor at midnight, another at twelve to-day; slight pain in the head; great intolerance of light and sound; singing in the ears; wound looks rather better; pulse 120, strong and sharp; tongue moist but loaded, particularly at the back part. Bled to eight ounces. Two grains of calomel every eight hours.

29th.—Blood buffed; pain in the head said to be relieved (?) by the bleeding; two rigors at the same time as yesterday: the wound does not look so well to-day; he is less irritable; pulse 120. Continue the calomel.

30th.—Has had a little sleep at intervals during the night; two more rigors; great sickness; pain, with some fullness, in the right hypochondriac and epigastric region, which is increased by pressure; breathing hurried; the wound appears worse; no pain in the head, and no cough; pulse 120; fæces black, foetid, and particularly offensive; countenance sallow. Omit the calomel; a blister to the epigastrium. Small doses of creosote, to allay the vomiting; and a few grains of sesqui-carbonate of ammonia, with spir. æth. nit. and mint-water, every four hours.

1st.—Two more rigors; no sleep; pain in the loins; pulse 108; urine scanty and high coloured; tongue loaded; skin hot and dry; complains of pain between the shoulders. Beef-tea; two grains of calomel at bedtime.

2nd.—Has passed a very restless night; had another rigor this morning; breathing occasionally difficult; evidently becoming weaker; the skin, also, is becoming daily more and more yellow; wound unhealthy and languid; pulse 116.

7th.—The changes that daily took place up to this morning, when he died, require no particular notice; he became weaker and weaker, the symptoms of jaundice gradually increasing.

Post-mortem examination — Head. Upon removing the bone, the dura mater was found to be perfectly free from disease; the longitudinal sinus, over which the trephine had been applied, was healthy, as were all the other sinuses, evincing no trace of previous inflamma-

tion. The brain was also perfectly free from disease, nor was there any effusion into the ventricles.

The lungs were congested, and of a dark red colour, with one or two depôts upon each lobe about the size of peas. The liver was much enlarged, the right lobe reaching down below the crest of the ilium. There was a large purulent deposit at the anterior margin, extending for some distance along the inferior concave surface of this lobe; there were also two or three smaller ones on the superior aspect. On cutting through the surface of this lobe, other deposits of different sizes were discovered, being hollow in the centre, and filled with pus; there was also a very considerable abscess in the left lobe. The right shoulder-joint was also affected, and contained a considerable quantity of pus.

We cannot carefully read over this very important and very interesting case without remarking, that after a comparatively slight injury of the head, a distant organ became secondarily affected, abscesses forming in the liver. A more minute examination will also point out how clearly the condition of the wound proclaimed the disordered condition of the system. Cases of this kind are far from uncommon; and, speaking of them, Mr. Abernethy remarks, "that these circumstances appear to me to be stated rather as occasional, than as occurrences which are common, and naturally to be looked for and expected; and I therefore think myself warranted in supposing that they have not made a sufficient impression on the minds of surgeons in this country at least." Dr. Cheston, in his valuable pathological observations, has recorded several cases of this nature, and we may also add that they have been familiar to surgeons for many years. In the works of Galen we find passages proving him to have been acquainted with them. Bertrandi (*Mémoires de l'Académie de Chirurgie*) mentions several instances in which secondary depôts took place in the liver after injuries of the head.

The subject of secondary depositions of matter taking place, as in the case now before us, in organs far distant from the original seat of the injury, involved, as it is, in mystery, is, nevertheless, one of considerable importance, and well worthy of our most careful and attentive consideration. That this is

far from being uncommon, after injuries and operations, is a fact that cannot be doubted for a moment. A man is brought into the hands of the surgeon, having received a blow upon the back part of his head; he recovers from the injury; all pain in the head is gone; he walks about the room, and expresses a wish to return home; suddenly he is seized with pain in the head, succeeded by rigors; there is pain in the right hypochondriac region; the countenance becomes yellow, the symptoms of jaundice daily increase, the man dies, and the lungs, liver, and one or two joints, are found to contain depôts of purulent matter. The question naturally arising is, how came they there? In the greater number of cases they succeed to injuries and operations, frequently after a blow upon the head. Now as they appear, in the majority of instances after accidents, in men who, before the infliction of the injury, were in a perfect state of health, we cannot for a moment suppose that they existed previous to the accident. Such a supposition is not consonant with reason. We cannot suppose such an extensive disease to have existed without disordering the health—without proclaiming its presence by a series of the most alarming symptoms. The disease, therefore, must be created after the accident; the fracture of the bone, or the wound of the scalp covering it, or the inflammatory action produced in one, or both, must have contributed to its production; in what way, however, must form the ground-work of our present investigation.

We define suppuration to be a peculiar process, by which a fluid called pus is formed in the substance or from the surface of parts of the body. The texture in which suppuration seems to be most readily produced by a certain degree of inflammatory action is mucous membrane, whether this lines excretory ducts or canals, or covers the inner surfaces of the respiratory or urinary organs.

Professor Carswell makes a distinction between the process of suppuration, considered as a vital act, and the mere presence of pus as a product of that process. "For if," says he, "pus be found in an organ in which neither the physical nor physiological characters of inflammation are to be detected, either during life or after death, the necessity then of establishing a distinction be-

tween the mere presence of pus and suppuration must be obvious." Great violence done to parts is one of the principal exciting causes of suppuration; but simple violence does not always occasion it; "for," remarks John Hunter, "the violence must be followed by something that prevents the cure in a more simple way—something that prevents the restoration of the structure, and the continuance of the animal functions of the part. The parts must be kept long enough in that state into which they were put by the violence, or what is somewhat similar to this, the violence must be attended with death in a part, as in many bruises, all mortifications, and all sloughs in consequence of the application of caustic which, when the dead parts separate, leave internal surfaces exposed. "And," continues Professor Carswell, in his *Illustrations of the Elementary Forms of Disease*, "formed by a process similar to that of secretion, the chemical composition of pus must vary, not only from the nature of the tissue from which it is derived, but likewise under the influence of various morbid conditions which are known to modify the products of secretions in general." "True pus," says Sir A. Cooper, "has certain properties which, when taken singly, may belong to all other secretions, but which conjointly form the true characteristics of this fluid, viz., globules swimming in a fluid which is coagulable by a solution of the hydrochlorate of ammonia. Pus also contains a very considerable portion of fibrine: thus we find fibrine, serum, and globules, entering into its formation. If I were to hazard a theory upon this subject, I should say that pus was composed of the constituent parts of the blood, slightly changed in their nature by inflammation" (*Lectures on Surgery*, page 121).

In addition to what we have already stated, we learn also that the secretion of pus is frequently suspended by disease: thus in fevers the peculiar state of the constitution induced by them has such an effect upon the local affection that a sore will appear to be almost dried up, at any rate its discharge will be very considerably lessened, but as soon as the febrile symptoms subside, pus is again secreted in as large a quantity as ever. The nature of the secretion is also altered by disease, and the appearance of the wound will announce the com-

mencement of constitutional irritation, even before any other symptom is present: the production of true pus ceases when disease attacks either the constitution or the sore; it changes its character, and becomes offensive, thin, and more transparent, containing a greater proportion of the extraneous particles of the blood.

The nature of the fluid most unquestionably varies; varies not only in its nature, but also in its effects. I know of no chemical difference between the pus upon the surface of a common ulcer and that of small-pox: that there is a difference I presume no one will take upon himself to doubt; but we only are aware of such difference by the nature of the effects produced in each particular form in which suppuration takes place upon the constitution. Doubtless, whatever tends to produce an alteration in the general state of the system influences more or less the nature of this fluid; at any rate renders the human body more susceptible of its influence—more liable to be acted upon by it. If, then, we can discover, by chemical analysis, no essential difference in the constituent parts of this fluid, I am inclined to think that peculiarities in the constitution, or in the nature of the parts in which it is secreted, will account for the varieties we observe in the nature of this fluid. For my own part I have again and again examined gonorrhœal discharges with a microscope, and at the same time pus effused from an ulcer, without being able to detect any difference. Long ago, however, Mr. Howship informed us that "he could not perceive any essential difference between such discharge and the pus collected from an ulcer." Now every surgeon is well aware that irritation, chemical or mechanical, on the surfaces of the female pudenda, or urethra of the male, which are the seats of gonorrhœa, may excite it. Contusion and forcible distension of the female pudenda will also bring on a discharge. When female children of tender years have been violated we have always more or less discharge; the introduction of a bougie; the injection of any irritating fluid; connection with women during the period of the menses, or who have a leucorrhœal discharge, will produce more or less inflammation of the urethra, and an acrid secretion that any surgeon would at once pronounce to

be gonorrhœa—which is, in fact, a disease of a highly inflammatory character, ending in the secretion and discharge of muco-purulent matter, varying, of course, in different constitutions, and influenced more or less by the general state of the system; capable of being produced in a variety of ways, always, however, commencing with an attack of inflammation, and ending in the discharge of pus—of matter which no one can distinguish from that which is secreted from an ulcer. There is nothing, then, in the nature of this fluid to induce us to suppose that the disease is specific, or that it is even a form of the venereal disease.

We have been induced to dwell longer on the nature of this fluid than we had intended, but not at greater length than its importance warrants. We have yet, however, to direct our attention to the most difficult part of our investigation, viz. the manner in which collections of matter are formed in the liver, and other internal organs, after injuries of the head, and other parts of the body.

We ventured to suggest, at the commencement of this paper, that the proof of the enjoyment of good health before the reception of a blow upon the head, was presumptive evidence of the previous non-existence of the purulent deposits found in the liver after such injuries. In the valuable lectures (now publishing in this journal) of Mr. Phillips, on Surgery, this subject is discussed with considerable ability. “It is difficult,” says he, “to explain visceral abscesses as a consequence of surgical operations, though operations are often performed on persons whose general health is good, and in whom we cannot admit that visceral lesions, so grave as those we meet with, can have existed before the injury or operation. Still, as on the one hand observation shows that a great many organic lesions may exist in a latent state, and as, on the other hand, visceral abscesses, consequences of wounds, present, by their multiplicity, their seat, and other circumstances, a great analogy with suppurating tubercles, many persons have maintained that these abscesses were no other than the result of the development of pre-existing tubercles. If this theory ought not to be adopted as a general rule, neither should it be repulsed in all cases. Our opinion is that it should not be admitted as a general rule; unques-

tionably, in most cases, around these abscesses phlegmonous inflammation may be detected without tubercles, or tubercular infiltration.”

This opinion is doubtless entitled to great respect, admitting, however, of much that can be urged against as well in favour of its adoption. It appears clear, that to the production of such secondary depôts two things are necessary: first, some exciting cause, as a wound of the scalp or an injury of the cranium; second, a peculiar state of the constitution, either existing previous to the receipt of the injury, or produced by some change which takes place in the part itself; for doubtless the general state of the system contributes in no inconsiderable degree to the production of certain specific diseases. Thus, a child may escape at one period of the year from rubeola, or any other disease to which children are liable, but at another time, from the strength being exhausted, from a cachetic state of the body, no resistance can be offered by the constitution, and the disease comes on.

Admitting then, on the one hand, the necessity of an immediate local or exciting cause, which we discover in the wound or blow upon the head, we direct our attention to that state of the system that predisposes to it; to that peculiar condition of the circumstances by which the patient is surrounded: it appears clear, we think, that certain conditions of the atmosphere, or of particular districts—in short, those which contribute to give rise to those fearful maladies, hospital gangrene and typhus fever—tend to produce inflammation of the veins; for I have never seen a case of phlebitis in which typhoid symptoms were not present. We will now enter more fully into the examination of phlebitis, and consider in review what has been written on the subject of inflammation of the veins, and the origin of depôts of purulent matter in certain viscera, at the same time offering such remarks as the cases we have seen, and the post-mortem examinations we have attended, suggest. We will therefore examine, in the first place, the causes of phlebitis; secondly, the symptoms that are present; and lastly, the manner in which the visceral abscesses before alluded to are supposed to be formed, after injuries and operations.

1st. The causes of phlebitis.

In the *Cyclopædia of Practical Medicine* there is a very interesting paper by Dr. Robert Lee, F.R.S., on diseases of the veins. He there states that he was informed by Sir A. Cooper that he once met with a tumor upon the saphena major vein. This tumor was laid open or removed, and inflammation of the vein soon succeeded, and destroyed life. A lady having a varicose enlargement of the vena saphena, Sir Astley cut it out, compressing the vein below, and requested her to keep quiet. Three or four days afterwards she was labouring under high constitutional irritation, the leg having an erysipelatous appearance; the great saphena vein became inflamed as high as the groin, and the patient died. Mr. Oldknow relates the case of a man who died after the application of a ligature to a varicose saphena vein. A woman was operated upon by Sir E. Home for femoral aneurism; by accident the vein was wounded, and the woman died. "Mr. Abernethy proposed to cut the saphena vein in cases of varicose veins of the leg; proposed, I say, for I believe he never did it; but, continued the learned lecturer, "when I was assistant-surgeon to this hospital, I cut this vein in a poor fellow's leg, and he died of venous inflammation; but still the operation had been performed before with perfect safety." (Notes of Sir B. C. Brodie's Clinical Lectures.)

Some years ago it was a very common practice to pass a ligature round the saphena vein for varicose veins of the leg, and for some time no mischief followed. But upon Sir A. Cooper observing several of his patients die in succession after the performance of this operation, he called the attention of the profession to it, and it was abandoned; for it was folly to suggest that as a remedy which proved far worse than the disease.

Inflammation of the veins appears to arise therefore, for the most part, from direct injury of them; from small punctures, as in bleeding. Mr. Abernethy believed that moving the arm soon after bleeding produced the disease. Dr. J. Thompson, of Edinburgh, thinks the state of the lancet as to sharpness has a considerable share in producing the morbid effects. A bad lancet may contribute, Mr. Abernethy thinks, to produce the disease; yet this is not sufficient to account for the accident, without supposing a peculiar irritability of the

constitution to be present, and this opinion is borne out by Sir B. C. Brodie, who remarks, "you bleed three hundred patients, and at length one is attacked with inflammation of the veins, and you are at once accused of having a foul lancet, when perhaps it was new, and used only for the first time." Breschet states that punctured wounds, particularly when the instrument is charged with some putrid or irritating matter, are often followed by inflammation of the deep-seated veins, and he attributes the greater frequency of inflammation of the veins of the arm in the present day, to the fact of bleeding with the lancet used for vaccination. We may also mention wounds received in dissection as an exciting cause of inflammation of the veins, and it is reported that Dr. Serrin died from the prick of a pin, which had been used for dressing a blister, and which wound, slight as it was, induced fatal inflammation of the vein. We must also take into consideration the state of our patient at the time he is bled. We must remember that there is more or less of excitement; generally more or less a tendency in the animal body to take on an inflammatory action at the time the operation is performed.

2d. The symptoms of phlebitis.

We are indebted to Mr. Arnott for some very clear explanations of the phenomena attendant upon this disease. The symptoms, he says, manifest themselves in from two to twelve days: "great restlessness and anxiety, depression of spirits, and prostration of strength; sense of weight at the præcordia; frequent sighing, or rather moaning. The common symptoms of fever are present; the pulse is rapid, reaching 130 to 140 in a minute, but is in other respects extremely variable. Under symptoms of increasing debility, and at a time when the local symptoms appear to be subsiding, secondary inflammations of a violent character, and quickly terminating in effusions of pus or lymph, take place in situations remote from the original injury; the cellular substance, the joints, and the eye, have been affected. Death is always preceded by symptoms of extreme exhaustion, such as those of a rapid feeble pulse; dry, brown, or black tongue; teeth and lips covered with sordes; haggard countenance; low delirium."

M. Cruveilhier, whose writings we shall directly more particularly examine, informs us that phlebitis of the

bones is one of the most frequent causes of abscesses found in the liver and other viscera. In 1814, he examined the medullary membrane of the long bones of such as had died in the Hôtel-Dieu with abscesses of the viscera, and low typhoid symptoms. There was suppuration in by far the greater number of those of the medullary membrane, sometimes extending throughout the whole length of the bone. Operations upon the bones are extremely likely to produce inflammation of the veins, according to this author; and he refers the constitutional disturbance to a miasmatic state of the system, the whole mass of fluids being infected: and he continues, "however extensive the phlebitis may be, if the pus does not enter the circulation, no accident follows from it; but as soon as the impediment formed by the coagula is removed, atonic adynamic fever, preceded by intense shivering, takes place, and is speedily followed by death."

It appears, then, that the veins are liable to all the morbid changes which are common to the soft parts in general, and that the membrane by which they are lined is peculiarly susceptible of inflammation. This inflammation may be general or local; it may be confined to the vein where the injury was first received; it may spread along the lining membrane to the principal venous trunk; and, in some instances, to the membrane lining the cavity of the heart. Sometimes this inflammation ends in the pouring out of coagulating lymph, by which the vein becomes obliterated; becomes a mere knotty cord. This frequently occurs in horses; in fact, the first case of phlebitis I ever saw was in the jugular vein of a horse of my own, which ended in the loss of the vessel on that part of the neck. When this inflammation is not very acute, it differs little from attacks of a similar nature in any other part of the body. "When," says Mr. Cooper, of University College Hospital, "the secretion of pus is in consequence of inflammation of the membranes lining a vein, the pus is either mixed with the circulating blood, or the inflammation having produced adhesion of the sides of the vessel, at certain intervals boundaries are formed to the collections of the pus, which in this manner form a chain of abscesses in the course of the vessel."

The appearances, then, will vary in our examinations after death, depending

as they do upon the length of time the disease has existed. 1st, It may destroy life in five or six days, before pus has formed, although in many cases it is thrown out much sooner. The inner covering then is red and vascular. 2dly, We may have the vein full of coagulated lymph. 3dly, Pus may have been formed in considerable quantities. Now all these effects may be local or general; may be confined to the particular vein injured, or extend along the venous trunks. 4th, We find dépôts of matter in the lungs, liver, joints, in parts far distant from the original seat of injury.

3d. How such secondary dépôts are formed?

We have endeavoured to divide inflammation of the veins into two stages; to prove that the formation of adherent coagulum is the first, and of pus the second period of this disease. The investigations of surgeons also prove to us that the conversion of the first into the second stage of the malady, is frequently produced by irritating parts in a state of active inflammation, by endeavouring at short intervals to extract dead bone, balls, or other foreign bodies; by cramming up an inflamed wound, as in the operation for fistula *in ano*, after the fashion of a portion of the French school; the frequent examination of wounds; the breaking down of newly formed adhesions, by the introduction of a probe or finger. I have twice seen fatal results brought on by this meddlesome surgery, by a system worthy the strongest censure. In his Surgical Dictionary, Mr. Cooper has at great length examined the subject we are endeavouring to discuss; and he reminds us of the important fact that the first effect of every phlebitis is the coagulation of the blood, which becomes adherent to the inner coat of the vessel; such coagulations take place both in spontaneous and traumatic inflammation of the veins. In consequence of the interruption to the current of the blood in the inflamed vein, it becomes stagnant, and effusion of serum takes place in the surrounding parts, unless the other veins are capable of carrying on the circulation. With respect to the local changes attending the suppuration of the veins, the first is the deposition of pus, and M. Cruveilhier observes that this takes place "not between the vein and the clot, but in the very centre of the latter. At first it has the appearance of wine lees, and then

it becomes white and opaque. This presence of pus in the centre of clots of blood has led to the idea that these clots are directly organized, and capable both of inflammation and suppuration, in the same manner as it is admitted that the pus or serum, which in pleuritic effusion is circumscribed on every side by a recently formed false membrane, is the product of an exhalation from this membrane itself." But it seems, contends Mr. Cooper, more rational to suppose that the coagulum in phlebitis, and the false membrane in pleurisies, serve, in some measure, as filters, through which the products pass, which are secreted by the internal membrane of the vein, or by the pleura. The presence of pus, then, in the centre of a coagulum, would appear, according to my view, to be a phenomenon of the capillary system.

[To be continued.]

ACCOUNT OF A CASE OF SPONTANEOUS RUPTURE OF THE HEART INTO THE PERI- CARDIAL SAC,

UNDER WHICH LIFE CONTINUED FOR
ABOUT TEN HOURS.

BY WILLIAM STROUD, M.D.

FREDERICK P—, aged 29 years, was formerly a domestic servant, but, having married about six years before his death, and become the father of two children, he left service, and opened shop as a green-grocer. He was a man of irritable temper, and rather acute mind; and, having encountered considerable loss and disappointment in his business, had for a good while been struggling against anxiety and vexation. He had, also, for many years been subject to periodical bleedings from the nose, to the extent of a quart or more at a time, repeated at short intervals. This evacuation, which is common to other members of his family, generally occurred in the month of March, or April, and afforded him great relief; but during the present year did not take place. Owing, as may be supposed, to the want of it, he had been for the last six weeks complaining of a sense of fulness in the head, with lassitude and somnolency, which induced him frequently to lie down in the day time.

On Saturday, April 27, 1839, between

five and six o'clock in the morning, he went out, apparently in good health, to make purchases in Covent Garden Market; but, soon after his return, about half-past eight, was suddenly seized with faintness, vomiting, numbness of the extremities, and temporary insensibility. His countenance became ghastly, his pulse at the wrist imperceptible, and he fell to the ground, as if in a dying state. Under the direction of W. Symes, Esq., of Tavistock Square, who promptly rendered his assistance, he was bled in both arms, and about three pints of blood were drawn with much difficulty, but seemingly with some relief.

Having been laid in bed, he complained of a distressing sense of tightness across the chest, and of weight at the heart, accompanied with sighing, depression, and thirst. He afterwards became very restless, but continued quite sensible, gradually sank, and died without a struggle about half-past six the same evening.

An inspection took place at eleven the next morning, when the following appearances were observed.

General conditions.—The body was that of a stout, very muscular, and well-proportioned young man. Its decumbent surfaces exhibited a deep-coloured cadaveric ecchymosis. The head was not examined. *Thorax.*—The lungs were slightly congested, and rather more mottled than usual with carbonaceous matter of an inky hue; the bronchial glands were sound; the pericardium was distended, and remarkably tense, containing nearly a quart of dark-coloured blood, part of which was imperfectly coagulated; the heart was large, and loaded with fat. Just below the termination of the superior vena cava was a ruptured aperture in the right auricle, large enough to admit the finger, and whence the blood found in the pericardial sac had evidently issued. The walls of this chamber were neither thinner nor softer than usual; and, with the exception of the hole itself, and the superficial layer of fat, the heart and its appendages were free from disease. The left ventricle was rather thicker than common, and its columnæ were large, and very strongly marked. *Abdomen.*—The stomach contained much water, which had been swallowed immediately before death, but, together with the liver, and all the other abdominal organs, was perfectly healthy.

REMARKS.—The rupture of the heart, or one of its great vessels, into the pericardial sac, is usually followed by rapid and almost instantaneous death; and the sudden arrest of the circulation, by the subtraction of a portion of blood necessary to its maintenance, and by the pressure on the heart of the blood thus extravasated, is quite sufficient to account for so terrible a catastrophe. In this, and similar cases, where life has been protracted for some hours, or even days after the fatal rupture, it is reasonable to presume the existence of certain modifying and countervailing circumstances; such as the laceration occurring in the auricles rather than in the ventricles, its being originally small, oblique, or obstructed for a while by coagula, muscular contraction, or the position of adjacent parts; an unusual capacity or dilatability of the pericardium, tending to diminish the compression of the heart; or, the great fullness and vigour of the system, enabling it to sustain the evacuation, &c.

In the case above related several of these circumstances were actually observed. The body was in a plethoric state, increased by the omission of a customary evacuation. This plethora, the result apparently of excessive nutrition, must have operated chiefly on the venous system; and accordingly, the rupture occurred in the right auricle, owing to which the circulation was less rapidly interrupted than if it had taken place in either of the ventricles. The pericardium dilated sufficiently to allow nearly a quart of blood to accumulate in its cavity, but at length became extremely tense, and death was occasioned rather by the forcible compression of the heart, than by the mere evacuation of blood; since the same individual had on several previous occasions lost much more at a time from the nose, not only without injury, but even with manifest relief. The blood discharged into the pericardial sac showed a tendency to separate into its constituent parts, as it would have done out of the body; but, being in contact with living surfaces, of which the vitality was gradually expiring, its coagulation was feeble and imperfect.

The case is further interesting by showing that, in certain constitutions, sanguineous plethora, especially when aided by mental irritation and bodily exercise, may produce rupture of the heart by merely dynamic agency, without the concurrence of structural lesion, or of

any other disease discoverable by the senses. It is scarcely necessary to add that, when such an injury has happened, it is entirely beyond the reach of human aid: and, consequently, that whenever the circumstances which lead to it are observed, the means of prevention should be early and effectively employed.

ACCOUNT OF

A CASE OF ANEURISM,

SUPPOSED TO HAVE OPENED INTO THE PERICARDIUM A CONSIDERABLE TIME BEFORE DEATH,

By THEOPHILUS THOMPSON, M.D.,

Physician to the Northern Dispensary, &c.

On the 21st of July, 1839, I was requested to visit, as a patient of the Northern Dispensary, Richard Tosfield, a blacksmith, of strong muscular frame. I found him lying in bed, with his lips and ears slightly livid, his skin perspiring, and his countenance rather anxious. He complained of pain on the right side of the sternum, increased by full inspiration. The right chest was prominent, especially in the situation of the third, fourth, and fifth ribs, where the sound elicited by percussion was dull, while the natural dullness of the cardiac region to the left of the sternum did not extend so far as usual. The sounds and impulse of the heart were distinctly observable on the right, but imperfectly on the left side of the sternum. The first sound of the heart was accompanied with a rasping noise, rather more abrupt than that commonly produced by valvular disease, and which was most audible at the middle of the prominent part of the right chest, scarcely at all under the right clavicle, and not in any degree near the spine. My friend, Mr. Hensley, of St. James's Street, happening to be with me, also examined the patient, and concurred in opinion that the heart was situated towards the right side. I concluded that the heart was enlarged, and the aorta studded with ossific depositions, but could not satisfy myself whether there was aneurism of that vessel. The pulse corresponded accurately with the contractions of the heart, and, except being a little quickened, presented nothing peculiar. Twelve months previously the patient had been attacked

with pain in the back and side, since which period he had suffered from palpitation, and had occasionally fainted at his work. During the two last months he had been several times visited by Mr. Bird, (the house-surgeon of the Dispensary) who finding irregularity of the pulse most observable in the right wrist, with prominence and pulsation of the right side of the chest, concluded that there was aneurism of the aorta. During the month of June the patient complained of pain in the epigastrium, and of some bronchial symptoms, including a troublesome cough without expectoration. Aperient medicines and digitalis had been administered with so much advantage, that he occasionally walked a mile, but during the last week he became considerably worse. I directed leeches to be applied to the right side of the chest, and digitalis to be continued in small doses; but, at the end of August, Mr. Harwood, of Tonbridge Place, who attended the case during my absence from town, found it necessary to suspend the latter remedy. In the month of September the patient became worse; and, on the 19th, I found him again confined to bed, with great lividity of countenance, and a very weak and rapid pulse. The impulse of the heart was feeble; its sounds were abrupt, but confused and irregular, and he still suffered from cough. The apparent suppression of the heart's impulse, and the weakness of the pulse, now led me to suspect softening. I prescribed a demulcent mixture, with tincture of henbane, and a drop of Scheele's prussic acid, three times a day. Under this treatment his strength, after a few days, improved; his pulse fell to 100, and although not strong was regular, and the expression of his countenance became tranquil and cheerful. The sound produced by percussion was still clearer than natural in the cardiac region on the left side, and perfectly dull over the middle of the right side, but the dullness had considerably extended since the last examination, both to the right and left. He continued better until the 29th of September, when, on getting up to relieve his bowels, he became suddenly worse, stared wildly for a moment, uttered an exclamation, and fell back dead.

The body was examined two days after death, with the assistance of my friend Mr. Hobbs, of Southampton

Row, whose notes, with a view to insure accuracy, I have embodied with my own in the following description of the appearances observed. Mr. Dolton, the present house-surgeon of the Northern Dispensary, also attended the inspection.

The body was muscular and moderately fat; the whole of the left ear and part of the neck were of a remarkably deep leaden hue. The superficial veins were much congested, and when cut bled profusely. On opening the chest a firm substance presented itself in the region of the heart, but occupying twice or thrice the usual space of that organ, and having the appearance of an enlarged and diseased heart with adherent pericardium. On making an incision into this substance, which was tense and unyielding, a dark-coloured coagulum escaped, and at first produced in our minds the impression that one of the cavities of the heart had been opened. It was, however, soon found to be a distinct and spacious sac filled with dark coagulum, and it was not until eight or nine handfuls of this coagulum had been removed that the heart itself was discovered, and sufficiently exposed for examination. It was enlarged, rather flaccid, and pushed backwards and towards the right side. Its surface was thickly studded with wart-like projections of a reddish or mahogany hue, and was connected in some parts by strong bands, in others by soft lymph, to the outer layer of the pericardium, which adhered very firmly to the diaphragm, and was in some places thickened to the extent of four lines. The inner surface of this membrane was rendered scabrous by granulated depositions resembling in colour those on the surface of the heart, but rather paler, and was covered with layers of soft lymph. The pericardial sac contained, at least, a pound and a half of coagulated blood. The aorta near its origin was dilated to more than twice its ordinary size: the inner membrane of this vessel seemed, in some degree, to have lost its natural elasticity, and exhibited a little steatomatous deposit, but no ossification. At the most dilated part of the aorta an opening was discovered, the edges of which were even, as if cut with a knife. This wound was probably made in removing the heart and dilated vessel from the chest; but, at one end of the wound, two or three

inches above the aortic valves, was a somewhat puckered opening, apparently produced by disease. On tracing this aperture, it was found to communicate with a sac, which was at first supposed to be the left auricle, but was soon ascertained to consist of the layer of pericardium investing the vessel. This pouch, which was larger than an orange, was full of dense coagulum, and lined with fibrinous layers. At its outer side, nearly on a level with the aortic valves, was a round smooth aperture, rather more than three-fourths of an inch in diameter, through which the blood appeared to have escaped into the cavity of the pericardium. The arteria innominata and left carotid and subclavian arteries contained some pale coagula; but were of their natural calibre, and free from disease. Both the auricles, but especially the right, were much dilated, as was likewise the right ventricle. The ventricles were soft in structure, and the walls of the left were about an inch thick. The cardiac valves were much attenuated, but not otherwise diseased. There was some effusion into each pleural sac, but especially into the right, and that portion of the left lung which overlapped the pericardium was emphysematous. This latter circumstance probably occasioned, at least in part, the preternaturally clear sound produced by percussion in the left cardiac region.

It seems reasonable to conclude that, in this case, the pericardium had not only been thickened by inflammation at some distant period, but had also been affected with more recent inflammation up to the time of death. The effused blood appears chiefly to have accumulated on the left side of the heart, and to have pushed that organ to the right side, partly in consequence of the connection of vessels, partly owing to adhesions between the heart and pericardium. The indications of great displacement of the heart observed at an early period, and the appearances detected in the post-mortem examination, particularly the roundness and smoothness of the opening into the pericardium, the great distention of that membrane, notwithstanding the increased firmness of its structure, and the evidences which it presented of recent and progressive inflammation, seem favourable to the opinion that the rupture of the aneurism into the cavity of the pericardium had occurred a consi-

derable time before the death of the patient. Pulsation near the prominent part of the chest, and a want of accordance between the pulse of the right and left sides, were observed by Mr. Bird, in June, but were not discoverable at the time of my first visit in July. Hence it may be inferred that the rupture occurred between those periods, although the patient lived till the end of September. To assume that life cannot be prolonged after such an occurrence would be unphilosophical. It is true that in most of the cases on record, especially in those related by Scarpa*, and Morgagni†, the evidence of immediate death is almost conclusive; but Laennec has hinted the possibility of an interval taking place between the rupture and the fatal result, and mentions a case which favours the suggestion. His words are‡:—"Il paraît même que quelquefois la rupture d'un anéurysme dans le péricarde peut n'être pas toujours suivie d'une prompt mort. * * * Je me rappelle avoir vu, il y a quelques années, sur une pièce présentée à la société de la faculté de médecine par M. Marjolin, un anéurysme ouvert dans le péricarde par une ouverture qui paraissait déjà ancienne, et comme fistuleuse."—I have not, however, met with any fuller description of the case cited by Laennec, and am not aware of any instance on record in which the evidence of prolongation of life, after considerable hæmorrhage from rupture into the pericardial sac, is equally strong as in that here reported.

The interest of this case in a diagnostic and practical point of view, and in its reference to some questions of medical jurisprudence, have induced me to propose it to the consideration of my professional brethren, by whom I hope the subject will be still further illustrated.

TREATMENT OF CROUP.

To the Editor of the Medical Gazette.

SIR,

HAVING read two papers on the Treatment of Croup, in your Nos. for July 3d and 17th, I have been induced to

* Treatise on Aneurism, translated by Wishart, p. 81.

† Epist. 26, Nos. 7, 17, 21.

‡ De l'Auscultation Médiate, 1826, vol. 2, p. 714.

send you the following communication on the same subject. Should you deem it worthy of a place in your valuable journal, you will much oblige me by inserting it.—I am, sir,

Your obedient servant,

THOMAS YATE, M.R.C.S.L. L.A.C.

Cranley, Guildford, Surrey,
August 29, 1840.

After attentively studying this disease in its acute form in many instances, as also the post-mortem appearances, I have come to the following conclusions upon the pathology and treatment of the same. The species of croup which Dr. Stokes terms "primary," and to which my paper has reference, is, I believe, pretty well agreed by all to be, an acute inflammation of the mucous membrane of the larynx, trachea, and of the bronchi also; this produces a secretion which almost immediately concretes into a thick firm substance, popularly termed false membrane, and which lines the inner surface of the air passages, to a greater or less extent. There is little reason to doubt that croup is a similar affection to bronchitis; but may not its different effects be accounted for in the following manner? Doubtless there is every reason to believe that the secretion in the first stage of croup is similar to that in the first stage of bronchitis, but the locality of the inflammation in the former produces a most material influence upon it. In croup, a current of dry air is immediately applied to the inflamed surface, and greatly favours the concretion of this already viscid exudation, for after it is perfectly formed, we find a thinner secretion thrown out underneath, favouring its separation and expectoration. This, however, in its turn, quickly concretes from the same cause; and this I consider is the reason why we get so short an interval of relief, even after a copious expectoration, in a very severe case, the spasm which always attends this affection being no way diminished. The above supposition may be easily exemplified by taking several long inspirations with the mouth open; a very unpleasant dryness will soon be experienced over the whole cavity, and particularly about the palate and fauces, but on closing the mouth, and breathing through the nostrils, the moisture soon returns. Now as a patient labouring under croup

breathes almost constantly with the mouth open, the inspiration at the same time being prolonged, we may easily imagine how this circumstance would act upon the upper part of the air-passages themselves, lined by a tenacious secretion. In bronchitis, before the air reaches the seat of the disease, that is to say the smaller bronchi, it becomes warm, and loaded with moisture by its admixture with the air already contained in the lung, but the expectoration of false membrane from the large tubes is by no means uncommon. It may be said, how is it that after death we sometimes find the membrane firmly adhering to the mucous surface beneath? I believe this to be the case only in very severe cases, when the inflammatory action has run so high as to stop the secretion and destroy the organ. I am, therefore, much inclined to favour the opinion, that, in the act of inspiration, the air materially assists the formation of this false membrane. Might not, therefore, the inhalation of warm vapour, if practicable, be likely to produce a good effect? But in many instances, from the extreme restlessness of the patient, and more frequently in consequence of the early age at which the disease makes its appearance, I am well aware we shall be unable to make use of this remedy, although, if proved to be of service, it might in many cases be had recourse to; but merely as an auxiliary, not by any means with the view of putting aside the use of any other remedies hereafter to be mentioned.

We have so many good descriptions of the attack and progress of this disease, that it would be useless in me entering fully upon its well known symptoms. It commonly, however, commences with slight cough, hoarseness, and fever, making their appearance in the evening, and almost entirely disappearing the following day. This state of things may continue for three or four days, attracting little notice, when suddenly the mother is alarmed, a few hours after her child has been in bed, to find it wakes up with all these symptoms greatly aggravated. There is a peculiar shrillness of the voice, as though the larynx and trachea consisted of a metallic tube; at the same time there is a sense of pain and tightness about the organ (although deglutition is not impaired, unless the pharynx be impli-

eated), a whizzing inspiration, as though the air-passages were dry and diminished in calibre, and a short dry croupy cough. In very young children the inflammation seems most frequently to commence in the larynx, and gradually to spread down the trachea to the bronchi. In some cases, however, it appears to attack the bronchi and trachea in the first instance, and subsequently the larynx, seldom extending beyond the glottis; but in children from eight to twelve years of age, the attack is often made upon the pharynx, tonsils, and uvula, producing a quinsy, and even suppuration of the tonsil, as in a case lately under my care of decidedly acute primary croup, no typhoid symptom being present. In these cases the croupy symptoms come on more insidiously, but the pharyngeal inflammation abating, we almost immediately get increased severity of the laryngeal affection, requiring prompt and active treatment.

Our first indication is to combat the inflammation, and put a stop to the morbid secretion; therefore blood should be drawn from the arm or jugular vein, according to circumstances: this should be followed up by the application of leeches on each side of the throat or upper part of the sternum, regulating the number according to the age and strength of the patient. I now have recourse to other antiphlogistic means, for after the free use of the lancet, and one efficient application of leeches, it will seldom be found necessary, if taken in good time, to repeat the remedy, for a state of debility quickly comes on, particularly if there is great obstruction to the breathing, which proves as dangerous as the disease itself, although in many instances I know repeated leeching must be had recourse to. An antimony and ipecacuanha emetic should be immediately administered; and as soon as its operation has ceased, I give a purge of calomel and jalap. I then place the greatest reliance upon the hydrarg. chlorid. continued in the dose of gr. ij. every one, two, or three hours, according to the severity of the symptoms, occasionally using the emetic to assist in throwing off the false membrane. One of our first remedies should be the warm-bath, immersing the patient in the water as far as the middle of the body, not up to the neck; indeed, put-

ting the feet and legs into hot water, will almost always be found of great advantage. A blister should also be applied over the sternum, but not till the inflammatory symptoms and febrile action have been diminished, and the pulse become softer. We must always use the precaution, however, not to apply it over the seat of the disease, but at some distance from the throat; to place a piece of silver paper or thin muslin between it and the skin, and not to let it remain on more than three or four hours, or the chances are ten to one we get a troublesome slough, which will either prove the cause of death or greatly retard convalescence. If these means should not prove successful, and the disease run on to the second stage, there is little hope of recovery, for the powers of the constitution quickly fail, owing to the circulation of venous blood—the functions of the lungs being almost entirely impeded. Here our only remedy is the antim. potassio tart. emetic, to endeavour to get rid of the adventitious membrane, together with stimulants and antispasmodics; for the immediate cause of death is no doubt spasm, and not altogether the mechanical obstruction offered by the false membrane, although it assists, and, as I believe, is partly the cause of the spasm, this being a natural effort for its expulsion, which effort sometimes, but very rarely, proves successful.

Many very able men, after bleeding, place the greatest reliance on calomel alone, giving five or six grains every two or three hours to very young children; others, amongst whom we find Dr. Stokes, of Dublin, prefer tartar emetic alone, but I have my reasons for not placing confidence in either treatment alone, but in both combined. I have seen a child die, who had been extensively leeched, and taken five-grain doses of calomel every two hours; but I have frequently seen two grains of calomel every hour, continued for eight or ten hours, completely cut short a confirmed croup, where only three or four leeches had been previously applied, and an antimony emetic occasionally administered. The practitioner who attempts to cure croup with calomel alone, will often lose his patient from suffocation, before the remedy can take effect, and he who trusts in emetics alone must employ

bleeding to a very dangerous extent, or exhaust his patient's strength by repeated vomitings, which often will end in suffocation at last; for although ant. tart. is a most powerful antiphlogistic, it does not seem to check the secretion, though it greatly promotes its separation and expectoration. Moreover, I generally combine ipecacuanha with it, for after taking antimony two or three times, I have known grain-doses produce no emetic effect upon a child, the "tolerance" being established. The best way to administer the calomel is to rub up two grains with an equal quantity of white sugar, and place it upon the child's tongue, in a dry state, giving it a spoonful of some fluid afterwards.

I am pleased to find Professor Hannay decrying sulphate of copper as a remedy in croup. The case he relates is, in my opinion, as clear a one of poisoning by cupri sulph. as any one can imagine. I hope he will fulfil his promise, and publish the post mortem appearances. This medicine must be worse than useless, its action being tonic, stimulant, and astringent. I should as soon think of giving it, even as an emetic, in croup, as of giving ant. tart. after poisoning by arsenic or corrosive sublimate; therefore I cannot but disagree with Mr. Robbs when he thinks it does not matter whether the emetic be composed of ipecacuanha, antimony, sulphate of copper, or zinc. His plan of giving nauseating doses of ant. tart. has long been recommended by a very high authority, viz. Mr. Porter, of Dublin; but I much prefer full vomiting, as advised by Dr. Stokes and Dr. Cheyne, who has undoubtedly given the profession the best article on this subject, in the *Cyclopædia of Practical Medicine*. I may mention here, that his plan of administering an emetic, and then abstracting blood, is, according to my experience, a most valuable practical fact, rendering it unnecessary to extract large quantities. I must say I never saw occasion to apply twelve leeches to a child only three years of age. Who could be surprised at the result of Dr. Zimmerman's case, where thirty-six leeches were applied within two days? I feel assured it is altogether unnecessary to apply twelve leeches at one time in any case of croup; for where a child exceeds four years, we may readily have recourse to the lancet

with the greatest advantage; and I most certainly would not put more than six or eight leeches on any child under that age. I cannot help disagreeing with Mr. Robbs, also, when he speaks against blisters and the warm-bath, for both are excellent remedies when judiciously used; but 108° is by far too hot a bath to put a child in; 98° is "the warm-bath" for an adult; and I believe it is customary, when we wish to use a bath at a higher degree of temperature, to place the patient first into the water at 96° or 98° , and gradually raise it. 108° would almost scald a child to death. I think 88° , gradually raised to 92° or 94° , will be found in every way sufficient to answer the purpose. The disease which Mr. Robbs terms "spurious croup," evidently depends upon irritation of the brain, as described by Dr. Cheyne.

Almost every writer on this disease differs in opinion; indeed, so little do the plans of treatment agree, that a young practitioner is considerably puzzled which to adopt. It is, however, very satisfactory to know that the judicious use of calomel and tartar emetic, employed at the commencement, will, after bleeding, prove almost universally successful; and indeed, although the first stage may be far advanced, the recoveries will far exceed the number of deaths.

OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

THERE are still two important questions before the profession as to the mode of dividing the internal rectus muscle for strabismus — namely, is the knife or the scissors the best instrument to divide the muscle? and is it advisable to employ a straight or a slightly curved grooved director to raise the muscle from the globe for the purpose of facilitating the division of the muscle?

The objections to the use of the straight or slightly curved director are the same under all circumstances, namely, the pain given to the patient during the act of passing the director beneath the muscle, which is always in proportion to the smallness and the depth of the eye, with respect to the brow and cheek, and

the difficulty caused to the surgeon by the patient's resistance from the continued pain during the division of the muscle, or search after uncut fibres. Therefore it needs only to speak of the scissors and knife, as employed without a director.

To the use merely of the scissors the objections which present themselves are, the bruised wound, the irregular division of the muscle, and the difficulty which often arises of obtaining a sight of the fibres of the muscle after the first incision, for the inner canthus is generally filled with blood, and unless time be taken to sponge the part, and stop the bleeding, the remaining steps of the operation must be involved in obscurity, and uncut fibres sought for and divided in the dark.

To the use of a knife without a director or hook, the objections are so obvious, that I believe few surgeons have tried the experiment; though, I regret to say, I have seen a surgeon of very great experience attempt this, and the consequences were, as might have been expected, a wound into the sclerotic, and the escape of the vitreous humour. Should the muscle have been secured by means of a hook, and a knife be desired to divide it, two questions suggest themselves, namely, should the muscle be divided from within to without, or from without to within? and what kind of knife is best adapted for the purpose?

The blunt-pointed bistoury has been employed to divide the muscle from within to without, between its insertion and the hook; but the objections to the use of the bistoury are, the difficulty of getting it under the muscle, particularly where the eye is small and sunken; the pain it occasions to the patient during the time it is being pressed forward through the muscle, after the manner of a sharp wedge, there being seldom room to permit of any sawing motion with the edge of the bistoury; therefore it must, more or less, while being pressed forward through the muscle, raise the edge from its socket; and, lastly, the danger there is of the patient making an accidental resistance while a sharp cutting instrument is fixed between the muscle and the globe.

The common scalpel has likewise been employed to divide the muscle between its insertion and the hook, cutting in a direction from without inwards. The

only objections to which are, the difficulty the surgeon experiences in applying the cutting edge of the instrument in a direction favourable to a quick and clean division of the muscle, and the danger, at the same time, of its being thrust into the eye during any sudden resistance of the patient.

To lessen these difficulties and dangers, I beg to suggest to the profession the use of a knife which has afforded me the utmost facility in effecting a speedy and clean division of the muscle close to its insertion.

It possesses all the properties of a scalpel, namely, utility, effectiveness, and safety, in a smaller space than any other instrument with which I am acquainted that has been adopted for dividing the internal rectus muscle: the blade consists of two parts, a rounded portion, resembling the blunt part of a hernia knife, and a small flat sharp extremity, having a transverse cutting edge, which at one end terminates in a shoulder by uniting with a short sharp front edge, while its other extremity forms a point by meeting the back edge at right angles, so that we have the transverse effective part of the blade in immediate connection with the useful shoulder and point. The annexed engraving is a correct representation of the knife as made by Mr. Weiss. The instrument described cannot be thrust into the eye by any sudden accidental resistance of the patient; and this safety is owing to the position of its straight cutting edge, which does not require any sharp part of the knife to be directed towards the globe of the eye during any moment of the operation: the muscle being slightly raised across the blunt hook, its fibres are divided transversely by the knife, its edges being directed towards the hook, but at right angles to it, so that the flat side of the blade is held towards the eye.—I am, sir,

Your obedient servant,
JAMES J. ADAMS.

27, New Broad Street, City.
August 17th, 1840.

A RARE DISLOCATION.

To the Editor of the Medical Gazette.

SIR,

IF a report of the following rare accident is not too lengthy for your journal, you would much oblige me by publishing it.

I am, sir,

Your humble servant,

N. J. HAYDON, M.R. C.S.

Bodmin, August 25, 1840

Dislocation of both radio-carpal articulations. The left carpus backward, the ulna being also dislocated from the right radius: the right carpus forwards, ulna not dislocated from radius, unattended with fracture.

John Davey, aged 13 years, applied to Mr. R. Rudall, of Sheepwash, on June 11th, 1840. He had been thrown very violently from a horse, and fell on the upper part of the palms of both hands, and on his forehead. On examining him we found a lacerated wound of the scalp, about two inches in length, inclining from the mesial line to the left eyebrow: the left wrist presented a considerable protuberance on its anterior aspect; the styloid process of the radius no longer had its position opposite to the trapezium, but was thrown before the carpus, and took up its residence on the scaphoid and trapezium: the ulna was dislocated from the radius, and rested on the unciform bone; the forearm was slightly bent on the humerus; the fingers similarly flexed on the hand throughout their articulations. During the reduction of this wrist the patient complained of no pain.

The right wrist presented a very considerable tumor on its posterior aspect, occasioned by the presence of the carpal head of the radius and ulna, and a very irregular knotty tumor terminating abruptly on its anterior aspect, caused by the presence of the bones of the carpus. The forearm was very considerably flexed on the humerus, and in a state between pronation and supination; the thumb strongly abducted; the metacarpal phalangeal articulations in a state of the greatest extension on the metacarpus; the two extreme joints slightly flexed. There was a strong aversion to have the arm moved, the slightest motion causing extreme agony: there existed in this arm no dislocation of the

ulna from the radius. A very careful examination was made to determine what parts came in contact with the resisting force. We found very extensive bruises on the palms of both hands, but not the slightest on the back of either hand. We could not obtain the slightest evidence of any fracture existing; and recollecting the opinion of Dupuytren, "That there was not a single unequivocal instance on record of a dislocation of the radio-carpal articulation;" and, "that he invariably found these pretended accidents always turned out to be fractures of the radius near the articulation," we were very careful in our examinations. Moreover, we were strengthened in our opinion that these were cases of dislocation unattended with any fracture, because the dislocations appeared so perfect, the two tumors in each member so distinct, the reduction so complete, the strength of the parts so great after reduction, the very trifling pain after reduction. Within an hour after the dislocation was reduced the patient could rotate the hand, and supine it when prone. This could not, we believe, have been done had there existed a fracture; and lastly, in the right arm the radius retained its exact parallel relation to the ulna, extending a little beyond it. On the left the ulna was carried a little inwards and forwards, and so remained after the radio-carpal dislocation was reduced. We should not have reported this case had it not seemed important, and one of very rare occurrence; for we find in one person from the same accident, *and from a force applied in the same manner*, one presenting a dislocation of the carpus backward, the other presenting the carpus dislocated forward.

Sir Astley Cooper, whose long experience gives to all his opinions great weight and value, states at page 502 of his work on Dislocations and Fractures, that "the dislocation of both bones is not of very frequent occurrence; but when it does happen the bones are thrown either backwards or forwards, according to the direction in which the force is applied." "In the dislocation of the radius and ulna *backwards*, the person falls upon the *back* of the hand, the radius and ulna are thrown upon the posterior part of the carpus, and the carpus itself is forced under the flexor tendons."

Dupuytren made some curious calculations as to what force would be necessary to effect a dislocation of the radio-carpal articulation, and states his most entire disbelief in the possibility of the accident. Baron Boyer, p. 256, vol. iv. of his "*Maladies Chirurgicales*," states, "Notwithstanding the violence of the efforts, capable of overcoming the resistance of the tendons and ligaments, so as to produce a luxation of the hand, this luxation can take place in four different ways; to wit, backwards, forwards, inwards, outwards. The luxations backwards and forwards are by far more frequent than those inwards or outwards."

The rarity of an accident of this nature induced me to forward a copy of this case to Sir A. Cooper, who suggests—"Is it not possible this patient might have fallen on the back of one hand and the palm of the other?" To this I can only answer, that the extensive bruises and laceration on the palms of either hand, more especially on the ball of the right thumb, while there is not the slightest bruise or laceration on the back of either hand, seem to afford fair evidence where the resisting force was applied. Respecting the opinion of Dupuytren, Sir A. Cooper says, "That Dupuytren was undoubtedly wrong, although the dislocation is rare."

The treatment of our patient was very simple. The left wrist was speedily reduced. The elbow being fixed, extension was made from the hand, at the same time gradually flexing the hand on the forearm. The right wrist, the elbow being fixed, was reduced by firmly grasping the thumb, the operator's thumb being applied over the outer part of its metacarpal bone, while his index-finger firmly embraced its ball; gradual and direct extension was maintained for several minutes; when the carpus resumed its position, a very distinct and audible "*click*" was noticed by several persons present. Splints including the forearm and hand, with roller bandages, were applied, and retained for eighteen days, the parts being kept cool with evaporating lotions. The progress of the patient was altogether favourable.

June 24th. — Attentively examined both wrists this morning: the patient remains free from pain, there is no deformity: considerable swelling and stiffness still continue, the usual effects

of extensive laceration and spraining of the ligaments. Splints and bandage again applied, and retained until June 28th, when they were discontinued, as the swelling had nearly subsided, and the wrists had regained sufficiently their power to admit of all the usual movements of the hand being freely exercised; a bandage was, however, still retained on the right wrist.

July 16.—We saw the boy this day at his usual work on the farm; complained of no pain, but considerable weakness. There remain a stiffness and some enlargement around the joints, but this appears to be gradually subsiding. The bandage was left off to-day, and the patient told to have his wrists pumped upon several times daily.

SOME REMARKS

ON THE

CONNEXION OF TUBERCLE

WITH A DEFICIENCY OF THE COLOURING MATTER OF THE BLOOD, AND ON THE EXHIBITION OF IRON.

By J. B. HARRISON, M.R. C.S.L., &c.

[For the *London Medical Gazette*.]

DISEASE may be regarded as a concatenation of morbid states connected as cause and effect, and pursuing a fixed course. One condition is the result of the preceding, and, in its turn, is essential to the sequent derangements. Now it has always appeared to me that in those diseases which are considered beyond the reach of medical skill, we should do well to investigate attentively and patiently the first symptoms of disorder, and endeavour to trace, with precision, the earliest deviations from health. The primary condition of disease may be one which we are capable of rectifying, and, therefore, it ought to be most accurately investigated. Rigid inquiries into the slight aberrations from health, which, in a strictly philosophical sense, lay the foundation of hopeless maladies, are, it is to be lamented, too much neglected; and when a succession of morbid conditions has carried on the train, and built up the ultimate disease, it is then too late to remedy the evil.

We have been led to make these remarks more especially with reference to the origin of tubercle, as it seems to us that much advantage might be de-

rived from an investigation into the state of the system which precedes the development of consumption, and further, that this condition is capable of being rectified.

It appears probable that one of the first steps towards the production of tubercle is that of a disordered state of the blood; an essential condition of which is a deficiency of the red particles. The word *anæmia* is sometimes used to signify that state of the blood in which the colouring matter is not in proper proportion, though, strictly speaking, it is applicable only to a want of the blood itself. But the abstraction of blood has, no doubt, an influence on the quality of the blood, and the two states are so commonly found united, and are so similar in their nature and symptoms, that it is not always possible to arrive at a rigid discrimination. Perhaps the female sex furnishes us with some of the most marked examples of this condition of the blood. It will readily occur to the mind that women are more especially liable to the occasions of the disorder,—how often the female system is drained by profuse hæmorrhage and repeated discharges, by protracted lactation, miscarriage, or disordered menstrual secretion. Hence the morbid delicacy with which we so frequently meet in the female sex—the pale lips, the extraordinary whiteness of the hands, the blanched conjunctiva, the dyspnœa and palpitations; in short the exsanguineous and corpse-like nature of the skin.

But this state of the system is also derived from other causes, as from that hereditary constitutional peculiarity which is incompatible with the generation of healthy blood. Sometimes it is dependent on the continued use of depraved and deficient food; in other instances, it is produced by debauchery and excess, or by the luxurious habits and modes of life in which the higher classes indulge. These causes operate, no doubt, injuriously on the blood, and whilst they impair its quantity, seem especially to destroy that constitution which is co-existent with a healthy proportion of the colouring matter. We will not presume to say that all instances of tubercular disease are found to originate from this anæmical state of the blood, for when the pathology of consumption is better understood it will doubtless appear that two or more causes, of very different natures, may produce a similar

effect; but it certainly seems borne out by observation that in very many instances tubercle arises from a morbid condition of the blood, and especially from a deficiency of its colouring matter. It is unquestionable that the red particles of the blood exercise an important office in the constitution of the vital fluid. One object may, perhaps, be to give this fluid a character by which it may be easily distinguished; by which its escape may, under all circumstances, be noted, and no dangerous hæmorrhage be permitted to go on. In the colour of the blood we seem to have a striking evidence of that providential care which is ever displayed in the works of Almighty wisdom, and perhaps none of those which are commonly adduced will appear more satisfactory to the medical philosopher.

But this, though one, and a very essential object, of the red particles of the blood, is not its only purpose. In the economy of nature we perpetually find the same property rendered available for a variety of ends, to which it seems equally well adapted, and on the fulfilment of which the preservation of the body is equally dependent. The red matter of the blood is possibly one of those essential agents in the balance of vital affinities to which the attention of writers has of late been so profitably given.

There are strong reasons for supposing that the presence, absence, or wrong distribution, of minute portions of matter, may exercise a very important influence on the arrangement of the animal organization, and by a kind of disposing affinity render the incongruous atoms capable of composition, and if we be allowed the expression, fill up the interstitial vacancies in the chemistry of life.

Nor can this be regarded as too amazing for belief, if we allow that the operations of life bear any analogy to the wonders of voltaic action, or the equally surprising metamorphoses of inorganic chemistry. We know how slight a cause is able to effect a total change in the physical composition of bodies, converting soft textures into hard ones, or crumbling the hardest into dust; and it seems by no means impossible, from the researches of modern investigators, that this subject will, before long, receive considerable elucidation. We find the following passages on the subject, in some of those recent publications for

which we are indebted to the munificence of the Duke of Bridgewater:—"The sap," says Dr. Roget, "holds in solution, besides carbonaceous matter, some saline compounds, and a few earthy and metallic bases; bodies which, in however a minute a quantity they may be present, have unquestionably a powerful influence in determining certain changes among the elements of organic products, and in imparting to them peculiar properties; for it is now a well-ascertained fact, that a scarcely sensible portion of any one ingredient is capable of producing important differences in the properties of the whole compound. An example occurs in the case of gold, the ductility of which is destroyed by the presence of a quantity of either antimony or lead so minute as barely to amount to the two-thousandth part of the mass; and even the fumes of antimony, when in the neighbourhood of melted gold, have the power of destroying its ductility. In the experiments made by Sir John Herschel, on some remarkable motions excited on fluid conductors by the transmission of electric currents, it was found that minute portions of calcareous matter, in some instances less than the millionth part of the whole compound, are sufficient to communicate sensible mechanical motions, and definite properties, to the bodies with which they are mixed.*"

Dr. Prout, in his valuable treatise on Chemistry and Digestion, has also entered into this subject: "Besides," says he, "the essential molecules constituting the ground-work of a living organized being, and which probably exert on each other, to a certain extent, the ordinary chemical influences of matter, it would seem that there are, at the same time, diffused throughout the whole living mass, in exceedingly minute proportions, various other matters, the molecules of which appear to be in a high state of self-repulsion. By these incidental matters it would further seem that the ordinary chemical properties of the essential elements are hindered from assuming a regular crystallized form. Moreover, these incidental matters entering into the composition of a living body, apparently furnish the organic agent new powers utterly beyond our comprehension; which powers the organic agent has been

endowed with the ability to control in any manner that, from the exigencies of the living organized being, may become requisite*."

The controlling molecules, to which Dr. Prout refers, are those which are commonly regarded as extraneous bodies—as sulphur, phosphorus, iron, sodium, calcium, magnesium, and the like, which we know are to be found in the composition of organic bodies. To the existence of these particles he also ascribes the difference of texture, &c. found in bodies of the same chemical constitution. "We may now observe," says he, "that they (the foreign bodies) seem to us to contribute towards the production of those striking differences observed among bodies having the same essential composition, and which diversity, at first sight, appears so mysterious. How these minute quantities operate we do not precisely understand; but we can imagine them to be interposed among the constituent molecules; further, that the molecules of these incidental matters are in a state of strong self-repulsion. Such being the case, it is not unreasonable to expect that they may have the power of modifying the arrangement of the constituent molecules, and thus of altering the sensible properties of the substance produced by their combination.

"We have stated our opinion that the molecules of incidental matter in organic substances are in a state of self-repulsion. This opinion is founded principally on the equal diffusion of those incidental molecules throughout the organic substances in which they exist, and on their consequent great distance from each other, which perhaps can hardly be otherwise explained†."

These observations would render it probable that the iron, and other organic matter in the blood, may be designed to influence the affinities of the blood, and prevent the operation of attractions, which would otherwise come into play, and destroy its homogeneous character‡. Now it seems, from the re-

* Page 28.

† Prout, *op. cit.* *ibid.*

‡ Mr. Couerbe has stated, (see *Ann. des Sciences Naturelles*, 1834, t. ii. p. 249.) that on the due proportion of phosphorus in the brain depends its variety and fitness for the maintenance of the mental functions; but, as Dr. Alison remarks, from whose work this quotation is extracted, this observation has not yet been confirmed by others. —See the Supplement to the *Outlines*, p. 46, third edition.

searches of modern pathologists, and especially from the inquiries of Dr. Carswell, (see the art. Tubercle, in the Cyclop. of Pract. Med.) that it is highly probable that tubercles originate from the existence of a state of blood which favours the cohesion and separation of certain of its constituent parts. The albuminous portion of the blood seems especially apt (possibly from a want of the repulsive molecules of inorganic matter) to exude and cohere into minute spherical masses, which are destitute of the power of acquiring an organised structure themselves, but grow by attracting to themselves fresh matter from the vessels*.

But it may, with reason, be objected, that though a deficiency of the red particles of blood, and perhaps indeed of iron in the blood, may be allowed as a principal cause of the changes in the constitution of the blood which originate tubercular disease, it does not by any means follow that we are able to introduce that metal into its proper place in the system. It must always be remembered, as it is justly observed by Dr. Prout, that "we have not in artificial chemistry" (and the same applies to medicine) "any control over individual molecules, but are obliged to direct our operations in a mass formed of a large collection of molecules. The organic agent, on the contrary, having an apparatus of extreme minuteness, is enabled to operate on each individual molecule separately, and thus, according to the object designed, to exclude some molecules, and bring others into contact†."

It is well known that in the cure of rickets we have a want of osseous matter in the system, or, at all events, an improper distribution of it; but it does not seem that we are capable, by the exhibition of the salts of lime, of remedying the defect. Fortunately, however, in the case of iron, though we could not, *a priori*, have arrived at the conclusion, we seem able to produce a really beneficial effect by its administration‡.

To many readers these remarks on

the influence of minute quantities of inorganic matter, in controlling the whole constitution of organised beings, may seem to border on the absurdities of homœopathy; but it would be unphilosophical to shut ourselves from the light of modern investigation, from the fear of ridicule, or because some men have carried their views to a ridiculous extent. Without recurring to chemical experiments to prove the agency of minute portions of matter, in altering the affinities and polarities of large masses, we have abundant evidence of it in the science of medicine itself. The influence of small doses of medicine, and of certain poisons, on the nervous system, could not surely admit of any explanation which did not recognize an equally wonderful power over organized beings; but the effects of vaccination are still more convincing proofs of the surprising changes which are produced by apparently inadequate causes. If we only consider that the vaccine lymph protects the body for a series of years without producing any continued palpable change, and without setting up any chronic disturbance in the system, during its preservative period, we cannot fail of being astonished at so wonderful a result. It seems, indeed, to be almost a supernatural agency; it defies all reasoning, and appears to be the triumph of experience.

However, the observations which are here offered as to the possible influence

found not to contain its proper quantity of the red particles of the blood.

The disposition to consumption produced by anæmia also engaged attention.

In this place it may not be uninteresting to insert the following quotation:—"In a letter addressed to the Royal Academy of Medicine, M. Coster announces that, from certain experiments which he has made, he hopes to prove—

"First, that it is possible, even in the face of predisposing causes, to prevent the development of the tubercular diathesis.

"Second, that even where the formation of tubercles has commenced, their progress may, in a great number of cases, be arrested.

"The following are a few of the experiments upon which M. Coster has built up his hopes:—

"Two years ago he placed a number of dogs, rabbits, &c. in the circumstances most favourable to the development of the scrofulous diathesis. Thus many of the unfortunate animals were shut up in dungeons, without light, incapable of moving, exposed to a moist cold by means of wet sponges which were hung up in the cages. Some of the animals placed in these conditions were fed on their ordinary diet; others were fed with ferruginous bread, containing half an ounce of carbonate of iron to the pound. All the former became ill, the greater part tuberculous, but not one of those fed on the bread containing iron presented a trace of tubercles."—*Lancet*, Feb. 15, 1840, p. 772.

* Vid. op. cit. p. 480.

† Prout, op. cit.

‡ Dr. Thompson is reported to have said, in a meeting of the Westminster Medical Society, Feb. 8, 1840, that in Vienna several horses had been fed upon food containing different quantities of iron, and that in the direct ratio of the quantity eaten, that is, of the iron contained in the blood, was the amount of the red colouring particles. On the same occasion Mr. Verrell stated, that the blood of poor people, when examined, was

of iron, and other inorganic matters on the blood, in preventing tuberculous concretions and other heterologous formations, must only be regarded, in the present state of knowledge, as conjectural; and if they should offer any rational grounds for the treatment of those states of constitution which precede the most fatal of diseases, they will answer every object intended.

If considerations like these should only lead any to give trial to a rational system of experiments, as to the mode of treating those diseases which are too commonly abandoned as incurable, it would do more to rescue the profession from impostors than all the invectives which can be heaped upon them. We do not mean to say there is any ray of hope for the advanced stages of these complaints, but probably more may be done than has hitherto been effected in the detection and treatment of those constitutional peculiarities in which they originate.

Whilst the attention of the profession has, perhaps, been too exclusively occupied on pathological appearances, and little hope has been held out for the relief of some of the most frequent and distressing complaints, we cannot be surprised at the encouragement which the irregular practitioners have received, even from the higher ranks of society, and those who undoubtedly possess considerable mental attainments. We have only to bear in remembrance the natural tendency of the human mind, when all other hope is destroyed, to cling with credulity to the most improbable or distant prospects of advantage.

In regard to the form in which iron should be exhibited, we have nothing particular to remark. We may observe, however, that the efficacy of the medicine does not seem necessarily to increase in the ratio of the quantity given. The portion of iron taken into the system may depend on a kind of elective operation, such as appears to regulate the reception of inorganic matter into the vegetable world. At all events, the large doses of the sesquioxide of iron which have been used, without a corresponding benefit, should not be allowed altogether to bring the medicine into disrepute.

The tincture of the sesquichloride of iron is, perhaps, one of the most elegant and efficient of ferruginous preparations;

and the divisibility of this compound may be one cause of its efficacy. On the same account the precipitated carbonate of iron, as recommended by Mr. Carmichael, is, no doubt, a very advantageous form for its administration*.

There can be no doubt that great benefit would arise from more attention being paid to the divisibility of medicines; and on this subject we are glad to avail ourselves of a quotation from the pen of one of the most practical and useful physicians which this or any other country has ever produced. "The mineral springs," says Dr. Armstrong, "which contain iron, have only a very small portion of that metal suspended in them, and yet they are far more efficacious than the ferruginous preparations which we prescribe; and here we are again led to conclude that our ordinary mode of administering this metal should be abandoned, and one instituted similar to that which nature has afforded to our observation. There is a divisibility in the preparations of nature which is unpractised in the usual combinations of art; and it would probably be well for mankind if this divisibility were much more frequently imitated in medical prescriptions†."

REMARKS
ON
CONTINENTAL EDUCATION.
FLORENTINE SCHOOL—BUFALINI.

[For the Medical Gazette.]

MY DEAR —: As I have already said, the German manner of clinical education is in use in the Tuscan schools; but even in Florence the whole system of their transmontine allies is not fully developed in regard to it. The real distinction on this point, betwixt the Universities of Austria and Tuscany, is the total neglect on the part of the latter of those specialities in the study of medicine which form so fine a feature of a continental education in this branch of science; we may, therefore, say, without hesitation, or fear of outraging truth, that the once free and genial Italian has basely copied from his conqueror all the ills of a forced education, and refused through indifference the excellencies it

* See the *Dub. Med. Press*, p. 153, March 4, 1840.

† See the observations on chronic diseases and sulphureous waters, affixed to his vol. on *Scarlet Fever*, p. 460, 2d edit.

offers, which national genius had attached to it at an earlier period. Special pursuit in the cultivation of our art is no mere dream of the imaginative mind, nor yet the short conceit of empiricism; for we find our reasonable countrymen accept it as a practical good in the daily routine of the physician, whilst the philosophic German acknowledges its value as a truth, in adopting it *a priori* in his schedule of courses of study. We must not heed so much the new tendency springing up amongst some of our colleagues in France in favour of an opposite doctrine, since these are, for the most part, men of opinion, and strive at a false unity in things, and too great simplicity of system. It is an easy task to act the roll of physician here; it is only necessary to make a fair diagnosis—to maintain the trifling value of remedies, and effect a belief of danger attached to those more potent—to praise the curative powers of unaided nature, and in fatal cases to admire how many morbid processes have conspired to steal away the life of the patient. The zealot is a thousandfold better than the sceptic in all matters; so also in medicine.

The Florentine medical and surgical clinique present respectively about thirty beds: eighteen in the females' wards, and twelve in that of the men. This is about the utmost number of patients one can attend to, according to the manner of the Germans. The cases are in general well chosen, for the Florentine teachers are strongly doctrinary, but not eclectic like the Germans; and hence we find them much more zealous physicians. To defend dogmas, and maintain personal opinions, arouses men to work with promptitude and energy. Bufalini, the clinical professor in the medical department, is an ingenious physician, and author of the theory of localisation; a set of views on pathology, founded much on truth; but, like all other theorists, he has carried his generalisations beyond their scope. His therapeutic agents are of course greatly modified by opinion, and we find in him neither the striking boldness of Tommasini, and the followers of Rasori; nor the timid trifling of the German school; nor the scepticism of the French. He seems a sort of middle man, who yet leans more to the confidence of the new Italian. I was sorry, however, to find him treat his patients on grounds merely logical; and the unavailing nature of

his mode of cure sometimes made me wish it were a holy mandate that physicians must adhere strictly to the dictates of experience. There were other cases, however, in the treatment of which he borrowed largely from such authority; one of them was a woman of about forty-nine years, attacked by canine madness; she had been bitten by a rabid dog eight months previous to her admission into the hospital. After the usual premonitory symptoms, the febrile stage began, accompanied with the horror of water and delirium. The pulse, at first increased in quickness, then gradually decreased, becoming lower and less frequent until the fifth day, when the unfortunate sufferer sunk in death; the other febrile phenomena progressed accordingly. Here our English authors were the chief guides in the treatment, and calomel, with opium and acetate of lead, were used without avail, till, at length, the injection of warm water into the veins proved of value; it quickly relieved the horror of water, almost curbed the delirium, and calmed the sufferings of the poor creature. Canine madness was now no longer a fearful disease; the physician could command its pains and its horrors; but the patient terminated her mortal career at the usual term of the malady, yielding peacefully her life, as all those do who die from progressive failure of the heart's action. Blood was drawn from the arm twice, each time previous to the injection, in order to guard against excessive plethora which might thence result, and to afford the means of a chemical analysis, as well as to fulfil some hopes of its proper utility in the cure. There is one peculiarity in the blood in this disease: it is found to contain much free prussic acid, independent altogether of any secondary change, or the trifling quantity naturally present in this fluid under the ordinary circumstances. It is sometimes very considerable; at other times less so; but it remains for future observers to prove if its presence be constant; therefore it would be too hasty to detect some relation between its development in the circulating mass, and the gradual failure of circulating centre and disordered functions of the mind. It seems, however, only to appear after the febrile stage is ushered in; and this is quickly followed by collapse. The mental disorder, in this case, also bears the nearest resemblance to the delirium

of typhus, which is, for the most part, devoid of organic lesion, or even of morbid change of any kind in the vessels and solids of the brain; and the opinion that this depends on some fine alteration in the composition and qualities of the blood, which may act like narcotic medicines, (for there are animal compounds that do so), becomes daily more probable. The autopsy was made most carefully, and with unwonted neatness; the preparation of the nerves, leading from the cicatrized wound on the back of the right hand to the brachial and cervical flexus, was nicely done; yet no perceptible alteration was found in any part. The brain, spinal marrow, lungs and air-passages, stomach and alimentary canal, liver, spleen, pancreas, kidneys, urinary passages and bladder, and all the parts appertaining to the abdomen, and elsewhere, were more than usually sound and healthful looking. Dr. Bardsley tells us he always found little red ulcers in the mucous membrane of the stomach; now, in this instance, I examined it most minutely, and found not even the minutest trace of anything bearing the slightest shade of likeness thereto, nor yet blood-shot-vessels; if any thing was remarkable, it might be a layer of very transparent glairy mucus—an usual attendant on nausea, and the operation of such medicines as exert a powerful sedative action on the circulation. These ulcers, seen by him, were probably accidental, and, may be, such as we often find in the stomachs of English patients after all febrile complaints, and possibly owing to peculiarity of constitution and diet, and medical treatment.

Bufalini and his assistant use the stethoscope fairly and well; but he does not fail sometimes to make too hasty conclusions in diagnosis on its authority. Whilst I was in Italy he resolved a case of disordered action of the heart in an adult man to be hypertrophy to an unusual extent, and, after treating his patient a long time on this supposition with a half drachm of tartar emetic daily, the poor wretch died from a composition of maladies. The autopsy proved, in opposition to his opinion, that no hypertrophy or morbid alteration of structure of the heart was discoverable by any one of the five senses. Any reasonable man in our country would have admitted the commission of a fault of diagnosis in such circumstances; but

not so the sanguine Italian professor, as he directly imagined he had cured an extensive hypertrophy by the large doses of the active antimonial! Never supposing for a moment the possibility of an error in the means of forming his first opinion, he came to the school the following day, and delivered a brilliant lecture on the case, when he declared to his enchanted class, amid enthusiastic greeting, the glorious deed accomplished; the enlargement of this noble organ corrected perfectly by the heroic administration of tartar emetic; and henceforth the news was sent from Florence to all Italy. He was determined not to doubt in the least his particular use of auscultation, even in one instance; and the old and accomplished Testa was here proved to have written his celebrated work on the maladies of the heart in vain; he, although he lived before the time of the stethoscope, would not have spoken so wildly, nor made such a great error in judgment. He would have simply seen one of those cases of nervous and sympathetic anomalous action of this organ, which are most especially manageable by means directed against the primary disease, and to the improvement of the general health, and specifically by the use of iron, either in form of sulphate, as our Abercrombie recommends, or still better, in the form of hydrocyanuret, or ferrocyanurate of this metal, as generally employed by the Italians.

We have two means of judging the physician: by his success and errors; and as Bufalini is destined to be famed in foreign parts, I have shown him to you under both colours, to guard you against that fatal charm which forms a sacred halo around a foreign authority. "I will write it down—'tis meet it should be known"—we have the best physicians at home; but alas! the man of opinions will still remain the many-people's man.

There is an excellent madhouse in Florence, and a distinct division for skin diseases, in the Military Hospital, for all classes of patients; but these are not all available to the school in a clinical view, since there is no clinique on diseases of the mind or of the skin, nor any on those of children, or of the eye, nor yet an obstetric clinique. This last hospital offers the means, among the soldiery, for clinical instruction on the cure of syphilis, and this is likewise left unheeded: thus custom

governs men, and governments rule amiss. The German style is therefore followed without its completeness. On the whole, however, the Tuscan physicians, together with the Genoese, obtain the longest practical education in their art of all continental nations, beyond France.—Very sincerely yours,

July 31st, 1840.

MEDICAL GAZETTE.

Friday, September 4, 1840.

"Licet omnibus, licet etiam militi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

WHAT IS WANTED IN MEDICAL LITERATURE?

If a country practitioner, who judged of the progress of medical literature by the advertisements of new books, were to be asked his opinion concerning it, he would probably reply, that the variety and abundance of fresh information were sufficient to gratify the most fastidious inquirer. And, indeed, there are sufficient facts to render this opinion plausible, if not correct. At least a hundred new medical books and pamphlets are yearly sent forth by the presses of the United Kingdom; and if to these we add the libraries annually disgorged in France, Italy, and a score of German Universities, the sum total will appear overwhelming. The *embarras des richesses*, or choice rendered doubtful by the variety of opulence, might seem to be the only difficulty left. The fact, unfortunately, is otherwise; and if asked what is wanting among new medical books, we must frankly answer, something practical and instructive. The impatient critic is ready to wander about and cry, "I seek a book!" as Æsop said, "I seek a man!" If titles, indeed, could satisfy him, they are not wanting; but it is too generally a Barmecide feast, with names

instead of dishes. "I have ten new title-pages now about me," says a bookseller, in Goldsmith, "which only want books to be added to make them the finest things in nature." The student, grown grey in painful experience, knows how often the enticing title-page, if not absolutely without the pretence of a book to follow it, is prefixed to a mere shade of a book—a thing of shreds, patches, and pretences.

Personam tragicam forte ut vulpes viderat,
"O! quanta species," inquit, "cerebrum non habes!"

But let us consider a little more fully some of the characteristics of the medical literature of the day. They are chiefly two in number; the one is the dedication of so much professional talent to the theory of physic, particularly to physiology; the other is the slight texture of the books which are nominally practical.

When we speak of the entire devotion of so many ingenious men to the study of physiology, it is difficult to express ourselves so as to avoid being misunderstood. To censure this pursuit, however mildly, seems unjust; it is like finding fault with the practice of physic itself; for it may be asked, without physiology, what is pathology? How can you determine the exceptions without knowing the rules? How can the physician assert that the pulse of his patient is too quick, if unacquainted with the regular beat of health? Nor can it be said that even this simple fact is well ascertained; the pulses of infancy and old age, in particular, seem to have been fixed from too small a number of examples. *Pour connaître homme malade*, says a French writer, *il faut connaître homme sain*. Nevertheless, we might almost apply to physiology what Boerhaave said of chemistry, that although it was an excellent handmaid to medicine, it was a very bad mistress. Those who pursue it with the greatest ardour sometimes care the least for its

practical applications; the pleasure is in the chase, not in devouring the game. Yet it is equally true, that even those who show too exclusive a devotion to physiology for their own practical advancement, may be eminently useful to others; from the philosophic heights which they have ascended, they can point out those regions to others which they themselves are not permitted to enter. When we consider, too, the patient industry and discriminating talent which are required to make even a moderate physiologist, we must allow that the numerous cultivators of the science exhibit irrefragable proofs of the sincerity of their professional zeal. We almost regret, however, to learn that so many now devote themselves to microscopic observations, as the connexion of their discoveries with practice seems but slender. Pupils, in particular, must rather shun this fascinating occupation. Indeed, though they should master the leading points of human physiology, they will do well to leave most of its refinements to a later period. If the pupil takes to the higher walks of the profession, the possession of his diploma will give him ample time for study; according to Dr. Young, indeed, the physician in a metropolis must be prepared to pass at least ten years without deriving the slightest emolument from his profession.* Perhaps this is rather too hypochondriacally stated; but, if it is, as we fear, a near approximation to absolute reality, the young physician, and we may add, the young surgeon, will have abundance of leisure for physiology in all its varieties.

What is wanting in this branch of medical literature is an author who shall bring down philosophy from the clouds to walk on earth; who shall not only combine the scattered fragments of so many experimentalists into one harmo-

nious whole, but shall show their practical bearing.

In this department, however, there is little to be ashamed of; and even when we do not reap immediate fruit from the author's labour, we may hope that he has been planting for posterity.

But in the books which are nominally practical, there is much to make us uneasy. Facts few and insignificant, lame reasoning, a wretched style, and a tricky pretence of novelty, too often make us blush for the author, both as a practitioner and as a man. Indeed, when accurately examined, the book is not so much puffing, as a puff. Those imaginative writers, in whose recorded dreams each gilded nothing sinks into its primitive zero, might tell us how, under some fairy wand, Dr. Z.'s work on Digestion, and Mr. X.'s treatise on the Spine, were resolved into five hundred advertisements in the Times and Chronicle.

These unlucky books—these advertisements in sixteen octavo sheets—are but one of the symptoms of the excessive competition existing in our profession. Each candidate for a subsistence is urged on by his anxious friends to "write a book on something;" and too often yields to these ill advisers. His work may be considered a morbid breaking-out produced by these stimulating applications; and time, which soon removes the offending work, as the natural remedy. The indecent haste, too, with which many of these productions are brought forth, deserves its portion of censure. We actually recollect a writer who promised in one part of his treatise to take up a particular subject again if he found that he had room! So that while printing the first sheets of his book, he did not know what space would be occupied by the remaining ones. After all, it is difficult to be very harsh with such authors; as the Frenchman said in the story, *il faut que tout le*

* Med. Liter. 2d edit. p. 18.

monde vive; and though the reply was, *je n'en vois pas la nécessité*, most persons will side rather with the poor writer, than with the cynical minister. It is right, however, that the student should be on his guard against these expanded advertisements, these books which are not ephemeral, as they do not live even a day, but, in the language of reviewers, drop still-born from the press.

We might here speak of sham second editions, and warn our readers against those forcible exhumations of dead books; but we gladly pass on to a more pleasing subject. Putting aside all the make-believe books written only for the columns of the newspaper, and the counter of the grocer, and the still more numerous host which are damned with faint praise, and live for half a season, medical authors, in this country at least, are too few. How many distinguished practitioners go off the stage with the applause of their contemporaries ringing in their ears, yet leave scarcely a line to be remembered by. This should not be. A mere summary of the results of extensive practice would be useful, and short hints would add to its value. Yet fear or indolence keeps them back. The ingenious author of whose *Esquisses* we gave a specimen three weeks ago, observes that "there are physicians rich in facts, in knowledge, and in experience, who constantly delay the publication of the results they have obtained. Why do they wait? Time passes on, science progresses, ideas change. What cannot be done at one time cannot at another; and thus it often happens, that work put off is work not done. MSS. long kept in the portfolio wrinkle, and become strange to the actual world of science. A man has worked at his book, and perhaps continues to work at it still; but is he ignorant that there is an enormous distance between an intended and a published work? We may here

apply the old proverb: "when one has ten steps to go, nine are only half way."

But if it is a loss to the medical republic that men of note keep back the results of their private practice, how much more injurious is the silence of so many hospitals! The registers of a dozen great infirmaries for twenty years would clear up more doubts, and solve more medical problems, than a myriad of ordinary books.

UNION SURGEONS.

IN our number for the 29th of May, we commented on the niggardliness displayed by the Poor Law Commissioners towards Union Surgeons, and their constant attempts to crush at once the poor and the profession. Those, indeed, who are the most eager to do the one are nothing loath to do the other. Colonel Wade, the Assistant-Commissioner, who is so staggered by a Union where the medical expenditure is elevenpence per head on the population, is equally mortified that the repayment of loans cannot be squeezed from the poor, by all the machinery of the New Law. This part of the Act has filled every one else with unutterable disgust; and as a law cannot be carried into execution when every one combines against it, the wages of the poor ploughman are not attached according to the provisions of the Act, and the wishes of Assistant-Commissioner Wade. This would dumbfound most men: not so the Colonel. He hopes in the midst of despair, and continues to cast his longing eyes on labourers' wages. "This part of the Poor Law administration, then, requires immediate attention and amendment; and, if possible, some more summary process for the recovery of loans should be devised than that afforded by an appeal to the Bench of Magistrates, and the attachment of wages in the hands of the master."

A more summary process suggests

itself to us, which we strongly recommend to the Colonel's notice ; it is that of employing a military force to collect the parish debts. In the cottage of the debtor a bed will probably be found (unless it has been pawned), and this, with a table and a few minor articles, will go far towards discharging a moderate bill. This will show people that the act is really meant to work, and that the "loan system" is of "easy application. A corporal's guard will, no doubt, be sufficient at first ; and if the parishioners should ultimately show any ignorant impatience, the debts may be collected, like tithes in Ireland, by a troop of horse. We doubt, however, whether the loan system will make the Commissioners very popular. According to Dr. Johnson it was tried without success by Dean Swift. He lent small sums to the needy. "A severe and punctilious temper is ill qualified for transactions with the poor : it was often broken, and the loan was not repaid. This might have been easily foreseen ; but for this Swift had made no provision of patience or pity. He ordered his debtors to be sued. A severe creditor has no popular character ; what then was likely to be said of him who employs the catchpoll under the appearance of charity ? The clamour against him was loud, and the resentment of the populace outrageous ; he was therefore forced to drop his scheme, and own the folly of expecting punctuality from the poor.*"

Mr. Sheridan asserted from his own knowledge that the whole of this account was a fiction ; but it is easy to see that it is, at least, a consistent one ; and that charitable loans, with forced repayment, would excite universal indignation.

We must content ourselves with touching upon one topic more. Sir

Edmund Head, in discussing the question whether the rate of remuneration for Union surgeons requires a general increase, argues for the justice of the present rate of payment, on the ground that it is right to take advantage of the indirect payment which accrues by the increase or retention of private practice ; and observes that "an attorney has often spent more in a canvass and election for a coronership than the office itself is worth, merely because it led to an increase of his other business." But the plain difference between the two cases is, that the country does not take advantage of the competition among attorneys to lower the fees of coroners to an unseemly minimum, and merely looks with neutral eye on the lavish expenditure of the candidates in post-chaises and agents ; while Unions engage surgeons at salaries which will not always furnish proper drugs, and any attempt at obtaining a decent recompense is crushed by the central power of the Somerset House triumvirate. He thinks the public can hardly be called upon to protect the medical profession against competition, and says, coolly enough, that "it is the interest of the public, as long as persons think it worth their while to be properly educated, to secure their services at the lowest rate which is compatible with their efficiency." Very likely ; but these superlatively low rates are *not* compatible with efficiency. The surgeon who attends a large district for 60*l.* or 80*l.* a year feels himself an ill-used man, whether the sum was proposed by a skin-flint board, or suggested by his own fear of being underbid. He knows that the bargain is not equitable, and, unless he is animated by extraordinary virtue, feels little inclination to pay a daily visit to a patient at the uttermost corner of the Union—five miles and a half by the nearest cut over the fields ! We must confess, however, that the

* *Lives of the Poets.*

Assistant-Commissioner hits us hard, when he says, "Competition is prevented in other professions by internal regulations, not by the assistance of that public who would profit by it. If an architect or a barrister violate the by-laws of the profession, he is treated as one who is not a gentleman. The same remedy is, of course, open to the medical men." *Fas est et ab hoste doceri*, and though we dislike Sir Edmund's tone, we admire his advice.

THREE REMARKABLE CASES OF DISEASE OF THE PHARYNX AND ŒSOPHAGUS.

BY PROFESSOR ROKITANSKY,
of Vienna.

1. *Dilatation of the œsophagus*.—K. J., ætat. 24, a servant, suffered for nine years from vomiting, which especially occurred after eating indigestible food. In the winter of 1833, he came to the hospital after four days' illness, the apparent consequence of having got drunk on beer. He complained of nausea, desire to vomit, faintness, hiccup, constipation, and thirst: the features were fallen; the eyes sunk; their lids livid; the skin dry; the temperature less than natural; the pulse very small and frequent; the tongue covered with a thick white fur; the abdomen large, rather hard, and somewhat sensitive in the epigastrium; the breathing short and quick, with a dry cough. Tartar emetic was given, and in the evening produced diarrhœa and vomiting of very stinking pulpy food, with great relief to the patient, but the cough and hiccup had increased. Oxyde of bismuth was given in half-grain doses with the emetic.

Next day there was copious vomiting of a brownish bloody material, with frequent hiccup, ringing in the ears, and cough, and the pulse was scarcely to be felt. On the following days, also, after leaving off the tartar emetic, the vomiting continued in a less degree. On the ninth day of the disease, however, it ceased; but the diarrhœa, hiccup, and coldness of the extremities, continued, and the general debility was increased. On the tenth day the diarrhœa ceased, and the body became uniformly and unusually warm; but, on the twelfth day, the diarrhœa recurred more violently than before, the abdomen became painful all over, and the temperature again fell below its right standard. On the thirteenth

the patient died, in an extreme degree of exhaustion.

At the post-mortem examination, the contents of the chest were found moderately healthy. The liver was brittle and full of blood, and consisted of coarsely granular, clear, and dark-brown substances. The gall-bladder was distended by thick, blackish brown bile. The spleen was shrivelled, dense, and purple-red; the pancreas pale-reddish, full of blood. The solar ganglion was purple-red; its outer substance beset by numerous punctiform extravasations of blood; the neighbouring venous plexuses turgid. The intestines were partially contracted; the jejunum contained a brownish mucus, the lower part of the ilium a dark-red mucous and bloody pulp, and the large intestine a yellowish soft fæces. The mucous membrane of the intestines was everywhere swollen: in the jejunum it was pale; in the lower part of the ilium dark red, with congested veins, and enlarged mucous glands. The kidneys were small, and full of blood.

The stomach contained a considerable quantity of blackish-brown fluid, mixed with chocolate-coloured lumps; its mucous membrane was swollen. The opening of the œsophagus was narrow, and formed a prominent folded ring in the cavity of the stomach, like the vaginal portion of the uterus. Above it, the œsophagus, up to the pharynx, was found dilated into a spindle-shaped pouch, which, at its middle, would have received a moderate-sized man's arm. It was filled, like a sausage, with a blackish-brown soft mass of small pieces, which formed a consistent cylinder covered externally by a layer of white mucus. The membranes of the œsophagus were generally thickened, especially the muscular coat, whose internal and circular layer of fibres was nearly a line thick. The muscular fibres were pale; the mucous membrane was thickened, and its tissue was traversed by very dilated but empty blood-vessels. From about an inch above the cordia, to the upper third of the canal, there were numerous ulcers, as large as lentils and silver *groschen*; they were round, with sharp-cut edges, and were here and there grouped or coalescing; their bases were formed within by the exposed muscular coat, or by a blackish brown adherent slough, in whose tissue one could see numerous vessels, with their orifices closed by coagulum.

2. *Diverticulum on the pharynx*.—A. A. æt. 66, a journeyman-tapemaker, of a tolerably robust form. On his admission into the hospital in August 1837, said that he had been healthy up to his seventeenth year, with the exception of the common diseases of childhood, and, especially, repeated swellings of the cervical glands: in that

year he observed the formation of a tumor in the right side of the neck, about three fingers' breadth below the angle of the lower jaw; it was not painful, but it gradually acquired the size of a pigeon's egg, and after three years it appeared to him to have extended a good deal forwards: at that time, *i. e.* in his twentieth year, he found a difficulty in swallowing, by being almost constantly annoyed by the sensation of a foreign body sticking in the upper third of the Œsophagus, from which he was sometimes relieved at night, when he lay on his back, by vomiting some of his food. He especially recollected having once suffered thus for three days, till the vomiting of a small quantity of perfectly undigested food, which he had eaten three days before, immediately relieved him.

This condition remained almost stationary for 43 years, but for the last three years the difficulty of swallowing had greatly increased: he could only take fluids, and even these at last caused him the same forcing agonizing sensation: the vomiting occurred more frequently, and was accompanied by rapid emaciation. Two months ago, moreover, he had had an inflammation of the lungs,

On examination, there was found on the right side of the neck a firmly-elastic tumor, nearly as big as a man's fist, reaching from the region of the larynx obliquely inwards and downwards to the right sterno-clavicular articulation, and even passing behind it into the cavity of the chest. In this tumor there was discovered the right lobe of the thyroid gland, hardened into a fibrous cyst, which the patient accused as the cause of his wretched condition.

On the left side of the neck it was noticed that the Œsophagus was blown out every time the patient drank, and that it formed a swelling as big as a pigeon's egg, which always disappeared directly after he vomited what he had drunk. Vomiting of the fluid just taken was produced by pressure on this swelling, as well as by lying horizontally on the back.

For three days, he said, he had vomited nearly the whole of the food that he had taken; every attempt to introduce an instrument into the Œsophagus was useless; it always came to a considerable constriction at one and the same spot, and beyond this it could never be passed. The patient was kept alive for eighteen days by nutritious enemata and baths.

In the organs of the chest and abdomen nothing remarkable was found on the post-mortem examination. The left lobe of the thyroid gland was small and flaccid; the right was converted into a fibro-cartilaginous thickly-walled sac, as large as a goose's egg, containing a turbid puriform

fluid, fibrinous coagula, and some bony concretions. This sac descended behind the right sterno-clavicular articulation into the cavity of the chest, receiving at its lower part a slight impression from the right clavicle, and flattening, in some degree, the trachea. The mucous membrane of the fauces and pharynx was thickened; that of the epiglottis and ary-epiglottidean folds was œdematous. At the inferior constrictor of the pharynx the mucous membrane was prolonged through the lowest horizontal fibres of that muscle into a diverticulum more than two inches long, and at least as wide as the pharynx, which was held by the cellular envelope of the Œsophagus in such a position that the canal of the pharynx led straight into its cavity instead of into the Œsophagus; so that whenever one tried to pass a finger or a sound into the latter it always passed into the pouch. It consisted, besides some few bundles of pale muscular fibres, of a thick layer of cellular tissue and a thickened mucous membrane, polished internally like a serous membrane, which was straightened at the bottom of the hernial protrusion by an irregular reddish deposit like that of lymph in serous cavities. Just below the mouth of the diverticulum the Œsophagus was very much narrowed, and its canal had only the form of a small transverse fissure: it continued thus also in its further course: its muscular coat was thick; its mucous membrane was constricted in thick longitudinal folds, and the veins ramifying in the subcutaneous cellular tissue were varicose.

3. *Fibrous Polypus of the Œsophagus.*—F. M., æt. 48, a day-labourer, of tolerably robust form, was taken into the hospital in February 1834. According to his account he had suffered some years ago from ague, and had thence become dropsical. About two months ago he first perceived a pain in the fauces, with difficulty in swallowing; the pain subsequently descended into the dorsal region, and was accompanied by cough and feverishness. In the hospital he had cough, which was especially troublesome at night, and afterwards cachexia, palpitation of the heart, anasarca, especially of the fore and upper extremities, and constipation, were the most prominent symptoms. The difficulty of swallowing seemed to have disappeared, for the patient, who, on his first admission, described it as but slight, at last ceased to feel it at all, and had a good appetite up to the 19th of May, when dyspepsia came on. After that time the dropsy rapidly increased, and he died May 27.

The stomach, at the post-mortem examination, was found moderately distended, and it contained, besides gas, a

greyish-white mucous fluid. Its mucous membrane was very much thickened, and covered with a grey, jelly-like mucus. The œsophagus was distended by a substance firmly seated in it, which, on opening its canal, was found to be a polypus, hanging from the pharynx, and reaching down to about two and a half inches above the cardia. It proceeded from the anterior wall of the pharynx, just below the posterior part of the glottis, where it was attached by a flattened round stem, about four lines thick, composed of the submucous cellular tissue, and it hung down in the œsophagus, covered by a thin mucous membrane. It was altogether seven and a half inches long, and it increased in size from above downwards, so that its slightly lobulated and knobbed lower end was two and a half inches in diameter. The œsophagus was closely contracted around its middle; externally, and especially towards its free end, it was blueish red; the mucous membrane covering it was injected, and covered by a puriform exudation; its substance was reddish yellow, very flaccid, soft, elastic, and composed of a fibro-cellular tissue. Just above the cardia there was an ulcer of the mucous membrane of the œsophagus.—*Medicinische Jahrbucher des K. K. österreichischen Staates; Bd. xxi. St. ii.*

THOUGHTS ON MEDICINE.

[Continued from page 809.]

SEE the critic take his measure and his balance; he measures you by his height, weighs you by his weight, and estimates you by his value; he has no other rule for his judgment. If, in writing, you show energy and fire, he says it is mere emphasis and declamation; if you display elegance he calls it tinsel and affectation; if you are simple and natural, he asserts that you fall into common-place; if you show learning, according to him it is pedantry; if you are sparing of quotations you are ignorant of what has been done before you. The magnifying glass of his malevolent criticism alters and distorts every thing. What is to be done, then? Wait. This great man, so difficult to be satisfied, takes up his pen, and wonderful to say! his subject is hacknied, his principles false, his logic pitiful. Add, that his style is incorrect, heavy, flat, and wearisome, and no one is ignorant that the style is the man.

A new idea can have no permanence, if passion, enthusiasm, and strong self-love, do not assist it; they are powerful and

active springs; the difficulty is to bring them into the service of the good, the useful, and the true.

General rule.—When the reviewer forgets the work, to attack the author, and to penetrate the sanctuary of private life, he ceases to be a journalist, and becomes a libeller.

We owe a portion of our existence to disease, as we owe the tithe of our life to misfortune.

How many diseases, pains, dangers, and infirmities, men would avoid, if they were fully imbued with that great principle of hygiene and of wisdom, that pleasure sometimes enters into the composition of happiness, but never forms its essence.

The town of Nancy gave fêtes to celebrate the recovery of its prince. "The Lorrainers struck two hundred gold medals with the arms of Nancy on one side, and those of M. de la Peyronnie on the other. He persisted in refusing to accept them; but not to disoblige such loyal subjects, he accepted an equal purse of silver medals." (*Eloge de la Peyronnie*, by Morand.) Suppose the same thing to occur at present, friendly reader, you have no doubt what would follow.*

There are nearly ten thousand organs in the human body, and each of them has a multitude of parts, which are themselves divisible, until we arrive at atoms subject to molecular affinities. Then setting out from this point, ascending from harmonies to harmonies, from one organic sphere to another, we arrive at the *ensemble*, the whole, the sensitive and moral unity, the *I*. This is man. But of what does this vital and plastic force consist? What is the hidden bond, the primordial element, which generates this surprising variety of actions? The unknown quantity in this problem has not been discovered. All the parts of the body have life, but not a *life*, and yet they converge towards this unity with an admirable concord; every faculty terminates and loses itself in the abstract and hyper-organic faculty of personality. By what means does nature effect this great phenomenon? The triple scale of ignorance still covers our feeble eyes. What problems to resolve! What

* The author means of course, that in the present day every one would take the gold. But do not immense competition and small gains almost force such conduct on the profession? To speak in our author's style, the hungry wayfarer snatches at a crab-apple, while the tenant of the gardens of Alcinoüs turns away, satiated, from peaches.—TRANSLATOR'S NOTE.

veils to lift! What depths to sound! You may now understand the splendour of Stenon's words: *Pulchra sunt quæ videntur, pulchriora quæ sciuntur, sed longe pulcherrima quæ ignorantur.*

You are irritated against a criticism; is annoys, it wounds you. Weigh it well, however; if it is by a fool, forget it; if it is by an envious man, forgive it; if it is by a severe friend, make use of it. In any case, remember that it requires as much talent to profit by a good critique as to be able to do without it.

OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

I DEG to trespass on your attention with a few observations on the operation for curing strabismus, as simplified by my friend Mr. J. G. French, of the St. James's Infirmary.

That gentleman is the first surgeon that has effected any real improvement upon the process originally practised, if not devised, by Professor Dieffenbach. The abandonment, as recommended by Mr. French, of the numerous hooks employed by Dieffenbach, by Liston, by the French surgeons, and by others, in this country, has led to some important consequences: the pain of the operation is lessened, the labour of the surgeon is curtailed, and the after-treatment simplified.

I have tested Mr. French's modified method in four cases, and I feel bound to bear my testimony to its sufficiency. I shall not trouble you with a detail of these cases, which have succeeded perfectly, because they contain nothing of novelty. I shall merely state, in proof of their authenticity, that they were performed, respectively, in the presence of Mr. John Malyn, Mr. French, Mr. W. H. Smith, and Mr. Taylor. The way in which I proceeded in all these was the following:—The patient was seated on a chair in a moderate light; an assistant standing behind covered the sound eye with one hand, and with the other raised up the superior lid of the affected organ. The patient having been directed to turn the eye upwards and outwards, I snipped the conjunctiva at the under edge of the rectus, and passed a curved probe beneath the muscle: by depressing the handle of the probe the point was thrust forward, and appeared above the upper edge of the divided muscle, and by a cut of the scissors was enabled to emerge. The fibres were finally divided upon the probe.

The operation, thus abbreviated, consists of but three steps:—

First, the snipping of the conjunctiva.

Second, the introduction of the probe under the muscle.

Third, the cutting out of the probe.

The usual formidable notes of preparation are avoided. The probe which I employ consists of two stems placed parallel, at a distance sufficient for the point of the scissors to pass between. It is curved into a hook in the shape of a semicircle, of which the diameter is six lines. The pattern may be had at Savigny's or Fergusson's.

The improvement suggested by Mr. French is so obvious, that it must excite surprise that it did not occur to those wholesale performers who have been daily operating upon dozens of cases. Dr. Franz, the pupil of Professor Dieffenbach, has announced the success of his tutor in 250 cases. The pupils of Mr. Liston have not forgotten to din into the public ear the successive scores of cases which fell under the hands of their instructor. Other surgeons also have expended a vast deal of ingenuity and many shillings in the invention of hooks, scissors, and directors, and in attempts at otherwise improving the process; yet it was left to the plain and practical understanding of Mr. French to render the operation consistent with the simplicity and considerateness of British surgery.

If Mr. French has not been anticipated in his improvements either in Germany or England, still less has he in France, notwithstanding the especial patronage and instruction of M. Dieffenbach; at least if we may trust the announcement of the "Constitutionnel," the French Times.

That journal says, "Quant aux nouvelles et nombreuses opérations pratiquées à Berlin par M. Dieffenbach pour la guérison du strabisme, et dont cet habile chirurgien envoie régulièrement la relation *un peu monotome* à l'Académie des Sciences, M. J. Guérin publie à leur sujet quelques réflexions qui nous ont paru judicieuses. Il paraît que M. Guérin a amendé et perfectionné le procédé opératoire de M. Dieffenbach, et que cependant il a été moins heureux que lui, puisqu'en effet et de son propre, il n'aurait obtenu qu'une guérison *un peu parfaite*, sur quatre opérations d'ailleurs très sagement préméditées et habilement faites." If such be the result of M. Guérin's "perfectionnement," the sooner he abandons them, and adopts those of Mr. French, the better for his patients.

But according to the same journal, even M. Roux, the Achilles of French surgery, cannot boast of any great success. "M. Roux parle sans enthousiasme de l'opéra-

tion Prussienne, qu'il a lui-même pratiquée sans un succès très marqué. That M. Roux feels no enthusiasm on such a subject, only places him in more advantageous contrast with his confrères in this metropolis, where the eagerness for fame has been so overwhelming, as to threaten to break down the barriers between honourable practice and quackery. We have had the art of puffing practised in every form, from the sham "official reports" down to the puff direct of the newspaper paragraphs, and all equally unproductive of a single valuable suggestion.

One statement of the "Constitutionnel" deserves a remark: "Mais on ne se cache point on Angleterre, que cette operation ('la guérison du strabisme,') a d'abord été faite et conseillée par M. Stromeyer dès Juillet, 1839. If the English surgeons who set this report in circulation had, in addition to their smattering of French and German, known a little of their vernacular surgery, they would have known that this same operation of dividing the internal rectus of the eye was performed by Mr. Anthony White on several animals, as much as a dozen years ago, and recommended by him for the cure of strabismus in the human subject. Being a native suggestion, however, it was consistently neglected, until it made its appearance in a foreign costume.

Two facts which, previous to the appearance of Mr. French's letter in your journal, surgeons totally overlooked, at once point out the superfluity of the apparatus employed in this operation: the utter uselessness of the speculum, of the hook, for fixing the ball, and of the tenaculum for holding down the lower palpebra, as well as of the formidable bandage over the healthy eye; and these are, 1st, the fact that under every variety of ocular action, the rectus must always be within reach of the surgeon's probe; and 2d, the narrowness of the lateral diameter of the muscle, which is much less than the normal aperture of the eyelids in the waking condition, and makes all means for greatly depressing or raising them unnecessary.

The probe, when introduced underneath the muscle, should be held loosely, for occasionally the eye is drawn spasmodically outwards, and the probe, if held tightly, would plunge in consequence deep into the orbit, and occasion pain by coming in contact with various nervous filaments; but when held loosely it follows the course of the eyeball, and produces no pain whatsoever.—Apologizing for this intrusion, I am, sir,

Your obedient servant,

D. O. EDWARDS.

August, 1840.

CANCNUM ORIS.

To the Editor of the Medical Gazette.

SIR,

IN the report of my evidence at a coroner's inquest, in a case of cancrum oris, inserted in your journal of last week, I find it stated that *I was inclined to think that the disease was contagious*. As such is not the opinion expressed by me, nor that which I entertain, I shall feel obliged by your noticing the error.—I am, sir,

Your obedient servant,

T. B. CURLING.

1, Mount Place, L. H.
August 30, 1840.

WESTMINSTER HOSPITAL SCHOOL.

WE are glad to find that the Governors of the Westminster Hospital, at a Board held on the 25th ult., passed unanimously a resolution, to annex the Westminster School of Medicine to the Hospital, because we are convinced that their means of usefulness will be greatly increased. We are surprised that the Governors of that hospital should be the last in the metropolis to recognise that most important principle.

All that now remains, in the short space between this and October, is to appoint efficient men as lecturers, and they may be assured of respectable classes.

APOTHECARIES' HALL.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF THE SPINE, *continued*.—

CARIES, *continued*.—*Its Course and Treatment*.—CURVATURE.—*Its Nature, Symptoms, Causes, Prognosis, and Treatment*.

THIS disease may terminate in resolution, but it generally goes on; the skin becomes hot and dry, the pulse is quickened towards evening and after meals, and the patient gets weaker. After a very variable period, usually of some months, though it may occur in a few weeks, pus forms, and a tumor may be presented in the loins, the sides of the thorax, below the crural arch, and sometimes in the thickness of the buttock; according to the height at which the disease is seated, and according as the fluid has taken the course of the dorsal, the intercostal, the iliac, or hypogastric vessels and nerves.

To a certain extent other circumstances besides the extent of its accumulation, and its distension of surrounding parts, explain the course which the fluid takes; thus the movements of respiration dilate the lungs, and displace the abdominal viscera; from this results, not only a uniform resistance, which is opposed to an excessive development of the tumor in the thorax and abdomen, but also an alternate frequent impulsion which pushes the fluid towards the exterior. It is then directed towards points where it meets least resistance, and according to the structure of the region which it occupies, and particularly of the

parts which correspond to the contour of the tumor, it is directed either towards the posterior surface of the column; on one or other side of the ranges of spinous processes; towards the region of the axilla, or the thickness of the arm, following the course of the axillary vessels (Delpech); along the psoas muscle, towards the brim of the pelvis, and when the disease affects one or more of the first four lumbar vertebrae, this course is almost inevitable, the inguinal ring, the crural arch, the groin, the anterior superior spine of the ilium, the inguinal ring, (Brodie) the thickness of the thigh; forming tumors on the back, the surface of the chest, the inner side of the arm, the anterior and inner surface of the thigh, the scrotum, the labium, the perineum, (Ribes) the margin of the anus, the posterior or external region of the thigh, or below the glutæus muscle; in all of which places they may open spontaneously: they have opened into the spinal canal, have perforated the œsophagus, and the patient has vomited the pus; they have opened into the lungs, (Gooch and Cayol); and into the colon, (Wedemeyer.)

We then see at one of these points a painless, soft tumor, fluctuating from the first, over its whole extent; the colour of the skin is unchanged. When it is presented below the crural arch, and indeed in other situations, it partly disappears under pressure, and may be enlarged by pressure upon the abdomen, or by coughing; but the other characters of the tumor are so marked that it is impossible, with moderate attention, to mistake it for a crural hernia; but yet this error has happened: it has been mistaken for an aneurism, (S. Cooper) for a bubo, (Boyer, Wedemeyer) for a hernia, for an abscess by the side of the rectum, (Cooper, Ribes;) but generally these mistakes are consequences of gross inattention, and neglect of a proper interrogation and prudent examination of the patient.

The tumor enlarges, the skin is strained, and ultimately gives way, unless previously punctured. During the formation of these abscesses the symptoms of compression of the spine often increase, but when a spontaneous or artificial opening is made, and the pus is evacuated, they diminish or completely disappear.

When the abscess opens spontaneously, whether the opening continues, and admits air, and the cavity suffers the consequent irritation, or not, the disease is rarely cured; still, recovery is not impossible. But in the greater number of cases, especially where the patient is scrofulous, the pains become more acute, the pus becomes more fetid, and when there is paralysis of the bladder and the rectum, the urine, after distending the bladder as far as possible, runs over, as it were, incontinently; and to obstinate constipation, succeed involuntary dejections. The integuments covering prominent bones on which the patient rests become sloughy; the nervous, circulating, and digestive apparatus, are irritated, and the patient dies marasmatic. When these abscesses are opened spontaneously, and when, at the moment we are called in, air has already penetrated, there is usually little hope of cure; still, issues, appropriate internal treatment, and a regimen proper to sustain without exciting the patient, should be tried, however little chance of success there may be; for even though they do not completely succeed, they always arrest its progress, and retard the fatal termination.

Treatment.—The spongy texture of the bodies of the vertebræ is very favourable for the rapid progress of caries, and their deep seat is very unfavourable for accurate diagnosis at an early period; it often masks the affection until it has made considerable progress, and renders it inaccessible to all direct local treatment. From these circumstances it results, that as soon as the disease is discovered we are bound to suppose it is somewhat advanced, and that it requires very active treatment. When, therefore, an adult complains of having suffered a long time, in the region of the spine, a pain which was at first diffused, but is now concentrated—when a young child arrives at the period when it should walk, but presents feeble limbs, or more especially when after having walked it is no longer able to do so, this feebleness not depending on any apparent disease—it is necessary to examine the spine carefully, to ascertain whether any projection or gibbosity exists. We shall usually find this appearance; but supposing we do not, the existence of pain in a subject predisposed to the disease is a sufficient authority for active treatment. At the same time that we treat by appropriate means a

particular symptom or the general predisposition, the patient should be kept in the horizontal position. If there be much tenderness at any particular point of the spine it may be leeches; but without loss of time active counter-irritation should be applied to the immediate neighbourhood. Cameron appears to have been the first to rely much on the revulsive plan, and to have communicated to Pott the advantages which he had obtained from it. The best mode of applying it is to fix on each side of the gibbus, or the spinous process to which the pain corresponds, a large moxa, which, when the slough is thrown off, should be converted into an issue, into which some persons insert two, three, four, or more peas. It has been recommended that they should be kept open so long as the disease requires them; but you will often find that difficult, and the tendency to fill up can in many cases not be easily repressed. Besides that, I believe the discharge, after a certain time, to exercise no revulsive effect; that it becomes a physiological condition. I therefore prefer making caustic or moxa issues around the point, and healing them up; leaving always one slough undetached.

These are almost the only means which we can employ when suppuration has set in. If there be amelioration, if the feebleness of the limbs diminishes, it is not less necessary to continue those means. If there be any digestive disturbance, the egesta should be examined to ascertain that there is nothing abnormal about them. If the strength declines we must seek to sustain it by good nutriment, and quinine; if the bladder become sluggish or paralysed the catheter must be regularly used. Never attempt, by mechanical means, to lessen the deformity; this would be a fatal mistake, because you might prevent union of the bodies of the vertebræ, which is the only cure, or rupture that which has already proceeded to some extent; indeed the deformity is the patient's salvation. But it is indispensably necessary to preserve the horizontal position: as a means of facilitating this object it may be wise to raise the shoulder and pelvis so as to favour it. If much inconvenience be suffered the patient may lie on his side, or even on his belly; any particular position fatigues after a time, and therefore it is well to vary it. When abscesses present themselves, which they do at different periods, though usually six, eight, or ten months from the first pains—sometimes not more than as many weeks—in a case of Brodie's not until two years—there is much difference of opinion as to the course most prudent to take: some persons maintain that so long as they are not large they ought not to be meddled

with, because, under energetic treatment, such as has been alluded to, the caries is sometimes cured, the pus is absorbed, the abscess is resolved, and its walls coalesce. In some rare cases, the pus, after remaining long in its cavity, is converted into a substance resembling adipocire; and occasionally a long time may elapse before it opens spontaneously. Boyer knew a case where it was two years. Other persons advise that they should be opened as soon as they appear, by an oblique puncture, and as soon as the fluid escapes that the opening should be carefully closed; and that so soon as it is evident that the fluid is again collecting, which is usually from thirty-six hours to five or six days, that it should be again punctured. These punctures made in a tolerably healthy tissue soon heal, and no doubt very little air is admitted; but usually after the third or fourth puncture the opening remains fistulous, the pus becomes fetid; then the general health suffers, and the patient dies in the last stage of marasmus. Petit, of Lyons, advised that the tumor should be punctured with a very small trocar, or needle heated to whiteness, and the fluid abstracted by means of cupping-glasses. Even when the abscess is large these precautions are sometimes taken.

CURVATURE OF THE SPINE.

The spinal column may be curved at any point of its extent; and according to the direction which those curves take, they are distinguished; thus the lateral curvature is termed *Scoliosis*, the backward curvature is termed *Gibbus* or *Cyphosis*, and the forward curvature is termed *Lordosis*. Altogether the nomenclature is wanting in precision: thus the terms curvature, deviation, torsion, incurvation, gibbosity, inflexion, &c., are indifferently applied to this condition. I think Guérin's nomenclature much less objectionable; he calls all deviations of the column from its normal axis, either to the right or left, a lateral deviation of the spine; he reserves the term curvature for the different alternate arches which the spine describes in all deviations; from that the terms, first, second, third curvature, &c. He applies the term *excurvation*, or posterior deviation, to all projections of the spine directly backwards from the normal axis. The *excurvation* is regular or angular, according as the convexity is more regular or more angular. He calls it *senile* when it is the result of age. However, we usually find the terms commonly used in our country as sufficiently precise; I mean *lateral curvature* and *Pott's curvature*.

The spinal column is very rarely removed from its natural direction on one side only, but it almost always presents, at least, two

curvatures in an opposite direction: thus, if there be a more or less decided curvature in one direction, we shall almost certainly have another in the opposite direction.

It is clear that, in the different curvatures, the organs contained in the chest and abdomen must suffer change of position; and as the course of these affections is usually slow, we can readily conceive that in the end the viscera may take a position very different from that they ought to occupy, without having their functions sensibly interfered with.

I believe that these curvatures do not exercise any considerable influence upon the form of the pelvis, when they are not a consequence of softening of the bones, or rickets. This opinion was supported by Meckel (Manuel, par Jourdan, t. 1, p. 745,) upon numerous facts, but has been called in question by Joerg (Ueber die Verkrümmungen, &c. p. 26,) and by Choulant (Deas Pelvium, &c. p. 15,) who think that curvatures of the spine exercise a certain influence upon the form of the pelvis, although there be no general disease of the osseous system: they add, however, that this influence is greater when there is general disease, and when the curvature is manifested during infancy. According to them, as the vertebral column has four natural curvatures (one in the neck, convex forwards; one in the back, convex backwards; one in the loins, convex forwards; and one in the sacrum, convex backwards,) it follows that, when one of the natural curves increases under disease, all the other curvatures must increase also; and when a natural curvature takes a direction opposed to that which is proper to it, all the others must do so too. It is in consequence of these different changes in direction that the concavity of the sacrum increases or diminishes. In the lateral curvatures the pelvis will be contracted, and take an oblique direction, consequent upon the lateral obliquity of the sacrum.

When the deformity is fairly developed, its existence is sufficiently evident, and the simplest examination is sure to detect it; but it is when the displacement is slight that it is most important to ascertain its existence, for it is then more easily combated than when it has already exercised a baneful influence upon the functions of important organs. The complications frequently cause more difficulty than the original disease.

Mothers are ordinarily the first to perceive a change in their children's forms; their perspicacity on this point is admirable. It has often inspired delicate and ingenious observations; the solicitude which such a discovery excites is often supposed by superficial observers to be exaggeration. A great number of cases are

mistaken until they become very marked, because they have been in the first instance carelessly examined. A deplorable source of error is found in the pride of parents: we could scarcely believe it, if we did not often see it, that parents, in other respects very sensible people, will not see deformity in their own children; they are often wilfully blind; conceiving something disgraceful in a deformity, they think it impossible that their children can be thus afflicted, and they will tell you that none of their family have ever been deformed.

It is very common to refer particular attitudes to bad habits; it will be always wiser to ascertain whether there be no other cause. The attitude of a patient is generally a natural consequence of a want to distribute the burden of the body more equally. At the age when deformities commence, attitudes are usually the result of inspiration—of instinct: we may be sure, at this time, there is a reason for them; the patient may not know it, but it is our business to seek for it. Nothing can be more senseless than the punishment often inflicted in these cases. The burdens which may be attached to certain parts of their dress, the contrivances to prevent their moving this or that part, in the hope of preventing particular attitudes, are frequently unjustifiable. These attitudes should be regarded as indices requiring careful study; they are often sufficient to indicate deformities as yet too little advanced to attract attention, but yet in that precise condition when they can be easily arrested. We remark, for instance, then, that an infant whose spine is deformed, when he stands for some time, does not place both feet on the same line; one is constantly in advance of the other. Another remark, which is very interesting, because it may be made early, is the way in which the child sits down; you will often see such a child seek a low-backed chair, and so place itself that one arm shall be passed over the back, by which he gets a support for the trunk. This position you will find will be always the same; the same arm will always be used as a support. Another point which precedes the curvature is a constant pain, changeable in its seat, but sometimes in the side, above the breast, sometimes in the epigastric region. This pain has no known cause; its duration is pretty constant, its intensity variable, its periods of calm and exacerbation uncertain. We find no disturbance in the functions of the organs where the pain is felt; nothing calms it, nothing relieves it. It is accompanied by a slow progressive inexplicable degradation of the general health. This symptom should always induce you to examine the spine. Another symptom which should lead us to examine the spine is a

periodical asthmatic paroxysm, in children of from eight to twelve years. Great digestive disturbance is often presented in these cases. When these kind of symptoms occur, the necessity of examining the spine is absolute; we must not be satisfied with examining through the dress. Too much attention cannot be given where the diagnosis is difficult; and depend upon it, on your own account, this is the safe course; for the public, who do not know the difficulties, rarely pardon the omissions or errors of medical men in such cases.

Lateral curvatures occasion a difference in the height of the shoulders; the one is higher than the other; the body inclines to the side opposite to the curvature; one side of the thorax is bowed, the other concave: on the concave side we see, between the last false rib and the crest of the ilium, a fold, formed by the integuments; this fold increases in proportion to the curvature. The lateral curvature increases, there is a twisting of the spinous apophyses, the entire trunk is a little curved, the ribs are also displaced; those on the concave side approach each other; those on the convex side are most strongly curved behind, so as to cause a projection: most frequently the sternum is oblique, and drawn towards the concave side. If the curvature occupy the upper part of the spine, the position of the shoulders may be much changed. The curvatures which affect the inferior part cause much less deformity than those of the superior part of the spine. After a time other curvatures are formed in an opposite direction to the first which was developed.

When the affection is at its highest degree, the natural direction of the pelvis is changed, the iliac bone of one side is higher than that of the other, and, under the influence of causes which we have described as destroying equilibrium, the sacro-vertebral angle takes a vicious direction, and the superior aperture of the pelvis is more or less contracted. When the lateral curvature is carried very far, the viscera of the chest and the abdomen change their position, the thorax is contracted, the circulation of the blood in the lungs is more slowly performed, the respiration is more embarrassed, the digestive functions are deranged. These circumstances sufficiently explain the sickly state of the bodies of individuals affected with considerable curvatures.

In posterior curvature, I am not here speaking of Pott's, the spinous processes project backwards, the bodies of the vertebrae are thinned, and there is a concavity forwards, as we have already seen; the ribs approach each other; the sternum is bowed. The cavity of the thorax, lessened

in its vertical and transverse axis, is enlarged antero-posteriorly; the abdominal cavity is lessened; its viscera compressed. The affection is more rare at the loins than the back, but it is often presented at the junction of both. This curvature is common in old people, and is often a consequence of particular positions. If we interrogate old people presenting this deformity, we usually find that their daily occupation was such as to oblige them to sit, or stand, for hours in a curved position. It is not uncommon to see this condition in women of forty to fifty, who, after having worn stays all their life, leave them off at that time. The extensor muscles of the trunk, having long been without exercise, are no longer capable of supporting the spine. Again, rheumatism of the posterior muscles of the spine may produce this condition. The patient, being unable to contract those painful muscles, bends forward. (See fig. 1.)

Fig. 1.

It is not very difficult to chalk out a line of demarcation between this curvature and that which is a consequence of caries. The absence of pain in the first is an important difference. The disposition of the spinous apophyses at the level of the tumor is important. A curvature from caries is angular; that we are considering is rounded. At the commencement of Pott's curvature a single spinous process projects, afterwards others may follow, but the resulting curvature is unequal. In the curvature we are considering it is rounded, even from the first, and the pain, paralysis, and abscess, are usually all wanting.

The forward curvature is rare. In this affection the bodies of the vertebræ form an arch convex forwards; the spinous processes are contained in a cavity, directed backwards; they constitute an obstacle which prevents this kind of curvature from becoming so marked as others; still the pelvis is inclined forward, the sacrum is raised posteriorly, the pubis is directed downwards, the spinous processes are in contact, and sometimes united; the extensor muscles are shortened. We meet with this affection only in the dorso-lumbar and cervical region, and the symptoms it produces are not very marked. It is never other than partial. When the dorso-lumbar region is principally affected, the belly is larger, the viscera are pushed forward. Sometimes the lumbar prominence can be easily felt; walking then becomes embarrassed and vacillating. This affection seems to manifest itself usually in feeble rickety persons, with large heads, and muscles too feeble to support them; in persons sustaining weight around the loins; such as women who carry about the streets baskets supported by a strap around this region, or men who support organs in the same way.

Our more immediate object is to consider lateral curvature. It does not often affect the cervical region, when it does not depend upon disease of the vertebræ. When it occurs under other circumstances it is often, as we have already seen, a consequence of wry neck. The vertebræ of this region frequently participate in dorsal inclinations; but they rarely present a curvature distinct from that of the back. Bampfield states that there was such a specimen in the late Mr. Brookes' collection. It was the skeleton of a man in whom the first, second, and third cervical vertebræ, together with the occiput, were united and considerably thinned on the right side, and described a left lateral curvature without trace of rickets or caries. Still the dorso-lumbar region is the common seat of the development of lateral curvature.

The changes presented in cases of curvature are often very striking. In many cases, on the concave side, when the inclination is great, the intervertebral ligaments entirely disappear; in others they are much attenuated; the bodies of the vertebræ are also much thinned on the same side: the direction of the spinous process is more or less changed, its vertical surfaces becoming more or less inclined to the horizontal. In most cases the texture of these parts is not changed, unless there be general disease of the osseous system. Where there are several curvatures, the vertebræ which establish the transition between two curvatures participate to a cer-

tain extent in the deformities of both. These deformities of the vertebræ produce remarkable changes in the dimensions, direction, and configuration of the spine. The vertical height of the column is lessened; the interval between the head and the pelvis is, by so much, diminished, and the whole trunk is shortened. This may be inconsiderable in slight cases, but in aggravated ones the change may amount to a quarter, a third, or even a half of the total length of the spine: this is easy to understand, when we see that there is occasionally not more than a couple of inches between the two extremities of a curvature, comprehending seven or eight vertebræ. (See plate.)

Fig. 2.

As to direction, the spine describes curvatures, whose numbers, seat, form, and extent, vary with the case. The most frequent disposition is that in which the last cervical, the first, second, and third dorsal vertebræ, describe a slight curvature with its convexity towards the left side, followed by a much more decided curvature towards the right, which extends from the fourth to the tenth or eleventh dorsal vertebræ; and another, less decided, towards the left, which includes the last, or the two last dorsal, and all the lumbar vertebræ. The upper curvature is sometimes wanting; then that of the dorsal region usually commences higher, and may occupy a portion of the cervical region: in other cases the inferior curvature is more decided, and includes a greater number of the dorsal vertebræ; and the midway curvature is then less marked, and comprehends the remaining vertebræ of the dorsal region. We much more rarely observe a single curvature extending along the greater part, or limited to a particular region of the spine: it is still less common to see four successive incurvations, whether almost of the same extent, or whether two predominate over the others. The great lumbar curvatures are often accompanied by an inverse flexion of the two last vertebræ in their junction with the sacrum. The inclina-

tions of the middle dorsal region towards the left are more rare than those towards the right, in the proportion of about one to seven; the contrary is the case in the superior dorsal and lumbar regions. The curvatures are almost constantly directed in an alternating sense, and succeed each other uninterruptedly; beyond the limits of the deviation the column usually returns to its vertical direction. The cord of each curve is not always in the median line, and its convexity is occasionally turned upwards or downwards. The central vertebræ (in a curve) most removed from the axis of the spine, are at a distance varying from a few lines to six or seven inches. As to configuration, the two sides of the spine undergo opposite changes; on the convexity the transverse processes are removed and are divergent; the intervertebral foramina are enlarged: on the concavity, the transverse processes come almost or altogether in contact; the intervertebral foramina are lessened: these, with twisting, are the principal changes in configuration.

The thorax undergoes changes almost as great, dependent upon the curvature of the dorsal region of the spine. The ribs are unequal; those on the concave side are in more or less complete contact, sometimes imbricated, are thin and narrow, sometimes shorter, sometimes longer than those of the other side. The ribs on the convex side have characters directly the opposite to those we have described: separated by spaces larger than natural, frequently large and flat at their posterior extremities, or even their whole extent, the ribs in the convexity have, in marked cases, a diameter double or treble those of the opposite side. The dominant character of the thorax consists, then, in the irregularity which succeeds to its former symmetry; its total capacity diminishes, because it does not gain in one direction what it loses in another. The shortening of the spine lessens its vertical height, and its capacity is still further diminished by the projection of the inclined vertebræ inwards in most cases. When there is more than one curvature in the dorsal region, each exercises an analogous influence on the ribs, so as to constitute many gibbosities, although one usually predominates. The scapulæ follow the thoracic displacement; one is raised and pushed backwards by the convexity of the ribs; the other depressed, especially its anterior angle. The spine is nearer the first, and if the gibbus be great, the vertebræ are seated under the corresponding scapulæ. Anteriorly the clavicle of the depressed shoulder is ordinarily more prominent than the other; its sternal extremity particularly is pushed upwards and forwards.

At an early period in the progress of curvature the vertebræ implicated are still moveable, when more developed motion of the parts is much interfered with. The ribs on the concave side, pressed one against another, end by becoming immoveable. With age a junction or true ankylosis is often established between the deformed bones.

It frequently occurs in lateral curvatures that the other parts of the skeleton, the thorax excepted, present no analogous deformity. The pelvis is generally well conformed, when the limbs present no traces of rickets: the facts published by Sandifort, Walther, Meckel, Shaw, and others, are a proof of this. In rickets, the curvature of the spine, when it extends to the last lumbar vertebræ, almost always corresponds with deformity of the pelvis. The spinal cord is curved in nearly the same degree as the spine; but, even when the curvature is very great, compression and paralysis rarely occur. The lungs are pressed in when there is dorsal curvature: the heart is generally found in the concavity of the curvature; the aorta follows all the curvatures of the vertebral column; so do the cava and the azygos.

The capacity of the abdomen is diminished, like that of the thorax, by the shortening of the loins, and projection of the vertebræ into this cavity. The lungs, the liver, the spleen, and the kidneys, often present at their surface more or less deep furrows, produced by impression of the ribs, the vertebræ, or even the ilium.

Causes.—Curvatures may be determined by an original vice of conformation, and then they are congenital: they may be formed at a later period; they are then usually slowly produced, and often without pain. The rectitude of the body depends upon the antagonistic and regular action of the muscles, and the natural solidity of bones: let the bones of the spine lose their solidity, and let the different powers acting upon them press unequally, the equilibrium is ruptured, and curvature follows. The natural solidity of the bones may be lessened by rickets, by softening, by serofula, by syphilis, by inflammation, and suppuration. The muscular action preponderates over the natural resistance of parts, and those parts take the direction which the muscles give them. The equilibrium of the muscles is destroyed when one set becomes more active than another, or when one set is so enfeebled as no longer to offer the necessary resistance to the activity of another, which remains in its natural condition: this we see in cases of partial paralysis, and especially in certain professions. This cause acts most powerfully at an early period of life; we also see it in diseases of muscles, rheuma-

tism, &c. The action of the flexor muscles naturally preponderates over that of the extensors, and especially in the fœtus; therefore the greater number of curvatures are in the direction of the flexors.

A very general impression exists that rickets is the ordinary cause of that want of solidity upon which curvatures depend, but I believe the opinion to be erroneous. Curvature of the spine and ricketty limbs are by no means ordinary concomitants. Two-thirds of the persons who present curvature of the spine have no bowing of the limbs, or enlarged extremities, or softening of bones, or deformity of the pelvis: by far the greater number are perfectly independent of rickets. The softening of bone is, in a large proportion of cases, a first cause; but it is not necessary that the softening should exceed what it naturally is in the child. Until after the second dentition, the vertebræ, by their spongy character, and the quantity of blood which penetrates into them, offer no very marked resistance; the intervertebral substance is soft and flexible. However little the equilibrium between the two sides is disturbed, there will be an inclination to one side or another; by that inclination a certain compression is exercised upon the vertebræ and the cartilages, on that side; and the compressed side of the vertebræ will not increase in the same proportion with those of the other side; the inclination is generally to the right: why the inclination should be so generally to the right is a point differently explained by different persons. The older anatomists conceived it to be dependent upon the arch of the aorta, and probably there is some truth in this; some persons have conceived it to be dependent upon the use of the right arm. The inversion of the curvature in left-handed persons, and its persistence in cases of transposition of the viscera, are far from being constant. It is true that in Grisolle's two cases of transposition, the column had accommodated itself to the inverse direction of the aorta; but as to the arm we see many cases where the curvature has been to the left, in right-handed people, and *vice versa*.

A lateral atrophy of the spine, whether produced in the way we have spoken of, or in any other way, is the first cause of curvature; and this as much more easily occurs as the vital powers are feeble. An hereditary transmission or predisposition seems probable, for it is not difficult to point out different generations of deformed people. Weakly children, deprived of proper food and clothing, are the common sufferers; girls to greater extent than boys: and especially is this the case in those children who grow very rapidly. It is

also common during long convalescences, dentition, or too early use of the intellectual faculties; it is also apt to appear under the influence of certain mechanical causes: those which produce a continued or permanent inflexion of either side, particularly when the bones are prepared to give way; and this is especially seen in young girls, who, before puberty, are employed daily in carrying infants, and always upon the same arm, which is no less injurious to the child than the nurse, because one side of its pelvis is always more raised than the other. Sitting or standing long in one position, as in writing, or working with the needle; the habit of doing every thing with one hand, are very prejudicial. Again, girls at school, especially when weakly, are apt, in their various occupations, of writing, drawing, music, and needle-work, to sit a great part of the day in one attitude: fatigued with this position, they stoop; the mistress thinks she does enough in telling them to sit up. To escape this fault finding, they get into an attitude apparently straight, but in reality they incline to one side. This position, by diminishing the length of the spine, brings the base of the thorax nearer to the pelvis; their fatigue is lessened, and the attitude becomes habitual. If to that we add a predisposition, the absence of such exercise as would strengthen the muscles, the influence of stays, which worn early have increased the muscular debility, we cannot be astonished that curvature is most frequent in girls. I have no doubt that the greater use of the right than the left side of the body may have some influence in these cases; but if it were as great as some would have us believe, children who have lost an arm should be very crooked. An unequal development of the lower limbs has a much more real influence. Still, with regard to particular professions and particular attitudes, however various they may be, I believe that alone they are not sufficient to determine deformity; but they may unquestionably become very efficacious occasional causes, when other causes are at the same time in action.

Once developed, the tendency of curvature is to increase, but it is not commonly developed before the infant abandons the horizontal position; still, monstrous fetuses, with deformed spine, are not uncommon. In rickety children the curvature may appear during the first year, or by the sixth month; but where it depends on ordinary causes, it seldom appears before the sixth year, and often later, towards puberty.

ON

SECONDARY DEPOTS OF MATTER.

Illustrated by Cases, &c.

BY JOHN CHARLES HALL, M.D. F.L.S.

[Continued from page 809.]

CASE II.—W. —, æt. 23, was admitted for a simple fracture of the femur, and a slight wound of the scalp. The wound in the scalp became puffy in several places, into which free incisions were made. Typhoid symptoms came on; the skin became yellow, as in the last case, and the man died. Upon an examination of the body the two ends of the broken bones were found bathed in pus; there was also an abscess in the liver.

CASE III.—For some cause or other, (which I do not at this moment remember) a surgeon applied caustic to the scalp of a gentleman who was his patient, which formed a very large slough. Suddenly he was attacked with a set of very odd symptoms; the abdomen becoming very much enlarged, and he died. Sir B. Brodie opened the body, and found the intestines glued together with lymph. The bone of the head, over which the slough had been made, was inflamed and highly vascular, and the dura mater separated from the bone.

CASE IV.—A girl was admitted with an extensive wound of the pericranium, by which the bone was denuded. Typhoid symptoms came on, and the girl died. The local appearances were similar to those observed in the last case; the bone being vascular, and the dura mater detached: there was also a very large abscess in the liver.

CASE V.—A young woman died after a very severe injury of the head. The dura mater was here also found detached, and a large abscess encircling a simple fracture of the thigh.

We have now fully traced the effects produced by those injuries—have proved such injuries to be the exciting causes of the various purulent depôts discovered in parts far distant. But we call in vain to our assistance the aid of anatomy to draw aside the veil that conceals these phenomena. The peculiar construction of our textures, which our forefathers concluded allowed the fluids to wander from one part of the body to the other, as through a sponge—in one word, the

whole system of organism—is incapable of accounting for so extraordinary a circumstance.

An inflammation which seemed to have nothing to do with that now under consideration (phlebitis) has filled up the great void that seemed to separate the suppurating wound from a visceral abscess: a series of experiments appear to have clearly established this proposition,—that every foreign body introduced into the veins in the living subject occasions, when its discharge by the emunctories is impossible, visceral abscesses completely resembling those consequent to wounds and surgical operations, and such abscesses are the result of capillary phlebitis in these same viscera. (Translated from *Nouv. Bibl. Med.*)

The experiments of Cruveilhier are certainly very clever, and tend to throw some light upon the subject under examination. That we may rely upon them I have no doubt; for having taken the trouble to make some of them myself, I found what this gentleman has stated to be perfectly correct. I did not certainly try all of them, and for two reasons; first, because I had not sufficient time to devote to them; and secondly, I wished not, for the purpose of idle curiosity, to put numerous dogs to the most fearful torture. When any practical end can be gained by such means, we have an undoubted right to seize upon every source whence information can be drawn; but the truth of such experiments having been confirmed, it is wanton cruelty to torture poor brutes for no good purpose, nor can such deeds be too strenuously condemned.

We shall now conclude this part of our examinations, by recording a few of the experiments to which we have alluded, and making such comments as they seem to demand. It is a question of some interest whether suppuration ever takes place without the existence of previous inflammation, and Cruveilhier contends that this can never be the case; but collections which he describes as extraneous matter may form in various parts of the body without such parts having been attacked by inflammation. Dr. Thompson doubts, however, “whether these collections of matter ever form without inflammation, and is inclined to believe that in whatever texture or part of the body scrofula manifests itself, these inflammations will be found to exist. The phenomena of inflammation, both local and general,

are, it is true, modified by the existence of the scrofulous diathesis; but they are, I believe, always present in such a degree as to justify us in giving to them the name of inflammation, and in classing most, if not all local scrofulous affections, among inflammatory diseases.”—*Thompson on Inflammation.*

John Hunter observed, that pus does not irritate the peculiar surface by which it is produced, although it may be highly exciting to any other, and, therefore, that no suppurating surface of any specific kind can be kept up by its own discharge, for if this were the case, any sore secreting an acrid and irritable fluid would be kept open by its discharge, and would never be induced to heal; and this may also be said of many other fluids: thus the bile, the urine, and the tears, do not excite the particular parts, the glands or ducts by which they are secreted, and yet they are nevertheless capable of irritating any other part of the human frame. From this I think, then, that we may very justly draw the conclusion that when pus once enters a vein, once mingles with the circulating blood, whatever may have been its previous nature, whatever effect it may have produced upon the part where it was created, it now either has changed its condition, or, acting as a foreign body, becomes highly irritating to the particular parts to which it is applied.

“If,” says M. Cruveilhier, “any irritating fluid is thrown into the femoral vein of a dog in the direction of the heart, (which can be accomplished after a few of the valves are broken down), and the collateral veins do not convey the liquid into the circulation, the injection proves immediately fatal; the limb in 36 hours becomes swollen; and if the animal then dies, or is killed immediately, bloody extravasations are found in the substance of the muscles, and in the cellular tissue of the limb. The large veins are distended with adherent and coagulated lymph or blood, and the small veins corresponding to the extravasations are also full of concrete blood, while those appertaining to the healthy parts are free. If the animal survives the experiment, collections of pus replace those of blood, at the same time that pus is substituted for the coagulated blood in the veins.”

This physiologist next devoted his attention to endeavour to find out what became of the pus in local inflammation

of the veins, when such fluids became mingled with the blood. When, however, it was so blended, it was difficult to discover its presence, and therefore quicksilver was employed.

"If a large quantity of quicksilver be injected into the femoral or jugular vein, the animal will become exceedingly depressed, and perish in from twelve to twenty-four hours, in a state very analogous to that observed in chronic catarrh. The whole of the mercury will be found again in the lungs, which will not be inflamed, but gorged with serosity that may be pressed out of them. But if the quantity of quicksilver be smaller, the animal will survive the experiment for a longer period, and then there will be perceived an induration around each globule of the mercury; in a later stage collections of purulent matter may be discovered."

A variety of these experiments M. Cruveilhier offers for our examination, varied as they have been by him a thousand different ways, and always with the same result.

The liver being the seat of a particular system of veins, which veins are destitute of valves, and have numerous windings in the mesentery, he says, "I next drew out a knuckle of intestine, and injected quicksilver into one of the mesenteric veins. In a dog which survived this operation twenty-four hours, the liver was studded with red, superficial, and slightly prominent patches, of the colour of wine-lees, and its texture, when cut into on a level with these patches, presented the same colour to the depth of four or five lines. In the centre of each small red induration was a globule of quicksilver, a certain quantity of which had penetrated into the small veins. In another experiment on a dog which had an umbilical epiplocele, quicksilver was injected into a small vein of the omentum. In about ten weeks the animal was destroyed. The liver was studded with numerous yellowish tubercles, some of which lay near its surface, others in its substance, and each having in its centre one or more globules of quicksilver. Some of them presented two distinct strata; one of a tubercular substance at the circumference, the other of puriform matter in the centre, in the middle of which were the mercurial globules. These observations seem

clearly to prove that all extraneous bodies introduced into the general circulation are inevitably conveyed to the lungs, and such as enter the abdominal venous circulation as certainly proceed to the liver; these viscera constituting a barrier, which they pass not beyond, except in certain cases. These experiments, observes Mr. Cooper, solve one difficulty, which clinical observations alone could never have solved: "How, in the hypothesis concerning phlebitis, is the pus conveyed from the general venous system into the capillary system of the liver? Should not the pus stop in the capillary vessels of the lungs? It seems as if abscesses should only take place in the latter organs; yet experience proves that abscesses of the liver are very common after injuries and surgical operations, notwithstanding that the capillary system of the liver only communicates directly with the vena porta and the hepatic veins; but this objection is at once reduced to its proper value by the demonstration of that subtle liquid, quicksilver, passing completely through the general and capillary system of the liver when injected into the branches of the vena porta, and, in other cases, passing through the general and pulmonary capillary systems, or, what is still more convincing, pervading several times the different orders of capillary vessels."

Professor Cruveilhier considers it, therefore, to be clearly made out that the pus which is introduced into the blood is retained in some part or other of the capillary system; that its tendency is to excite every where capillary phlebitis; that this inflammation is more likely to take place in the lungs than any other part, next in the liver, and next in the spleen; in fact, it appears clearly proved that pus, like quicksilver, once taken into the circulation, may be detained in the lungs or liver, or any other part of the system; it then produces circumscribed spots of inflammation, and this proceeds more or less rapidly to a state of suppuration.

This certainly appears a much more rational way of accounting for the secondary depôts found in various parts of the body, after injuries of the head, and various surgical operations, than to suppose that they existed previously in the parts where they are discovered, and were excited to take on a new sphere of

action by some peculiar state of the system induced by the wound of the scalp, or the injury done to the bones.

We have been led already to discuss this subject at greater length than we at first intended. There is, however, another query which must, if possible, be answered, viz., why do not visceral abscesses take place in cases of copious accumulations of matter, as in chronic pleurisy and peritonitis? and, secondly, is a wound necessary to their development? Quesnay has noticed a great difference in relation to consecutive effects between abscesses of long standing and the suppuration from recent wounds. Now to what are we to trace this difference? Are we to conclude that absorption of pus takes place in the one and not in the other? We know that a large abscess, the opening of which has been delayed, sometimes disappears, its fluid contents having been absorbed and taken into the system; yet it appears that the constitution does not suffer, and that this extraneous matter is thrown off by the various outlets of the body; therefore it would certainly appear that there is a very considerable difference between the effects produced by the introduction of this fluid at once into the circulation, and the introduction of similar matter by previous absorption.

M. Cruveilhier, in conclusion, adds, that what M. Dance proposed as a conjecture he has proved to be true,—that in several cases of “wounds of the head the veins of the diploe have been found purulent, and this state co-existing with numerous abscesses of the liver and lungs. Several convincing preparations of this were presented to the Anatomical Society, and at the present time it may be announced as a demonstrated truth, that, in cases of wounds of the head, the visceral abscesses of the liver, the lungs, and the spleen, are the consequence of phlebitis, and more especially phlebitis of the diploe; but the observation that inflammation of the veins of bones is a cause of visceral abscesses applies not only to the veins of the diploe, but to all the veins of bones; and I lay it down, as a general proposition, that phlebitis of the bones is one of the most frequent causes of visceral abscesses after wounds and surgical operations implicating the bones.”

This conclusion is at any rate as rational as any we can come to, and far more so than many of the theories

that have been from time to time advanced. The subject, however, is overshadowed by clouds and difficulties that the scalpel of the anatomist cannot break through. It is surrounded at present by a veil that human talent and understanding in vain endeavour to penetrate.

But our examination has led to some satisfactory results, inasmuch as we have discovered some of the more frequent causes of phlebitis. We are obliged to extract blood from the arm, but we are not obliged to induce death by passing a thread round a vein, or by breaking down newly-formed adhesions with a silver probe; and therefore, although unable to trace the disease through all its ramifications, we nevertheless are able to discover some of the more frequent causes producing it, and if we avoid them not, we are not only willfully blind, but culpably negligent also, and answerable for the lives we thus destroy. But this leads us to consider next the treatment of that peculiar state of the system which we have thus considered, and which we have found to arise after injuries and operations.

We have divided inflammation of the veins into two stages: first, adhesive inflammation, and second, a more advanced period comes on, when we find that this stage has passed away, and the suppurative process commenced. This view of our subject will be found of practical importance in our prognosis. I have not, be it remembered, spoken of inflammation of the veins arising without any apparent cause; traumatic phlebitis has more particularly occupied our attention; but in the *Cyclopædia of Practical Medicine*, Dr. R. Lee has taken up this part of the subject in a manner that leaves me nothing to say; in a manner that will amply repay an attentive perusal, and from his long and patient examination of uterine phlebitis, his remarks are entitled to the respect the opinions of this gentleman always demand. We may, however, be allowed to say that uterine phlebitis is known to be one of the worst forms of puerperal disease, and that, next to inflammation of the veins from wounds, one of the most common cases is phlebitis of the lower limb, consequent to uterine or hypogastric phlebitis; but this may arise under two distinct conditions of the body:—

1st. After parturition.

2nd. In cases of cancer of the womb.

We have stated the division here made is of practical importance, inasmuch as it is only during the first or adhesive stage, during that very early period of the affection when the blood is just beginning to coagulate within the vessel, that the cure can be attempted with any reasonable hope of success; for when the second stage comes on, when pus is formed and introduced into the system, medicine is of little avail; at least, all the remedial agents with which we are yet acquainted. Our treatment must be both local and general; copious bleeding, both with the lancet and with leeches, cold lotions to the part, and the free administration of calomel and opium. This is all we know at present of the treatment of the disease; but when the second stage comes on, the lancet and leeches can do no good. The quick and feeble pulse, the brown tongue, the cold wet hands, the muttering delirium, point out what it will be proper to administer. Wine, brandy, and then opium and anionia, will be the best medicines; clysters of strong broth must be thrown up, and every means taken to support the declining powers of life; but they hold out little or no hope of success, and in spite of all we can do our poor patient is hurried to the grave.

There yet remains one point of practical importance in the treatment of phlebitis that must not be overlooked, as it is important to know at what period we are to give up extracting blood. We answer, so soon as the second stage has commenced. True, I may be answered, "by taking away the blood you remove also a portion of the poison." Granted; but in taking away the blood you also lessen the powers of reaction, and the mere taking away of this fluid does not prevent the secretion of pus, which goes on as rapidly as ever. Now when a poison is once introduced into the system, as in the bite of a viper or the rattle-snake, the vital powers are shortly reduced to a very low ebb, and it certainly cannot, in such cases, be the rule to take away a very large quantity of blood. The first stage, then, of phlebitis over, so far from reducing the animal powers, we must endeavour, by every means in our power, to strengthen and support them, for by so doing, although we may not be able to preserve life, we undoubtedly prolong it, and in lengthening the span of human exis-

tence we most certainly are doing our duty.

We have now very carefully collected numerous facts tending to explain the subject we have attentively examined, and, without offering any very decided opinion, we leave the reader to examine the evidence before him, and from it and the book of nature he must draw his own conclusions; at the same time we venture to suggest that the subject most unquestionably offers a very wide field for discovery, and will doubtless amply repay any time that may be spent, any trouble that may in after life be devoted to exploring it.

7, Bath Place, Kensington,
August 1840.

AN INQUIRY INTO SOME OF THE CONSEQUENCES AND CAUSES OF FAILURE
OF THE
NEW OPERATION FOR THE CURE
OF STRABISMUS OR SQUINTING.

By E. W. DUFFIN, Esq.

Surgeon.

[For the London Medical Gazette.]

THE observations hitherto published on the division of the tendon of the internal rectus muscle of the eye for the cure of obliquity of vision, have been principally confined to the various methods of performing the operation, or to the suggestion of some new instrument to facilitate the accomplishment of that object.

The few cases thus far reported have been all so highly coloured, and so remarkable for their complete success, that, were we to credit implicitly their various authors, we should be led to the happy conclusion that failure is next to impossible, even in the hands of the most unskilful; and that in no instance will any visual deformity remain when once this devoted tendon is severed from its attachment to the eyeball. That it is a very scientific, beautiful, and highly satisfactory operation, in dexterous hands, no one can deny, perhaps the most so of any in surgery; but that cases both of complete and partial failure are of daily occurrence, though vaunted as successful, will, I imagine, be readily conceded by every candid surgeon whose field of observation has been sufficiently extensive to enable him to arrive at any really accurate, practical, and legitimate conclusions on

the subject. Indeed, so far from being universally successful, there is too much reason to fear that the operation will, ere long, fall into unmerited disrepute, in consequence of the imperfect and injudicious manner in which it is often performed, and the inauspicious results that have been occasionally observed to proceed from it.

To divide the tendon of the adductor oculi really well, and to liberate the eye with *certainly* and in an *efficient manner*, so as to secure the utmost benefit capable of being conferred, at the smallest possible cost of suffering and inconvenience to the patient, requires much more dexterity, neatness, and address, than is commonly believed. At first sight the simplicity of the operation is such, that almost every one is induced to attempt it, but comparatively few succeed to the full extent, in conformity with the principles just inculcated. To attain this delicacy and excellence, it is essential that the surgeon should perform the operation a vast number of times. That the first attempts, therefore, of the unpractised almost invariably prove only partially successful, cannot surprise us. I have myself operated one hundred and seventy times, and assisted others to an almost similar extent, as well as had opportunities of examining a variety of cases operated upon by individuals of every degree of talent, and feel satisfied that the statements I make will be found correct by every impartial inquirer. Many of my own early cases were only partially successful, and some of them were decided failures.

The original obliquity of vision, it is true, may be removed; but if, in its stead, there be substituted a staring vacant projecting eye, of apparently disproportionate size, or a disagreeable leer, or if a mere alteration only in the nature of the obliquity be effected, it is very questionable how far the expression of the eye is bettered by the change.

When the operation is imperfectly performed, a few fibres of the tendon, perhaps, or some apparently insignificant band of fibrous adhesion having escaped the scissors, the patient loses the power of turning the eye horizontally inwards, so as to bury the cornea in the nasal canthus to the same extent that he could do previously, and thus the inexperienced may be misled. If, in

like manner, in his effort to accomplish this movement, it be found that the patient is still capable of directing the pupil either upwards or downwards, and only slightly inwards, we may rely upon it that the operation is incomplete, and that when the eye is left at rest, this modification of the original evil, will, in a minor degree, be found to persist. Now, the operator being satisfied, from the extent to which he may have laid bare the sclerotica, that he must have divided the whole of the tendon of the adductor, often erroneously concludes that this slight obliquity arises from sympathy, and that, in the course of time, it will entirely disappear. But unless we can imagine that the unsevered parts will gradually relax, or become elongated, it is impossible that the eye-ball can ever emancipate itself thoroughly from its confined position. I have lately examined several cases that were operated upon, when this mode of relieving strabismus was first practised in this country, and do not find that time has thus far effected any amelioration, nor do I think it at all probable that further improvement will ever take place; but the contrary.

When the operation is complete in every respect, the patient is wholly incapable of directing the pupil of the eye beyond the centre of the orbit, either in a horizontal or oblique line.

In the course of a fortnight or three weeks after the operation, if the tendon has been simply divided, and not disturbed or displaced by pushing the muscle back into the posterior and lateral part of the socket of the eye with the handle of a scalpel, as has been recommended by some surgeons, it appears either that a new insertion of the muscle takes place, so that the patient recovers, in a very considerable degree, the power of directing the pupil towards the nasal canthus, or that certain of the other muscles, by a concurrence of action acquired by the natural efforts to render vision single, enable the patient to perform this movement. If any reunion take place between the divided tendon and sclerotica, and experience proves that this does happen, the fact that it can be established without return of the original evil is very important, and militates against the practice of displacing the muscle, as above stated, after its attachments are separated.

These movements of the eye upwards and inwards, or downwards and inwards, have been noticed by Mr. Liston, Dr. Franz, Mr. McMurdo, and indeed by every other operator, each of whom has explained it on a different principle. The theory which is most correct, therefore, remains to be proved by future inquiry.

In the report of Mr. Liston's cases, in the number of the *Lancet* for July 18th, of the present year, Mr. Ancrum observes, "In some instances, after the internal rectus has been cut across, the patient possesses the power of turning the eye inwards and downwards; this arises from contraction of the inner border of the inferior rectus." "Mr. Liston," he continues, "is in the habit of partially or completely dividing this muscle in all these cases." Now I do not by any means call in question that in some few instances it may be necessary to divide the inferior rectus partially or completely, because I am satisfied that this muscle may occasionally be implicated in the production of the deformity, as well as the adductor. But when, after dividing, as I have thought, completely the rectus muscle, and the patient has still retained the power of directing the eye downwards, and a *little inwards*, I have always found, on instituting a very careful examination, that a few tendinous fibres, or a band of adventitious cellular attachment, generally situated above the tendon of the muscle, still remained unseparated; and on dividing these the patient could no longer direct the pupil to the nasal canthus, nor carry it beyond the centre of the orbit. It is truly astonishing how very small a portion of this fibrous adhesion remaining unseparated is sufficient to mar the finish of the operation. These fibrous bands or digitations are sometimes seated very far back, even beyond the greatest diameter of the eyeball.

In the dead eye the cellular tissue is so delicate, lax, and unresisting, as to be scarcely appreciable. Indeed, it is with difficulty we can imagine it capable in any way of contributing to the deformity. When endowed with life, however, the bands formed by it are very powerful agents in retaining the eye in its unnatural position, and offer considerable resistance to the scissors, on being cut. It would seem that these bands proceed from condensation of the cellular tissue connecting the muscle

with the sclerotic coat, and which gradually adapts itself to the shortened state of that muscle. In some instances we find them strengthened by the effects of inflammation occurring during childhood; and in numerous examples it is the supervention of this apparently unnatural adhesion that renders the strabismus permanent.

In the first instance there can be little doubt that the affection depends on muscular spasm by no means necessarily persistent. I think, moreover, I have observed this adherent fibrous character of the submuscular cellular membrane to be more extensive and marked in persons who squint most. The movement of the eye downwards and inwards then, when the patient makes an effort to direct it to the inner canthus after the complete division of the tendon of the adductor, arises, I apprehend, from the natural action of the inferior rectus muscle, whilst the eyeball is still partially bound down by the tendinous bands of attachment alluded to, and that all we have to do, ninety-nine times out of a hundred, in order to succeed in perfectly rectifying this diagonal and abnormal movement of the globe, is to carry the dissection sufficiently far to separate completely these adherent fibres, however far back, high up, or low down on the sclerotica, they may be seated. I have met with this feature in the course of the operation in very numerous instances, and have always overcome it by the means just stated.

In no case have I ever cut the fibres of the inferior rectus; and in none have I ever dreamt of cutting the superior oblique muscle, as Dr. Franz informs us he has done, in order to remedy a position of the eye *upwards* and *inwards* the reverse of that we have been considering. Dr. Franz, however, it appears to me, has deceived himself in this respect. Indeed, I do not believe that any one has yet divided either of the oblique muscles, or that such an extension of the operation will ever be necessary. If we consider the following statement of Dr. Franz attentively, I think we shall be disposed to doubt whether he divided the superior oblique muscle, or only some unusual tendinous expansion or fibrous adhesion, such as above described. Indeed, the manner in which he relates that he accomplished the undertaking convinces me

that it could not have been either the muscle or its tendon which he cut. "I proceeded," says he, "to the operation, and carefully and entirely divided the internal rectus muscle, as in all my former cases. I now removed the hook from the conjunctiva, and leaving the eye at rest, after the lapse of a few minutes I examined its state again, when I was not a little surprised to find that the division of the muscle had not proved efficient, for although the inversion was certainly modified, the eye was yet turned upwards and slightly inwards.

From the direction in which the eye now stood, and its movements obliquely upwards towards the glabella, I was induced to think that the present state of this eye, the internal rectus having been entirely divided, would be well adapted for an experiment to investigate the true action of the oblique muscles; and as the patient bore the operation with very little inconvenience to herself, I determined at once to divide, first the superior oblique, in order to convince myself whether the present direction of the pupil depended actually on the action of the inferior oblique only, and then to divide the inferior oblique likewise, if the direction of the pupil should require it. I passed the hook again through the conjunctiva for drawing the eye outwards, and, without enlarging the wound in the conjunctiva, passed the curved scissors under this membrane, cutting through the adipose and cellular tissues with the blades of the scissors *so directed as to meet the tendon of the superior oblique*, which I soon distinctly felt between the blades, and divided, as was proved by the resistance and the peculiar sound with which the division of a tendon is always accompanied. On removing the hook again from the conjunctiva, and carefully examining the eye, I was not a little surprised to find that it was now perfectly straight, the pupil occupying its proper position. The division of the inferior oblique was, therefore, not requisite. The patient could not move the eye inwards, but in all other directions the movements were free, (MED. GAZETTE, June 24, 1840.) Now it occurs to me that it would not have been so easy a matter to arrive at the tendon of the superior oblique through an opening made in the conjunctiva at so great a distance from it. It might

have been possible for Dr. Franz to have divided the second belly of the muscle within a short distance from its transit through the trochlea attached to the frontal bone; but he informs us that he did not cut in that direction, but "*with the scissors so directed as to meet the tendon*:" hence he must have been at least three-fourths of an inch distant from the only point at which he could have cut the muscle by such a proceeding.

To have divided any part of the tendon by passing the scissors through the wound already made in the conjunctiva was next to impossible. Their points must have travelled over nearly one-half of a sphere, and been lost to the view of the operator long before they reached the object they were to cut. In my mind there is no doubt that after severing the principal band of tendinous fibres, by which the adductor is inserted, Dr. Franz encountered an adventitious band of fibrous attachment, such as I have already described, seated so high up, that he was led to consider it the tendon of the superior oblique. From what I have myself experienced, I can very readily imagine any one falling into this error.

1st September, 1840.

[To be continued.]

ON THE PATHOLOGY OF STRABISMUS.

BY EDWARD HOCKEN, ESQ.

[For the London Medical Gazette.]

As the subject of strabismus has of late been made of considerable importance, by the attention it has received in regard to the performance of Dieffenbach's operation, it has appeared to me worth while to investigate narrowly its pathology, to be thus enabled to lay down some practical rules why, when, and where it may be performed with reason, and every chance of success, provided that other circumstances present no impediment.

Taking a general view of strabismus, we may infer that all forms are originally dependent upon some lesion of innervation of the orbital nerves, of the third in convergent and oblique squinting, and of the sixth in divergent: the

lesion itself being in most cases excess, in some few a deficiency of innervation, thus producing either excessive or deficient action of the recti muscles. Now this derangement in the functions of the nerves of the orbit may be slight in kind, and transitory in duration, depending on excitement of the general nervous system, as in spasmodic strabismus, or, on the contrary, severe and permanent, as happens from numerous exciting causes; then, under these circumstances, from increased or diminished vital attraction between the capillaries and the affected muscles, changes are brought about, rendering the disfigurement independent of the nervous condition; the muscles, in the case of excessive innervation, becoming hypertrophied, or from the contrary condition, namely, defective innervation, atrophied, enfeebled, and, perhaps, softened. These remarks would scarcely apply to congenital cases, where the affection would probably depend on original lesion of conformation, or muscular condition; being connected or not with congenital amaurosis, obliquity of the orbit, or other defects of the eye-ball or lids.

Now, before proceeding to consider the pathology in detail, it may be advisable to make an enumeration of the principal exciting causes: these will be found to be numerous, and frequently complicated. Strabismus may be hereditary or congenital, may originate from imitation or habit, from improper education of the eyes, abdominal irritation, blows on the head, blows and other painful impressions on the eye, wounds of the orbit, various disorders and diseases within the encephalon, long retention of the head in one position, disparity of vision in the two eyes, disturbances of the nervous system, ulcers on the cornea, opacities of that tunic, the aqueous capsule, and lens, which partially obstruct vision, and, lastly, certain conditions of the pupil.

Strabismus, from these various exciting causes, may be reduced to the following pathological leadings:—1st, from affections of the brain; 2dly, abdominal disturbance; 3dly, affections of the general nervous system; 4thly, from idiopathic conditions of the orbital nerves and muscles, unconnected with disturbance in other organs; 5thly, and lastly, from congenital conformation, complicated or uncomplicated.

1. *Affections of the brain.*—The affections of the brain which produce strabismus are very numerous, and may be either functional or organic. The condition itself may be inflammatory: thus squinting occurs in the course of acute or chronic encephalitis, general or partial, it is frequent in the advanced stages of hydrocephalus, or may derive its origin from organic changes, the consequences of inflammatory action, or somewhat analogous processes, as in softening, induration, atrophy, hypertrophy, &c. Again, the pathological cause inducing the strabismus may consist of organic disease situated within the cranium; as simple or malignant tumors of the brain or bones, fungous growths, thickening and other tumors of the membranes, exostosis, and other diseases of the cranial bones, and, lastly, diseases of the vessels.

The affection may be symptomatic of cerebral congestion, this being either active, passive, or mechanical; apoplectic attacks, the disordered circulation preceding or producing it and the subsequent effects. Strabismus may also originate from disordered circulation arising from anæmia, and the derangement of function induced in the hydrencephaloid disease; to this head perhaps we may also refer the irritation of teething.

The last class of cerebral derangements that I shall mention is that induced by injuries of the head—namely, simple blows, unattended with any other marked symptom, the effect of concussion or compression, or from wounds or other injuries of the cerebral nervous matter.

2. *Abdominal disturbance.*—The derangements of the abdominal viscera producing sympathetic strabismus are usually functional, being either acute, gastric, or gastro-enteric dyspepsia, produced or connected with hepatic derangement and morbid biliary secretion, or from irritation of the gastro-intestinal mucous surface; on the contrary, the indigestion or biliary disturbance may be chronic, and, in children, frequently depending on worms, or atonic dyspepsia, may be complicated with their presence, and, finally, the combination of symptoms may indicate uncomplicated strumous indigestion.

3. *Affections of the general nervous system.*—These may consist of, first, simple excitement second, derangement

from the presence of either the exciting or depressing passions; third, from a condition of permanent debility and irritation, induced by long-continued and excessive use of intoxicating substances—as alcohol or opium.

The influence of the first form, namely, simple excitement, is seen in cases of spasmodic strabismus; in the most marked forms of which the direction of the axes of the eyes is, during ordinary circumstances, quite natural; but the deformity becomes apparent, and the eye-ball is obviously drawn in one particular direction from exciting occurrences, or from intense application or employment of the organ. Even in less marked cases, where there is slight but permanent deviation, it is frequently increased considerably when the patient is conscious of observation, or is exposed to circumstances which hurry and derange him.

In the second division of squint from affections of the general nervous system, this latter is greatly but temporarily disturbed: we see this form most frequently in children. Under this head we must include fright, fits of passion, fear, anger, the irritation of dentition, (in which last the disturbance is more prolonged, and acts especially on the brain) convulsions, &c. Cases are on record where the attack was occasioned by a violent fit of crying, convulsions from different causes, a sudden fright, as from forcibly bathing children, notwithstanding many expressions of terror. Mr. Middlemore has observed it to occur from the application of a blister behind the ear; but these cases never lasted any length of time, or were in any one permanent. In some of these forms of strabismus I think that it is not improbable that partial disturbance of the cerebral circulation is induced, or some effusion of serum or blood takes place. I have seen some cases of the third and last form of nervous disturbance, where squinting, with confused and double vision, was thus produced.

4. *Idiopathic conditions of the orbital nerves and muscles, unconnected with disturbance in other organs.*—This division of the pathology of strabismus includes all those cases where an alteration is produced in the natural condition of innervation, followed by change in the nutrition by strictly local causes, and it includes, first, idiopathic lesion of innervation; second, excessive use of

certain orbital muscles, however produced; third, painful local impressions on the globe.

The orbital nerves are themselves subject to disease, complicated or not with other affections of that part; thus, there may be enlargement or atrophy of the nerves, or hypertrophy of the neurilemma, and absorption of the nervous matter; the nerves may be compressed or involved in orbital inflammation, or organic disease. The nerves or muscles may be injured in wounds of the orbit.

An increase of innervation, followed by hypertrophy, may attend the excessive employment of any of the orbital muscles, whilst their antagonists become atrophied from disuse. In this manner we can easily account for strabismus originating in imitation or habit, improper education of the eyes, long retention of the head in one posture, disparity of vision, opacities of the cornea, aqueous capsule, or lens, and some malpositions of the pupil.

In the case of disparity in the vision of the eyes, the organ which is imperfect in its retinal functions interferes with the accurate use of the other; and here nature sets about a process to rid herself of this annoyance: the imperfect eye is turned out of the axis of vision by an increase of action in one of the recti muscles, and this, in time, becomes habitual, and the then natural condition of muscular action, the one muscle being increased, the other diminished in bulk; but even here the normal direction may, in most cases, be temporarily restored by the patient's efforts whilst the sound eye is closed. In those forms of squint depending on corneal and other opacities, and on malposition of the pupil, there is modified muscular action to adapt the eye to receive the due impression of light which the situation of the opacity or the pupil would otherwise have prevented.

An ulcer of the cornea may be the first originating cause of strabismus, since here the pain attending its progress is relieved by turning the eye completely away from the influence of light, and, also, as Dr. Mackenzie has explained, by easing the friction of the ulcer in the natural movements of the organ. The increased and irregular muscular action thus produced is attended with a squint, which, by constant repetition, at length becomes habitual, as in the former cases.

The third division of this pathological head includes the effects of painful impressions on the globe, which originate irregular innervation and muscular action. We find that even the application of irritating and stimulating substances to the conjunctiva suffices occasionally to excite this abnormal action; especially, of course, in predisposed individuals. Blows on the eye may also have the same effects, or the influence of a sudden glare of light on the retina. Dr. Mackenzie has narrated an instance in which the strabismus was occasioned by the injection into the eye of the essential oil of orange-peel, causing considerable pain and smarting. Can the communication subsisting between the third and fifth nerve, through the medium of the lenticular ganglion, have any thing to do with these cases, or with the production of strabismus from dentition?

5. Congenital Strabismus.—This includes two varieties, viz: complicated and uncomplicated forms. In the first it may exist in connexion with arrest in the development of some part of the brain, being connected with its own peculiar symptoms, with congenital amaurosis, partial cataract, or organic defects of the eye or orbit; in the second the squint is the only morbid condition, and then we must suppose that there is congenital contraction and hypertrophy of some muscle, with atrophy of its antagonists—similar, in fact, to what occurs in the varieties of "Talipes."

Pathological Anatomy.—This has pointed out nothing more to elucidate the pathology than what we should *à priori* assume, namely, the altered condition of the muscles, the various morbid changes within the cranium, and the pathological conditions within the orbit already mentioned.

In a case operated on by Mr. B. Lucas the muscle was unusually developed; it was fully twice as large as he expected, or as anatomy reveals it to be; it was also powerfully contracted, giving it a rounded appearance, and was very red and vascular, which accounted for the hæmorrhage.—*Lancet*, vol. ii. 1839-40, p. 523.

Having reviewed the pathology, we may now with confidence speak of prognosis, and thence draw some practical aphorisms for the performance of Dieffenbach's operation.

Prognosis.—In forming a prognosis

we must be guided entirely by the knowledge we are able to obtain of its exciting and proximate causes, the preceding and accompanying symptoms, their duration and complications. Strabismus from organic cerebral disease, disparity of vision, partial opacities of the cornea, aqueous capsule, or lens, and displacements of the pupil, are not adapted to the performance of the operation, and are generally unfavourable under any treatment, unless where opacities are naturally removed in young persons, or where operative measures succeed in partial cataract or displaced pupil. The following may be enumerated among the favourable cases, frequently yielding to mild treatment during an early period of their existence, or offering favourable chances of success by the operation, when they have by long continuance become habitual:—Strabismus from abdominal irritation, from habit and imitation, improper education of the eyes, painful impressions on the organ, spasmodic squint, and other forms from the disturbance of the general nervous system; long retention of the head in one position, ulcers of the cornea, and strabismus from functional disturbance of the brain; to these we may add uncomplicated and some cases of complicated congenital squint.

The theory of the operation is this—that when we divide the hypertrophied muscle its weaker antagonist is, for the time, the only acting power; hence it has been surmised that the eye ought to assume an opposite displacement to the habitual squint; but experience disproves this, at least for any length of time, for its contraction serves only to restore the organ to its normal direction, in harmony with its fellow. During the healing of the divided tendon the muscle originally weak gains strength and volume by its increased exertions, whilst the hypertrophied muscle loses both, never again to recover them in the prior degree, and, at the same time, the muscle previously contracted becomes elongated, since it is united whilst the eye is retained in its healthy direction by its antagonist. Hence the principle is the same as in the cure of the varieties of Talipes, &c.: here the division of contracted tendons allows of the placing of the abnormally situated parts in a right direction and healthy situation, aided by, and the situation maintained

by suitable mechanical measures, so that reunion of the divided parts takes place whilst they are thus situated, and permanent elongation is insured, at the same time that muscles, previously atrophied from disuse, are again, from the change of position, called into active service, and in this way the parts are restored to their due balance of strength and appearance, provided that the osseous system admit of such subsequent changes. In two cases operated upon by Mr. B. Lucas, he had an opportunity of ascertaining what became of the muscle after its division. "After having made," he says, "the incision of the conjunctiva in the usual manner, I clearly saw the mark of the original attachment of the muscle in both cases, and a short distance behind this point (from a line and a half to two lines) I found the muscle adherent to the sclerotic."—*Loc. cit.* p. 525.

Finally, I may lay down the following aphorisms to be kept in mind in the treatment:—

1st, That strabismus depending on disparity of vision, produced by some variety of amaurosis, partial opacities of the cornea, aqueous capsule or lens, and displacements of the pupil, would preclude the performance of Dieffenbach's operation, unless such conditions could be removed by appropriate treatment.

2nd, That strabismus from cerebral disease is to be met by treatment directed to the primary cause, and that the continuance of dangerous head symptoms would render any operative measures, directed to the cure of the strabismus, improper.

3d, That spasmodic squint should be treated by remedies directed to the general health, and that, at all events, whilst only occasional, the performance of the operation would be improper.

4th, That all forms, during the early stages, dependent on sympathetic disturbance, affections of the general nervous system, and cases, to the exclusion of those already enumerated, depending on idiopathic affections of the orbital nerves and muscles, are to be treated by general and local measures, directed by their pathology, to the exclusion of the operation.

5th, That the operation may successfully be performed in congenital cases, without any serious complication, and in every case where the squint has become habitual, provided that it is uncompli-

cated, and that its exciting cause, whatever it may have been, and its pathological origin, if disease or disturbance of the abdominal viscera, brain, or general nervous system, have been entirely eradicated.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

The Retrospect of Practical Medicine and Surgery for the year 1840. By W. BRAITHWAITE, of Leeds. No. I: January to July: pp. 200.

WE have here presented to our notice a modest unpretending volume, containing, according to the import of its title, an analysis or digest of the various British and Foreign journals that have appeared during the past six months. We have long thought that such an epitome, tabulated and arranged in a compact form, would be highly valuable to the general practitioner, because it would enable him, with the least possible expenditure of time, to inform himself of the advances made in a profession in whose practice he is engaged. Nor can such a book as the present be unacceptable to the more elaborate reader, since there is no one who would not find considerable profit and advantage in a perusal of the most interesting and important articles, after they have appeared in the various journals. We cannot do better, however, than let the author speak for himself. He says that "There are very few medical men in the present day, probably, who take the trouble to read every periodical, for the sake of gleanings from different parts that which is the most valuable and practical; and there are still fewer who could afford to take them all in, and especially those country practitioners who have not the advantage of subscribing to a public medical library. The work will form a kind of general index to all the medical journals of the day, pointing out those articles which are more particularly useful, and refreshing the memories of those gentlemen who have already read the articles, and, perhaps, forgotten them. It seems a pity that such a thing was never before attempted, and that all the valuable

matter which is to be found scattered in the different medical journals has not been re-spread before the profession, so that a parting bird's-eye-view might be had; for we are quite sure that a great majority of the profession are totally ignorant of the great mass of practical information which is constantly being published in one journal or another, simply because that information is in too *scattered* a form to be readily found by the active practitioner. He has to read too much to find the valuable matter which he wants, and probably his time, his habits, or his income, will not allow him to do this."—*Preface*.

We think the Editor has shown a considerable degree of judgment in the selection, arrangement, and condensation of the different articles; and the judicious remarks which he has appended to many of the subjects will be found highly serviceable to the reader. Regarding it as the first of a series, we hail its appearance with unalloyed satisfaction; and if the succeeding volumes be executed in a style commensurate with the present, our hearty wishes for its success attend it; because we think it will extend to a wider sphere that utility which is the constant aim of the public journalist, and enable the country practitioner especially to keep pace with the rapid improvements in medical science.

MEDICAL GAZETTE.

Friday, September 11, 1840.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

NEW PRIZES FOR THE MATERIA MEDICA.

Our readers will have been gratified to see in our advertising columns that the Society of Apothecaries intends to give annual prizes for proficiency in the knowledge of the *Materia Medica* and Therapeutics. Although we cannot altogether side with those who censure the devotion of the present age to speculative medicine, as some fruit has

already been reaped from it, and more may reasonably be expected, still we feel the utmost satisfaction when a step has been made in extending or teaching those branches of knowledge without which medicine, as a practical art, falls to the ground. Now, few things can be more necessary to the practitioner than a sound knowledge of the tools with which he works—the medicines which he daily prescribes; but, like other necessities, it is often dispensed with. We are not here speaking of a minute acquaintance with the botanical and chemical history of drugs, but of a knowledge of their most obvious properties; one need not go far, indeed, before one meets with the humiliating confession, that a practitioner on such an occasion did not prescribe a particular remedy because he did not know the dose!

Even those who are fresh from their studies are often deficient in this point. It is strange, as we observed a few years ago, that those who have breathed an atmosphere of drugs for five years should not be familiar with the *Materia Medica*; nay, in some instances, should not recognize the commonest articles when placed before them*. Yet so it is; and it appears, from the return made to Parliament, that the rejections at Blackfriars for ignorance of the *Materia Medica* have been very numerous.

Accordingly, the Worshipful Society, well knowing that the best method of producing useful merit is to try to get finished excellence, (as we encourage racers to improve the breed of saddle-horses,) has instituted prizes for proficiency in the *Materia Medica*. The chief conditions are as follows:—

1. Candidates are to have entered on the third Winter Session of their medical studies.

2. A gold medal will be given to the

* *MED. GAZETTE*, vol. xx. p. 696.

best man, and a silver one to the second best.

3. Those who pass satisfactorily will be arranged in two classes; in the first, their names will stand in the order of their merit; in the second, alphabetically.

4. The first examination will take place in October, 1841.

Those who are interested in more minute particulars will find them on the wrapper of our number for August the 21st.

The wording of the conditions appears to allow students to contend for the prizes who are not apprenticed to apothecaries; for it is said that "all medical students will be considered eligible as candidates for such prizes who have commenced the third winter session of their medical study, and bring testimonials from their teachers," &c. This does the Society infinite credit, so that we trust it will not turn out that we are wrong in our interpretation. This prize-examination will be eminently gratifying to those who pass through it; for even those who have not been so fortunate as to attain the honours of the first class, and who, consequently, can only boast of the simple approbation of their examiners, will have the satisfaction of reflecting that they have accumulated a store of knowledge which will be useful to them every hour of their lives. The intelligent pupil cannot fail to have remarked that the medical student, as well as the medical practitioner, passes through an unappointed examination in every company. The literary and the scientific seem to prepare questions to which they expect extemporaneous answers, and he who knows nothing of the history of his art, and of the sciences which are ancillary to it, sinks from the rank of a practitioner to that of an artisan.

It is right to remember that the art of medicine depends on the gradual ac-

cumulation of facts for many ages, and did not first begin to be practised with clearness forty years ago, as is tacitly assumed by many writers. Thus the late Mr. Twining, in his work on the Diseases of Bengal, supposed that the laborious and accurate observation of facts began only of late years to be "substituted for the vague conjectures of former years." Yet, to take one instance, ipecacuanha, the medicine which he recommends so strongly in the treatment of dysentery, had been used long before his time in that disease. Indeed, Helvetius received a large reward from Louis XIV. for this very thing.

The controversy between two London surgeons as to which of them first recommended incisions in erysipelas, might easily have been settled by any one who recollected that it was Freind's common practice: and other methods or opinions, broached from time to time as novelties, are to be found in Celsus, or perhaps even in Hippocrates."

The practical good sense which has always distinguished the examinations at Blackfriars, will, no doubt, allow due weight to the therapeutical subdivision of the subject; and when picked men offer themselves for examination, and strive for the golden prize, which is to attest the highest qualifications, the history of the art will not be altogether forgotten.

The first question that will naturally be asked by the diligent student, anxious to prepare himself for the honourable strife, is, what is the *materia medica*? Over how great a range of substances will the examination extend? We should conjecture, then, that it will comprehend all the simple substances, as well as the preparations of the London Pharmacopœia; and, in addition, all those agents which are commonly prescribed for the restoration of health, though not included in the list. Such are, bathing, mineral waters, electricity, and various

wines; sherry alone being mentioned in the Pharmacopœia. If there are any drugs which, though excluded from the London catalogue, enjoy an European reputation, they may possibly form a theme for inquiry. In good truth, however, it is rather difficult to find any which deserve this fame, if they have it; bistort and arnica are among the few which occur to us; and we believe it would be difficult to carry the number to a dozen. It is true that the practitioner will find in his travels, that drugs rarely or never used in England, from the abundance of better remedies, are reasonably employed in other countries. Thus the expressed juice of *Senecio vulgaris* (groundsel) is a common medicine for worms in Corfu; and the most popular remedy in Malta is oil of sweet almonds, which is used on all occasions.*

Still, such topics belong rather to local or provincial, than to general medicine. Here, the *Senecio vulgaris* is, we believe, never used in regular practice, though Gray calls a weak infusion of it a common purge; and oil of sweet almonds is considered merely an equivalent to olive oil.

Supposing, however, the examination to be limited to the drugs and preparations of our Pharmacopœia, with the other medicinal agents which we mentioned above, the field of inquiry will be wide, but not too extensive. For though pharmacology was once contracted by the French surgeons to eleven substances,† during an agitated period of "war and foreign levy," what was necessary then would be madness now. The poor inhabitants of Lapland must be content with the ground bark of trees for food, and indigenous plants for remedies; but if we can get corn from North America, and drugs from South, why should we do without?

Another question naturally presents itself—how deep will the examination plunge into the mysteries of botany? Not *very* far, we hope. The curious, we had almost said the dreary, subtleties of botany, have so little to do either with the practice of physic, or with that large and liberal knowledge of medicinal substances for which the eager student thirsts, that we hope extreme minutiae may be spared. This is not the place to touch on the constant splitting of genera, and the painful changeableness of medicinal nomenclature which is its result; but we would ask a practical question. When examiners ask to what natural order a plant belongs, *whose* natural order do they mean? There is a sufficient variety to choose from. Thus, Dr. Lindley, in his *School Botany*, places the fig among the *Urticacæ*; Dr. Willshire, in his *Principles of Botany*, among the *Artocarpæ*; Dr. A. T. Thomson, among the *Ficoideæ*, at p. 147 of his *Dispensary*, (ninth edition,) and among the *Urticacæ* at p. 398; Mr. Pereira follows Dr. Lindley, and puts the fig among the *Urticacæ*.*

Perhaps it would be best to refer plants to De Candolle's natural orders, excepting in cases where the London College specially cites some other botanist. For this, and other reasons, it would be desirable that the more eminent teachers of the *Materia Medica* should publish an abstract of their course; and we are happy to add that in this point we are backed by the practical authority of the Society of Apothecaries. In their last Regulations, after recommending a regular course of periodic examinations, they say, "The use of a class-book also, for each particular branch of study, would better enable the student to reduce into order the numerous facts placed before him, and to refer again and again to such points as require a sustained exercise of

* Hennen's Medical Topography of the Mediterranean, pp. 248 & 539.

† Young's Med. Literature, 2d edit., p. 452. ‡

* MED. GAZETTE, vol. xviii. p. 937.

the powers of reasoning, for their full and clear comprehension."

In chemistry three points are to be considered; the one is the proximate and ultimate composition of drugs; the second is the decompositions which take place in the preparation of officinal remedies; the third is the doctrine of incompatibles, or of decompositions which ought *not* to take place in prescriptions. All these topics merit the deepest study; and in all of them, but especially in the first one, a class-book sanctioned by high authority would be of unspeakable utility. It would spare the student much valuable time now lost in wandering from manual to manual in search of the information which he requires, and from the disgust occasioned by their mutual contradictions. We trust that the style of the examination will be such as to make it indispensable for every student to master the greater part of the London Pharmacopœia; its formulæ should be as familiar to him as household words. For want of this necessary knowledge, we often see practitioners hammering out some crude and awkward prescription, when an excellent formula was at hand, had they only remembered it:

But knowledge to their eyes its ample page
Rich with the spoils of time did ne'er unroll

or, rather, it was unrolled, but they refused to look at it.

It would be too *exigeant* to ask the student to examine the Edinburgh Pharmacopœia; and were he to read it very diligently, it might confuse by its discrepant resemblance to our own. The difference of the plants, too, to which the same vegetable substances are referred, would obscure his recollection of the London catalogue. There is one part, however, of its *Materia Medica* which he might transcribe into his common-place book with advantage; we mean the method of recognising the adulterations or imperfections of vege-

table substances, a topic which has been passed over in the London Pharmacopœia. Thus tests are given for gamboge, catechu, yellow bark, oil of cinnamon, conium, copaiba, creosote, creta preparata, croton oil, claterium, olive oil, opium, &c. &c.

Come we, lastly, to the therapeutic part, that part which lends value to the others. Much may be gathered in this department, as well as the rest, from the valuable lectures of Mr. Pereira, with which our readers are familiar; and there is considerable merit in the Dispensatory of Dr. A. T. Thomson, in spite of the numerous errors of the press or pen.

It is natural that such works should dwell chiefly on the opinions and practice of late writers; but we wish that they could afford a little more space to set forth those of earlier physicians. Who does not feel greater confidence in the rough virtues of buckthorn, when he hears that to it Sydenham attributed much of the success of his early practice; and who does not prescribe Tunbridge or Pyrmont with a livelier confidence, when he knows that Boerhaave has said, "*in ferro est aliquid divinum; sed nunquam præparata ejus artificialia id operantur, quod acidulæ martiales.*"

MEDICAL EXPERIMENTS.

By DR. J. C. G. JÖRG.

(Concluded from p. 897.)

Camphor.—This drug was first taken dissolved in spirit, and afterwards in substance. The solution contained a grain in eight drops, and the doses were from 4 to 28 drops. When taken in substance, the doses varied from half a grain to 12 grains. Dr. Jörg likewise gives at length Alexander's famous case, where that bold experimenter nearly destroyed himself with ℥ij. of camphor. The reader will find a short abstract of it in Christison, p. 647. It appears from the experiments of Dr. Jörg, that camphor is primarily a stimulus to the intestinal canal and brain, and secondarily excites the urinary and genital organs, and the vascular system. It affects the intestinal

canal chiefly as a nervine remedy, not so much by any bitter or acrid matter, as by a volatile ingredient; hence it acts almost like alcohol or any powerful and purely spirituous fluid; still these are not its only effects, for its bitter and acrid constituents also come into play. Its power of acting like a spirituous fluid, and causing a sense of burning in the mouth, and of warmth in the stomach and intestines, is increased by taking it dissolved in spirit; in this way, too, its nervine properties become more prominent.

Camphor is to be given in atonic diseases only; and it is not a sufficient indication for its use that some function is suppressed which it has the power of stimulating, unless the *vis vitæ* is at the same time in a low state. Thus it would be wrong to give camphor as a sudorific in acute fevers with a dry skin. From its property of stimulating the intestinal system, it is admirably adapted for diseases where, with great general debility, the functions of the intestinal canal are especially paralyzed. Since camphor does not inflate the abdomen, as valerian, serpentaria, and arnica do, it is unquestionably to be preferred in intestinal tympanitis of an atonic or putrid, but not an inflammatory character.*

The dose should not exceed half a grain to a grain every four or six hours.

Castor.—The results of the experiments with this substance may be summed up in a few words; it has no effect but that of causing eructations. The highest dose taken was xxiv. grains; but Alexander, who, more than half a century ago, took it in much larger doses, came to the same conclusion. It seemed one day to raise a thermometer placed upon the pit of his stomach one degree.

Musk.—The doses of this substance varied from half a grain to fifteen grains. It excited eructation, oppression of the stomach, want of appetite, (sometimes increase of hunger,) and dryness in the œsophagus; confusion, vertigo, weight, and heavy pains in the head; it acts as a stimulant upon the intestinal canal, but more especially upon the brain. As the secondary effects of this stimulating power, we have yawning, sleepiness, prolonged and deeper sleep, and relaxation of the whole body. When musk excites the whole nervous system considerably (as it is wont to do in sensitive persons) its power extends to the muscles also, causing trembling and shaking, or, in larger doses, convulsions. Musk

also increases the activity of the vascular system, making the pulse quicker and fuller, as appears from many of the experiments. Hence it belongs to the general stimulants, or remedies which heighten the *vis vitæ*; but on account of its especial action on the brain, which is perhaps reinforced by the continual odour from the stomach, it must be used with caution.

Dr. Jörg is of opinion that musk stands below camphor as a stimulant, and is especially inferior to it in cases where the organs of assimilation are much weakened. Unless, therefore, we wish particularly to profit by the narcotic power of musk, we shall in general do well to choose some other stimulant; partly, he says, because the smell of musk generally depresses the spirits of the patient and his friends, as it is almost universally looked upon as the last medicine prescribed before death; and partly because it is very dear and often adulterated.

The quantity of musk required for an effective dose was very different with different experimenters. Three grains with one did more than ten or fifteen with another, because the smaller dose was taken by very sensitive persons. But since this remedy, if prescribed in conformity with the rule *contrarium contrario*, will be taken only by those whose nervous sensibility is dulled, not sharpened, it is clear that the smaller doses which act upon the healthy would be inefficacious with the sick.*

Hence when the patient, anteriorly to his malady, has been very sensitive, from three to five grains will suffice for a dose; if rather torpid, from six to ten grains, or more, must be given. The interval between the doses should be eight or twelve hours.

St. Ignatius's Bean.—This remedy was first taken in the form of a tincture made with one part of the drug to eight parts of spirit. The doses varied from 4 to 200 drops, and met with very various powers of resistance in the club of experimenters. Thus Lippert, who seems to have been strychnine-proof, obtained only one half-fluid stool from 180 drops, and no effect at all from 200; while Meurer, in consequence of a dose of 40 drops, was attacked with the following symptoms: extreme giddiness, so that he could hardly stand upright; shooting pain in the head; tinnitus aurium; apparent motion of the surrounding objects; an incapacity of retaining the same idea for a moment; nausea; increased flow of saliva; and want of appetite. He slept better than he had done the preceding night after a dose of 32 drops, but he was attacked by headache at intervals for about 48 hours.

* Some years ago Dr. Tradini published in the *Gazette Médicale* three cases of tympanitis cured with camphor. He recommends much larger doses than Dr. Jörg, as he gives six or seven grains every four hours. There is an abstract of the cases in the *Medical Quarterly Review*, vol. iv. p. 260.—TRANSLATOR'S NOTE.

* This rule, though just, seems to us to have been hitherto but little attended to by Dr. Jörg in his estimation of doses.—TRANSLATOR'S NOTE.

The society afterwards took the drug in powder rubbed up with sugar of milk, but the largest dose was only four grains.

Dr. Jörg informs us that the *Faba St. Ignatii* primarily sharpens the activity of the intestinal system and the brain, and, in a general point of view, stimulates both organs, but with many peculiarities. Among these are its remarkable influence upon the salivary glands, and, doubtless, upon the pancreas and the mesenteric glands; and also the disappearance and re-appearance of its effects. This, however, is not always the case; the symptoms caused by this drug do not always suffer a remission and an exacerbation, nor does the re-appearance observe any regular interval.

Dr. Jörg recommends its use in weakness of the stomach, and in weakness of the eyes connected with inactivity of the brain, as an alterative in chronic diseases, and as the means of breaking, by a sudden shock, a morbid chain of symptoms whether in mind or body.

Dr. Jörg informs us that the dose should usually be half a grain or a grain, but if the tincture be used, the dose should be somewhat more than proportionably greater. It should not be repeated till after an interval of 24 hours; nay, the interval may sometimes be prolonged to 48 or 72.

Assafœtida.—The doses which were taken of this drug varied from half a grain to fifteen grains. It appeared from the results that *assafœtida* is a powerful stimulant to the alimentary canal, from the mouth to the anus; but it stimulates the upper part of the tube, the œsophagus, the stomach, and the small intestines, more than the lower part, or large intestines. This is a natural consequence of its affecting the intestinal canal chiefly by a specific acidity, and this acidity being decomposed principally in the upper part of the tube. Hence *assafœtida* is a good remedy for assisting digestion, but not for opening the bowels. It likewise stimulates the brain, but it is probable that this is only a secondary effect, and is a result of its stimulating the abdominal ganglia, and increasing their sensibility. It likewise stimulates the circulation, the urinary and the genital organs.

From these properties, Dr. Jörg deduces that *assafœtida* is very erroneously prescribed in hysteria, and in many hypochondriacal cases. Nor is it prescribed only in unsuitable cases, but in over-large doses. Half a grain will in general be a sufficient dose, though there are cases where two, three, four, or five grains may be taken at once; the remedy must not be repeated oftener than every twenty-four hours at the most.

Opium.—The society first took this drug

in the form of tincture prepared according to the Saxon Pharmacopœia, excepting that simple distilled water was substituted for cinnamon water. It was made by digesting one part of purified opium with three parts of rectified spirits and three parts of distilled water, until the opium was dissolved, and then filtering; the tincture, therefore, was about three times the strength of the London one. The doses varied from half a drop to thirty-six drops. When opium was taken in substance, the range of doses was from 1-12th of a grain to three grains.

The following are the conclusions at which Dr. Jörg arrives:—

“Opium first of all attacks the brain, and that more than any other organ, causing rapid and considerable congestion in it; and hence, in the beginning, it causes, in a proper dose, the feelings of lightness in the head (it seems as if the head itself were borne up by the air, as if it flew,) unusual cheerfulness, and also a state like intoxication; afterwards, confusion, giddiness, heaviness, oppression and pain in the head; lastly, sleepiness and even deep and sound sleep. Inasmuch as opium, like all the more powerful narcotics, chiefly attacks the anterior part of the brain, in so far does it especially affect the eyes and the nose, creating a sense of dryness there, and also secondarily obscures the sight, probably because it causes congestion in these organs.

“The stimulating power of opium, however, extends also to the whole nervous system; but the state of primary irritation frequently lasts so short a time, that it escapes our observation; for when the congestion in the brain has reached a considerable extent, (and, when opium has been taken, this often happens in a very short time, — in a few minutes, if the dose has been considerable,) the secondary state, or state of depression, comes on, particularly in the nerves under the influence of the will; and relaxation, weariness, faintness, immobility of the limbs, &c. supervene so rapidly, that in general we entirely overlook the preceding excitement. But if, on the other hand, opium is given in the proper dose, so that the primary excitation of the brain and nervous system is but moderate, those phenomena are offered to our observation which spring from an exaltation of nervous life; among these I number an increase of common sensation, or of the consciousness of existence, a more intense and exquisite perception of the external world, and greater activity in the muscles. But whether this state, with the corporeal and mental sensations flowing from it, lasts a short or long time, it is followed by the opposite condition, the intensity of which is proportioned to that of the previous

excitement; with this peculiarity, however, that the depression lasts much longer than the preceding increase of nervous life.

"Next to the brain and nerves, opium exerts its stimulus especially on the intestinal canal, and primarily causes powerful contractions of the stomach and of the small intestines, and, in a less degree, of the large ones; hence it causes oppression of the stomach, and perceptible but not painful movements of the intestines, and griping and colic pains, with a desire of evacuating the rectum; and also debility, nausea, and lessened or increased appetite. But in this great organ likewise the primary excitement is followed by a secondary depression of the *vis vitæ*, and hence there come on constipation, retention of flatus, and a tympanitic state of the abdomen, with a frequent desire to go to stool, although for a long time the *fæces* cannot be evacuated. For a long time the contractions of the intestinal canal seem to remain too weak to move on the harder excrements.

"From the stimulating effects of opium upon the nervous system and the intestinal canal, we learn its cardinal operations, on which its other numerous effects depend. When given in the smaller doses it does not act upon the whole of the two systems just named, while in the larger ones it extends to the vascular system, the skin, the urinary organs, and also the genitals; in such a manner that it calls forth in them alterations of more or less importance and variety, according as it is used in larger or smaller doses, and finds in the body a greater or less susceptibility to its impressions. What morbid symptom cannot a remedy produce, which primarily and secondarily changes the condition of the whole nervous system, and of the intestinal canal, in the way that opium does? Can we be surprised if occasionally palpitation, quickening of the circulation, hardness, largeness, and fulness of the pulse, or retardation, smallness, and contraction of the beat, and even an intermission of several beats, should arise; if the temperature of the body sometimes is increased and sometimes diminished; if at one time sweat breaks forth, at another the hot skin remains dry; if the urine deviated from the standard in quality or quantity; if the generative organs sometimes seem to be entirely quiescent, or sometimes too active; if rheumatic pains harass the extremities, &c. &c.? Nay, if in a more intense degree of its action, convulsions and apoplexy make their appearance?" (pp. 437-439.)

Dr. Jörg comes to the extraordinary conclusion, that opium ought very seldom to be used. He tells us that for the last ten years he has very rarely used opium, and that he is firmly convinced that it is

really indicated in very few cases of disease, but that in these few cases it is an indispensable medicine. The only ones he mentions are an excited, but not inflamed, state of the intestinal canal, with increased secretion from its inner surface, and consecutive vomiting or diarrhœa; and an excessive secretion from the kidneys, the genitals, and the skin.

Dr. Jörg recommends that the dose of opium should not exceed from one-twelfth to one-fourth of a grain, at intervals of 6, 12, 24, or more hours. When given as a clyster, in gruel or decoction of linseed, to soothe irritability of the bowels, the dose is to be from half a grain to a grain.

Digitalis.—A quarter of a grain was the smallest, and three grains the largest dose taken by any of the club, with one exception: Lippert carried the dose as far as ten grains, without any effect, though his medicine was weighed out from the vial which supplied the other members. (p. 445.) A few of the experimenters likewise took the tincture, infusion, or decoction.

The results of the experiments shewed that digitalis acts primarily as a stimulus to the brain, the intestinal canal, the urinary and the genital organs; and secondarily, as a sedative to the vascular system. We believe that the credit of having discovered that the sedative action of digitalis is preceded by a stimulant one, is entirely due to the Leipzig society.

It is to the power which digitalis has of stimulating the brain, that Dr. Jörg attributes its want of success in hydrocephalus; in another of his works (*Ueber die Kinderkrankheiten*), he observes, that by means of his experiments he discovered in a few weeks what Gölis was sixteen years in finding out, namely, the inutility of digitalis in acute hydrocephalus.

Dr. Jörg likewise disapproves of the foxglove in all dropsies where there is decided inflammation, and in whooping-cough; and doubts whether in many diseases of the heart its secondary or depressing power will not be unprofitable or injurious. Next to the powder, the decoction seemed strongest. The dose of the powder is not to exceed a quarter of a grain, half a grain, or, at most, a grain. The preparations being more or less uncertain, must be given in doses containing a proportionally larger quantity of the drug. The doses of foxglove, says he, are repeated too frequently; the intervals between them ought to be of 12, 24, or 48 hours.

Tincture of Iodine.—This preparation was made by dissolving 48 grains of iodine in an ounce of alcohol, and the doses varied from one to eighteen drops. The results showed that iodine acts primarily as a stimulus to the intestinal canal, from the

mouth to the anus; and it would appear that it excites the parietes of the intestines in a manner similar to that of healthy and very concentrated saliva and pancreatic juice. Hence in healthy persons it produces a salt taste, increased secretion of saliva, increased hunger and thirst, perceptible and increased movements of the intestines, slight griping, discharge of flatulence, excrements, and so on. Its stimulating power, however, extends to the brain also, as is the case with all remedies which considerably quicken the activity of the intestinal canal; hence it causes confusion in the head and heavy pain, sometimes of one, sometimes of another part of it. It also augments the flow of blood to the trachea and lungs, bringing them into a state approximating to inflammation, or actually inflaming them. This action seems to extend even to the Schneiderian membrane, and hence it secondarily causes increased secretion of mucus in the bronchi and the cavities of the nose. As iodine so powerfully excites the intestinal canal, it must necessarily affect the urinary and genital organs when its action reaches a very high degree, or is kept up very long.

After a few more observations, Dr. Jörg concludes his account and his book by asking—

“Who would then wish to limit this splendid remedy merely to the treatment of bronchoecle? We shall obtain most from it in diseases of the abdominal viscera, in weakness of the intestinal canal, in obstructions of the abdomen, in scrofula and similar maladies. Where particularly the vegetative processes of life are prostrate, and this morbid state is accompanied by diminished *vis vitæ*, it promises the greatest performances. Yet it must always be used with caution, lest it should excite inflammation, or too great a luxuriance of growth, or resolution of the tissues. (*Zu beträchtliche Wucherung oder Auflockerung.*) From two to eight drops every 24 or 48 hours will be the usual dose.” (p. 500.)—Abridged from Dr. Jörg’s *Materialien zu einer Künftigen Heilmittellehre*. (Our scanty compendium can hardly give a notion of the German minuteness and diligence which are conspicuous in every page of the original. Its merits are undoubtedly very great. Yet, in many instances, Dr. Jörg appears to have concluded too hastily from the healthy to the sick. He believes in the discutient powers of arnica, though the society afforded no tumor to discuss; surely the anodyne and antispasmodic powers of opium are beyond the reach of doubt, though among the happy experimentalists of Leipzig there was not a pain to be soothed, nor a spasm to be resolved.—

PRACTICAL OBSERVATIONS

ON

PECULIAR AFFECTIONS OF THE THROAT,

ARISING FROM ABSCESS BETWEEN THE PHARYNX AND SPINE, AND OCCURRING IN CHILDREN AND ADULTS;

Exemplified by Cases.

By CHRISTOPHER FLEMING, M.D.,

Member of the Royal College of Surgeons, Ireland; Member of the Court of Assistants; Lecturer on Surgery, &c. &c.

[At the request of the intelligent author, we insert the following paper, which originally appeared in the Dublin Medical Journal.—ED. GAZ.]

The several obstructions, mechanical or otherwise, which occur in the fauces, and impede the functions of respiration or deglutition, have particularly attracted the attention of the profession. They are frequently met with, and in the majority of instances they are referrible to causes sufficiently manifest. Occasionally, however, considerable difficulty attends their diagnosis, particularly in children, from the extreme obscurity and anomalous character of the symptoms. Such difficulty occurred in those attendant on inflammation at the back of the pharynx, terminating in abscess, illustrative of which I beg to subjoin the following cases.

Of a family of five boys the eldest, aged seven years, the youngest one year and eight months, three were attacked as follows, without any assignable cause.

The youngest, a healthy child, went to bed well; after about two hours awoke with vomiting, which attracted no particular attention; passed the night tranquilly; next morning appeared heavy, took his ordinary mid-day sleep, and was found, about two o'clock, P.M., in convulsions. Immediate assistance was procured, which, notwithstanding the most prompt and active treatment, proved unavailing. I saw him for the first time about two hours before death; he was then comatose, and almost pulseless; the left side was wholly paralytic; the right slightly convulsed. He survived the attack only twenty-two hours, dating from the supervention of the convulsions—thirty-nine from that of the vomiting.

On examination after death, considerable vascular turgescence was found within the skull, and throughout the substance of the brain. No other appreciable lesion was discernible.

This occurred on the last Friday in May, 1836.

On the following Sunday, the third boy, aged six years, was attacked. He was a remarkably delicate child, and much emaciated, being then only convalescent from remittent fever. He now vomited repeatedly, complained of violent pain in the head, and had other smart febrile symptoms. However, by mild depletory measures, he passed through an illness of three or four days' duration, without any remarkable occurrence.

On Monday, the fourth boy (the subject of this communication) sickened with precisely the same train of symptoms. His age was three years and a half, and in appearance he was healthy. The premonitory symptoms of his attack, at first mild, after about thirty-six hours assumed most intense severity, and without unnecessarily particularizing their progress, it may be stated, that the most aggravated form of high inflammatory fever set in, principally engaging the cerebral organs, and requiring the most energetic treatment to combat it. On about the fourth day, convalescence appeared established, and Dr. Crampton (whose valuable assistance I had throughout the progress of this case) discontinued his daily attendance.

From day to day a peculiar fixed position of the head, and stiffness in the neck, now attracted attention. The head was drawn back. The muscles, at first tense, became completely and permanently rigid, and the movements of the head painful, and remarkably limited. Soreness of the throat was complained of, and also great difficulty in swallowing, at times accompanied with violent spasmodic efforts. There was no cough, and the voice remained perfect. The articulation became remarkable—the words being as if drawled out with pain and difficulty, and at times perfectly unintelligible.

Repeated and careful examination of the fauces and neck could not detect any apparent local cause for those symptoms, which, with varied degrees of intensity, advanced, producing equally alarming constitutional disturbance and debility.

At first, disposed to attribute them to concurrent local causes, such as the quantity of mercury administered during the acute illness of the child, the cold from the renewed application of ice to the head, or some partial internal effusion, the result of the acute inflammatory attack, more serious mischief was now apprehended from their increasing severity and permanency. The treatment adopted was principally with the view of promoting the absorption of any fluid effused, and consisted chiefly in the exhibition of mild mercurial alteratives, and the application of counter-irritants of the region of the occiput.

On about the tenth day, the symptoms had reached their acmé; the child, emaciated and weakened, had no relish for food, and appeared to drink merely to allay thirst, the efforts at swallowing being convulsive and painful. He was now in a perfect state of somnolency, regardless of every thing about him, when accidentally, while sitting beside his bed, I perceived that *position* most remarkably influenced the severity of the prominent symptoms. Stupor in the recumbent posture, almost amounting to perfect coma, in the sitting, or even semi-erect, resolved itself into a comparative sensibility. Respiration, slow, laboured, and stertorous, or rather roaring, (as described by the attendants on the child,) in the former position, became comparatively tranquil in the latter, and a pulse, in the one, ranging only a beat or so above forty, in the other assumed a more natural character. Again, fluids were more frequently darted convulsively forwards through the nostrils or mouth, than passed into the stomach, or were ejected, as in the act of vomiting, and the recurrence of the symptoms of cerebral compression took place on returning to the recumbent posture, which for the last three days had been almost the permanent one.

I now considered that this relation of symptoms might still be caused by mechanical obstruction in the pharynx, although repeated examinations on former occasions did not lead me to this conclusion. An additional obstacle presented itself in the fixed position of the jaws, so that it was only by considerable force I could so far separate them as to admit of even getting my little finger between them. On forcing it back, I accidentally, but distinctly, felt a tumefaction beyond the base of the tongue, giving, as well as a compressed finger could indicate it, a sense of yielding. To get a view of it was utterly impossible. The soft palate and uvula were easily discernible, but the depression of the tongue gave so much pain, and the separation of the jaws was so very limited, that further investigation was totally out of the question. Indeed, in addition, the evidence, even from touch, was necessarily momentary, from the severe paroxysms of dyspnoea attendant on the examination. Although I had never heard of, nor witnessed, a case of the kind before in children, it at once occurred to me that this might be an abscess at the back of the pharynx, mechanically producing the above symptoms, and having stated this as my opinion to the family, the assistance of Dr. Crampton and Mr. Cusack was immediately procured. After a patient, though extremely unsatisfactory examination, they coincided in opinion with me as to the presence of a

tumor in the situation alluded to, and it was determined that I should perforate it with an explorator which I had provided for the purpose, with the view of ascertaining its actual nature,—a doubt existing on this head, not alone from the extreme firmness of the tumor communicating a very indistinct sense of fluctuation, but also on account of its probable anomalous nature, from the previous acute and present chronic cephalic symptoms. With every necessary precaution I accomplished this object, though with considerable difficulty, and, to my great gratification, witnessed the sudden gushing forth of a large quantity of healthy purulent matter. The whole features of the case were almost instantaneously altered. The somnolency was removed, deglutition was facilitated, and more cheering prospects manifested themselves. Nourishment was freely given throughout the day, and quinine administered in small and repeated doses.

At my evening visit I perceived that the stertorous breathing had returned, and that the more prominent symptoms, which had ceased since the operation, were again in some degree present. I examined the throat, and fortunately found the separation of the jaws now accomplished with ease. The abscess was again filled, with the opening closed. I introduced a carefully protected sharp-pointed bistoury into the site of the opening, and freely enlarged it downwards. The relief was instantaneous. I now directed the trunk of the child to be elevated as much as possible, and the head depressed. The night was passed comparatively tranquil; the quantity of matter which escaped through the mouth was considerable, largely staining the pillow. The next day the boy was able to play with his brothers, and subsequently his improvement was progressive, though slow.

He is now a fine healthy boy. I do not particularize the treatment adopted during his convalescence; there was nothing peculiar in it, its principal object being to improve the general health. The next case which I shall select is that of a boy aged seven months, proving the remarkable fact of the occurrence of such an affection during the first period of childhood, as the former does during the second.

In April 1838, I was sent for to see this child by the father, who stated that he had great apprehension his little boy was labouring under water on the brain; that many children of his immediate family had fallen victims to it, and that the symptoms under which this child laboured were exactly those by which the attacks of the former had been ushered in. On visiting the child I found every indication of gastro-enteric derangement, so common

at this period of life, and very suspicious cerebral complication, rendered more so from the fact of hereditary predisposition. In addition, I found that some lymphatic glands, on the left side of the neck, near the angle of the jaw, were enlarged and painful, evidently depending on ulceration behind the corresponding ear. The mouth, fauces, and pharynx, were free from lesion, and one of the incisors on the lower jaw had just made its appearance.

The treatment was principally directed to the abdominal system, and to the relief of the glandular irritation noted. After a few days, improvement was so manifest, that I had omitted a visit on Friday.

On Saturday morning I received a hurried message to see the child, and found that the more alarming symptoms had all returned during the previous night, that the restlessness was incessant, that the vomiting was constant, that the flushing of the face was renewed, that the breathing was loud, laboured, and very irregular during the night, and that he constantly started from most disturbed sleep, which would only be tolerated in the nurse's arms; that every attempt at putting him in the cradle aggravated the pulmonary symptoms. In addition, I observed that the head of the child was rather drawn back, and that the chin projected somewhat unnaturally. He immediately screamed when the jaws were attempted to be separated, and in the region of the neck there was the greatest tenderness, particularly over the glands above alluded to. The integuments were free from discoloration, yet still the tumefaction was decidedly increased, and the slightest motion of the head appeared to give great pain.

At the moment, I was disposed to attribute the recurrence of those symptoms to a smart attack of inflammation in these glands, and was led to hope that the combating it would relieve them. The treatment was accordingly directed with that object in view. Leeches were applied; fomentations and poultice used, and a smart mercurial purgative administered.

Sunday.—Night spent wretchedly; no alleviation of symptoms, with the exception of those connected with the inflamed glands; they are better: the other symptoms are, if possible, more aggravated. In addition to those enumerated in the report of yesterday, there is now a gurgling noise in the fauces, as if from accumulated mucus, and throughout the lungs there is evidence of considerable effusion into the larger bronchial tubes; there are repeated and apparently painful and difficult efforts at swallowing, accompanied with frightful paroxysms of dyspnoea occurring at irre-

gular intervals, during which the countenance becomes suffused, purple, and almost convulsed, and it is remarked that those immediately supervene on attempting to place the child in the cradle; there is incapability of sucking, though great desire for the breast, the nipple of which is seized with avidity, and equally rapidly ejected with a sudden and spasmodic regurgitation of the milk. Any fluid placed in the mouth either remains for a short time, and then gradually dribbles out, or otherwise produces a paroxysm accompanied with similar phenomena. At the moment of my visit, the repeated exertions of the child at the attempt of swallowing, the severe dyspnœa, and the great accumulation of mucus in the fauces, with the very restless state of the child, led me to apprehend the supervention of a fit of convulsions. I thought I recognised some of the features of the above case, when, from some unintentional act in my examination, a most severe paroxysm supervened. The child appeared suffocating. I rapidly passed my finger into the fauces, and feeling a fulness, I made pressure against it, which was increased by a convulsive effort of the child. A sudden discharge of purulent matter got exit through the nostrils, and temporary relief was obtained, until I procured the additional assistance of Sir Henry Marsh and Mr. Cusack.

Perhaps about an hour or so had elapsed from the above occurrence when we met in consultation. At this time the breathing, though principally nasal, was more tranquil; and a small quantity of fluid had been swallowed, but with much difficulty. The appearance of the child could not but make an impression upon those who saw him. The nostrils were filled with matter which trickled down the lip; any attempt at placing him in a recumbent posture was instantly followed by frightful dyspnœa, rendered still more serious from the great accumulation of mucus in the fauces. I directed attention to the throat, but notwithstanding every effort, no accurate view could be had of the back of the pharynx. The narrow space behind the root of the tongue was filled with pus and bubbles of frothy tenacious saliva, to clear which away repeated unsuccessful attempts were made. Here the freedom of separation of the jaws allowed of free, though rapid examination of the fauces, but the back of the pharynx could not be seen. I, however, felt a distinct tumefaction, and failing to puncture it with the grooved curette, as in the former case, I was obliged to rest satisfied with what had been done, arranging to watch the progress of the symptoms, and to support the child by every possible means, by introducing fluids through a

tube passed through the nares, and by broth enemata; to be prepared, if necessary, to open the trachea should any fresh symptoms of suffocation supervene; and in addition, to keep constantly cleared away the accumulating phlegm at the back of the throat.

By visiting at short intervals, and carefully enforcing the above injunctions, the strength was supported, and the symptoms to a certain extent stayed. Next day they were stationary, though it was quite evident that considerable obstruction yet existed in the throat; however, the strength was improved, and the countenance of the child decidedly better. Another day passed without any material change, when the discharge from the nostrils ceased, and evidently, any opening made, or rather the ruptured portion of the sac had closed. Difficult respiration in any but the erect posture, or on an inclined plane with the head considerably depressed, recurred. Perfect inability of sucking and swallowing again set in, and suffocation appeared impending, when Mr. Cusack saw the child, and was still more satisfied of the presence of a tumor at the back of the pharynx. It was so tense and so unyielding, that did not the history of the case justify the presumption that matter was present, the absence of any sense of fluctuation would have caused extreme doubt; another difficulty presented itself in its being below the level of the tongue. The very limited space to operate in, together with the risk of wounding the neighbouring vessels, on account of the disposition of the swelling rather from the median line towards the left side, suggested the propriety of selecting some instrument the action of which could be accurately gauged. That which I had used in the former case was objectionable, not alone from the want of sufficient command of it from its conformation, but also from its shape. It was agreed that delay might be safely hazarded until next day, leaving word however, that should any urgent symptoms set in, I should be informed.

Next day, I found that throughout the night great apprehensions were entertained lest suffocation should have taken place. All other bad symptoms remained, if not aggravated, at least stationary; and having arranged in the interim with Mr. Cusack, an instrument was contrived which succeeded most admirably. It consisted of a trochar about four inches long, one extremity of the canula being slightly curved, the other with a ring on its upper surface to receive the fore-finger; into this canula was passed a jointed stilette, with, at its opposite extremity, a ring for the thumb, and a moveable screw to graduate

the projection of its point. Mr. Cnsack having firmly supported the head of the child, I passed the fore-finger of the left hand towards the back of the pharynx, there resting the point of it, and guiding the armed trochar with the concealed stilette along it, accurately fixed it on the tumor, pressed forwards the stilette to its limited mark, and withdrawing it by an opposite manœuvre, was gratified to see a quantity of healthy purulent matter darted forwards on the child's clothes.

The relief was immediate; the hæmorrhage trifling; and the result permanently successful. In this case it was unnecessary to renew the opening; the discharge, at first temporarily ceasing, returned, and the cure was rapid.

The boy is now a fine healthy boy. The constitutional treatment was similar to that adopted in the last case.

Such is the history of two extreme cases of acute abscesses at the back of the pharynx, occurring in children, selected from others of the same nature, which I have witnessed within the last three years, and necessarily with opportunities comparatively limited. I have brought them forward as remarkably illustrative of the symptoms attendant on their progress; as novel at that period of life, in the records of medicine, as far as I have been enabled to learn, from the investigations I have made; and as corroborated by the testimony of others.

I cannot instance the history of any similar acute case occurring in the adult, which came immediately under my observation, although I have watched for such with much anxiety for no very short period. I have attended many severe cases of tonsillitis, which have terminated in suppuration, some of which I have opened between the pillars of the fauces, and some on the anterior part of the velum. I have met with abscesses of the velum itself, and of the uvula, and I have met with one or two of that description, so accurately and so beautifully described by Petit*, which form behind the tonsil, and I believe always implicate more or less the auditory apparatus, but I have never been able to detect an abscess situated distinctly at the back of the pharynx, or perhaps, I should rather say, that the symptoms attendant on such did not attract my attention. That such collections take place cannot, however, be questioned. The experience of our surgeons in extensive practice will bear testimony to the fact of their occasional, though extremely rare occurrence, and will, I am sure, confirm the statement,

that their attendant symptoms are so equivocal and anomalous, that if discovered, they have been so by the merest accident. The first systematic author I find particularly alluding to their presence, is Sir Astley Cooper. In his lecture on Abscesses, he thus expresses himself: "Abscesses are also dangerous, from their being situated in vitally important parts, such as the brain, heart, or lungs; or when they are not seated in parts of vital importance, from their pressure on essential organs."

"CASES.—A woman was admitted into Guy's Hospital for a complaint in the throat, occasioned by *swallowing a pointed bone*. All she complained of at first was a soreness in the throat; but she was shortly after seized with difficulty of breathing, which increased greatly, and she died.

On examination after death, I found, upon making an incision into the pharynx, that between it and the forepart of the vertebræ a large abscess had formed, which, by pressing the pharynx forward on the epiglottis and glottis, occasioned difficulty of breathing, and in the end destruction of life. Shortly after this, Dr. Babington came to this hospital with a friend of his, who was labouring under great difficulty of breathing. He requested me to examine his throat. Having put my finger on the back of the pharynx, and felt fluctuation there, I told him that this was a case of which I had seen an instance, where the patient had died from a collection of matter formed in the same situation. I immediately procured a seton needle, and including it in a canula, like a trochar, I put it down into the pharynx, let out a considerable quantity of matter, and the patient was relieved. Here was a case which, but for this operation, would probably have terminated fatally, by the pressure of the matter on vitally important parts."

In the "Dictionnaire de Médecine et Chirurgie Pratiques," under the article "Pharyngotomie et Pharyngotomie," another case will be found, in which the presence of an abscess at the back of the pharynx was detected, and its puncture followed by successful results. But in each and all of those recorded cases, it is a remarkable fact, that the abscess was actually formed, before a suspicion of its existence was entertained, so extremely equivocal were its premonitory symptoms, even in the case where the exciting cause naturally led to the examination of its immediate seat. Hence, it appears to me, that the subject is one of extreme importance, and fully deserving of separate investigation.

[To be concluded in our next.]

THOUGHTS ON MEDICINE.

[Concluded from p. 927.]

CALLICRATES is a medical system-monger. He takes an idea, and attaches himself to it; broods over it, fecundates it, fashions and stretches it beyond all measure; and it sometimes becomes a fixed idea, a monomania. Let him once bestride the back of his systematic chimera, and he is ready to fight to the last extremity. Experience, facts, phenomena, observations, inductions, principles, however opposed to his system, do not trouble him in the least; he applies his magnifying-glass to them, and from that moment sees what he wants to see, and as he wishes to see it. "There is nothing," he says, with energy, "better demonstrated or more certain; a man must be very ignorant, or very dishonest not to see as I do;" this is the pathognomonic symptom of his madness. After this every proof suits him, every argument is good. However little you press him, Callicrates will maintain that white is not white, that a stick has not two ends. He reminds one of that bold and subtle dialectician who had an answer for every thing. Some one said, "the north wind is blowing;" "by no means," he replied; it is the south wind—but it is going home."

When a student came to solicit the protection of Louis, the celebrated secretary of the Academy of Surgery, the latter never failed to ask, "Do you know anatomy?" "Yes, sir." "Well, then, describe the stool which stands before you." Louis was right, and used an excellent means of fathoming a man's understanding, and making out his future destiny; in this way he judged of the sagacity, the logic, and the methodic manner of the candidate. There is an infinity of things in our art which are like Louis's stool, and many persons would find it difficult to describe them well.

Let us be good and just, let us be frank and open, but do not let us be dupes. Let us say as a man of sense did: "I give you notice that I cannot allow myself to be bitten without leave asked; I want to bit myself, or, at any rate, to give my vote so as to know who is to ride me."

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF THE SPINE, *continued.*—
CURVATURE, its Prognosis and Treatment.

Prognosis.—The prognosis, in cases of curvature of the spine, depends upon the age of the patient, the duration, causes, degree, and complications of the disease. Certain curvatures, which have not yet become permanent, and which are dependent on a general disease, or upon debility of the muscular system, may, in a few instances, disappear under a favourable modification of the general health; but it is always dangerous to rely on the power of nature to cure these cases, because experience has demonstrated that in the greater number of cases this hope would be deceived. The younger the patient, and the less decided the curvature, the more chance of success does prudent treatment offer. In aged persons, and even in adults, a well-directed treatment perseveringly employed may arrest the progress of the disease, but will not effect a complete cure. If the disease be dependent upon change in the vertebræ, the prognosis is always more unfavourable than when it depends upon muscular debility. If there be several curvatures the chances of success are less than when there is only one; and if they be of long standing, as alteration in the vertebræ increases day by day, the disease is incurable. But, although there may be no age in which we are interdicted from hoping that a cure may take place, yet there are

other elements of prognosis to be taken into account: for instance, we cannot hope to remedy a deformity depending upon tumefaction of the intervertebral cartilages, without modifying the condition of the system under which they have been developed: as a basis for prognosis, therefore, we must endeavour to ascertain the cause: we must then seek to ascertain whether the deformity is increasing; because if it be, what power is to sustain the body when the curvature is considerable? The muscles cannot; their action is essentially intermitted. Ossification can alone give the necessary support, and no change in form can then be expected.

The remark "that for two or three years there has been no increase of deformity;" that, still more important, of the progressive and complete cessation, for some time past, of all the indefinite symptoms of inexplicable functional lesions which accompany the disease, are strong presumptions that the time for ameliorating the deformity is passed. To discover this state we are advised that the patient must be undressed, he must lie on the back, the relaxed muscle must be rubbed with a stimulating liniment, the retracted muscle with astringents, and by convenient tractions we must seek to straighten the spine. If in these attempts the patient experiences a sense of tension and weight at the situation of the curvature, and not at the points of insertion of the contracted muscles, we may conclude that ankylosis exists. This becomes still more clear when temporary or permanent extension brings no change in the column; if, on the contrary, a change is apparent, we may encourage some hopes of amelioration. Ankylosis is not very frequent; we do not usually meet with it except in old and very decided curvatures, and in persons advanced in age.

It is important to consider whether in any particular stage of the disease it is

curable. In a first degree, when the chances of cure are greatest, the symptoms are vague enough to escape even the watchful vigilance of a mother, and medical men are rarely called upon to see them, and if they are they frequently detect nothing, reassure the parents, and refer the inconvenience to vicious attitudes. At this time the spinous processes have suffered no deviation. The characteristic sign which is generally present before any curvature of the spinous processes is apparent, is an elongated prominence between the spinal border of the scapula and the spinous processes. Even in this degree there is in the attitude and the walk some embarrassment, which it is true often escape notice. Pass to the next stage, the curvatures become marked, the dorsal predominating; the trunk is generally inclined to the right, the shoulder is raised. The left side is hollowed, the excavation commencing at the axilla, and extending to the ilium. The right hip projects, the left is almost effaced. Here the chances of cure are greatly lessened. Pass on, and the condition becomes remarkable for the angular prominence of the ribs posteriorly; the ilium approaches to the base of the chest, the gibbous condition and shortening of the trunk are very striking. The superior curvature then extends high; the shoulders are so raised that the head almost seems as if it were shrunk between them, the stature becomes greatly lessened, the arms present a length very disproportioned to the trunk, the fingers are long, the lower jaw prominent, the cheek bones projecting, the nose pinched. Palliation is all that can be expected at that period.

What is essential for you to bear in mind is the attitude of patients in this condition. You must distinguish between those which are natural and those which are artificial, suggested by parents for the purpose of lessening the appearance of deformity. We may see a patient incline forward the arm which corresponds to the raised shoulder, to endeavour to lessen it, and to incline in an opposite direction that of the other side. If the deformity be very great this dissimulation cannot be practised; the left arm looks longer than the right: not that the right is really shortened, but as it is placed further back, it cannot be brought so far forward. Add to that the right arm seems pressed against the chest, whilst in consequence of the depression the left is separated from it. The legs are not equally resting on the ground. It is commonly imagined that this attitude depends upon an inclination of the pelvis; but it does not. Whatever may be the degree of incurvation of the spine, so long as there is no difference in

length of the lower limbs, the two crests of the ilium should rest on the same plane. Often patients have the right knee bent, and the limb resting against the left, which supports the weight of the body, when the predominant curve inclines to the right. At other times it is the left limb which is flexed, and the right limb which supports the body.

Sometimes the disease runs through its different stages rapidly, in a year for instance; usually it is several years increasing; it sometimes remains stationary up to old age, or to the occurrence of some serious disease.

It is very common to hear patients complain of anomalous pains, sometimes dependent upon pressure of the spinal nerves as they pass out sometimes upon the twisting of organs; respiration and circulation are often disturbed, and the countenance is pallid. The digestive organs are interfered with: there is often much debility of the lower limbs. In a majority of cases the existence of such individuals is not greatly prolonged; they die of phthisis, heart disease, or some chronic affection. Still, every considerable deformity is not quickly mortal. When the curvature is very gradually produced, when important organs become almost insensibly accustomed to the pressure to which they may be subjected, when the patient is naturally robust, and the deviation is restrained from making further progress, health may be restored, and the patient may attain old age; but these are exceptions, on the faith of which we should not be justified in neglecting all available means of cure. It is believed by many persons that the inclination towards the left side is more dangerous than that towards the right, because it interferes most with the heart's action. I do not wish you to understand that the curvature towards the right has little danger, and that the left has much. You may see in museums many specimens of old people in which the displacement was to the left.

Treatment.—After what has been said, you will already have concluded that no uniform plan of curing curvature of the spine can be admitted. You are not among those who believe that any original feebleness of the constitution is a general or unique cause of all curvatures, or that a tonic plan of treatment is capable either of curing or even arresting them. You will not tell the friends of the patient that with puberty will come increased muscular power, and a disappearance of the deformity. When that puberty arrives, the curvature may be beyond the resources of art. Yet this is a common error. Go to the sea-side, and you will find many patients in this condition, sent down year

by year to seek what they will never find. You cannot be altogether surprised at this error; there is muscular debility; that debility interferes with exercise; the absence of exercise destroys muscular contractility; and the reasoning which too often follows is not that the diminished muscular power is a consequence, but a cause of the deformity. They are, therefore, principally occupied about restoring the strength, while, in a large proportion of cases, the feebleness is secondary; this is losing precious time in useless treatment. A further loss of time is sustained by waiting for the proper season for particular watering places, giving them a long trial, and frequently returning to them from year to year, whilst the deformity is becoming incurable. Another serious source of error in treatment is, that many medical men persist in regarding all curvatures as *ricketty*, and resorting to accredited means for lessening the softening of the bones. Another injurious though more just idea arose out of this idea—the dictum that absolute rest would cure, or, at least, suspend the progress of the deformity: so general was this opinion, that formerly there was scarcely a school, I was going to say a house, where the inclined plane was not to be found. Here, on the hard board, a poor child was constantly doomed to lie, almost motionless, for months, or even years, and this sometimes on mere suspicion. But in this country it was ascertained that softening was not the most frequent cause of deformity, and that prolonged rest is marvellously favourable to increase the evil. Unfortunately many people have gone to the other extreme, and, having ascertained the evil of prolonged inaction, are unwilling to acknowledge its utility, within proper limits, and would proscribe it entirely. But an absurd practice still exists, founded on the idea that beauty of form cannot be acquired without the assistance of art, and the feet are doomed to suffer from tight shoes, the trunk from stays representing an inverted cone; and this is too much regarded. The work of Andry is a monument to attest all the absurdities which may be committed when we cease to take nature for our guide—but happily this mania is disappearing.

The treatment of curvature rests on very simple indications; restore the equilibrium which has been destroyed between the two sides of the spine. To accomplish this we must remove the known causes of this difference; we must use every prudent means of restoring the energy and regularity of the powers of the system, and we must place the affected parts in a physical condition most proper to bring about amelioration. Formerly the first of

these means was entirely neglected, and the treatment was almost purely mechanical. The proof of this is furnished by the different machines which have been proposed as remedies. In our time the treatment of these affections has become an object of careful study, and at present it rests upon a better basis—a more attentive observation of the disease. You must carefully inquire, in each case, into all the circumstances likely to throw light upon the causes; you must seek to ascertain their mode of action; you will not then base your treatment on uncertain hypotheses, but on more or less completely ascertained facts. Sometimes it will be necessary to substitute for a long-continued attitude, a consequence of immobility, or inaction, a varied exercise, sometimes to repair by rest the exhausted powers, broken down by long disease, or painful labour. Sometimes we substitute for the exclusive use of one limb that of the opposite one; we must frequently change the familiar position of persons having particular occupations; we must remedy some painful affection of the legs, or of the side of the body which causes the patient to adopt the vicious attitude; we must ascertain whether any article of clothing, such as an ill-fitting tightly-laced stays, disposes to it. Most of you may be familiar with Green's cases: two sisters presented curvatures in opposite directions, caused by sleeping together face to face, and who were cured by simply changing their position. If we could impress upon the nutrition of the concave side as much energy as is possessed by the other, we might be able by this means alone to remedy the evil; and the occasional disappearance of curvatures under improved health naturally leads to the employment of tonics, and other means likely to restore the destroyed equilibrium. Therefore we order change of air, salt and other bathing, frictions, flannel next the skin, muscular exercise, animal food, wine, bitters, bark, steel; varying them according to the case; according as the curvature coincides with a sanguineous or lymphatic temperament, a scrofulous or other diathesis.

But the treatment of curvature of the spine would usually be insufficient and incomplete, did we not change the physical conditions by which the unnatural form of the spine is maintained, and which, left to themselves, would constantly tend to increase the mischief—I mean the downward pressure. Two powers direct this pressure, the weight of the organs supported by the column, and the muscles by which it is inclined in different directions. To counterbalance these powers two kinds of means present themselves—

mechanical agents and muscular exercise. These means act as antagonists against the powers by which the spine has been flexed. The one equalizes or diminishes the pressure, the other gives the muscles increased power of resisting incurvation; but an association of both is the perfection of treatment.

Compression of the curvature seems to have been the first idea of mechanically relieving it, by bringing the curved portion nearer to the proper axis of the spine. Hippocrates indicates it, and Paré carried it a little further. A case in which this principle was carried out was described by Levacher, in the 17th century. Andrey recommended that it should be applied, by fastening within stays cushions to correspond with the convexity of each curvature. The apparatus of Venel and Van Gescher did not differ essentially from those of Andrey. In the apparatus of Joerg, compression is applied by means of an elastic band; but a kind of extension was also applied by means of a piece of wood covered with leather, which extended on the depressed side from the axilla to the hip (fig. 1.) Various modified, this

Fig. 1.

principle has been carried out with more or less success, the success depending more upon the sagacity with which the principle is carried out, than upon any abstract merit of its own.

All the means based upon this principle have a common inconvenience, that of struggling disadvantageously against the superincumbent weight, which more or less completely annihilates their action; and, having this serious disadvantage, they act only through the intermedium of the ribs, as was long ago pointed out by Levacher. Acting first upon the thorax they increase its deformity, and the action is not transmitted to the spine until the flexion and depression of the ribs can be carried no further. On the other hand, the discomfort and inconvenience attached to a cir-

cular compression, the danger even which may result to the chest, the abdomen, and the pelvis, does not in many cases allow of our employing a sufficient force to maintain the rectitude of the trunk. As applied to the loins this kind of pressure has still less efficacy. It is only recent lateral curvatures, those in fact which can be almost completely effaced by muscular action alone, that will yield to such means. It may, however, be sufficient to sustain the trunk in the intervals of more active treatment. But it has this serious disadvantage; it gives the muscles no opportunity of acquiring more power.

Some persons have been content to reject mechanical assistance, and to rely on the power of the muscles of the spine to work a cure. A century ago the study of the action of particular sets of muscles in particular attitudes had induced Andrey, among others, to recommend that when one shoulder was depressed, it might be raised by standing on the opposite foot, placing on the depressed shoulder, or under the arm of the same side, some slight burden. These attitudes may be useful when the position of the scapula is the consequence of habit, will do no good when the curvature is permanent, but may increase the evil, by adding a second curvature to the first. The opinion is still cherished and acted upon, that this kind of muscular action is alone sufficient to remove curvature, provided it act in a direction opposite to that which tends to increase the mischief. For the purpose of carrying out this treatment a variety of games have been invented. We have already seen that, in a majority of cases, the principle is essentially inapplicable. In a large number of cases the supposition of a default of equilibrium between antagonist muscles has no real foundation, unless we take the unequal prominence of the muscles of the two sides, caused by bony irregularity, for a true disproportion between these contractile organs. It is only in a few cases, therefore, that we have feeble muscles to strengthen on one side of the trunk more than another; and if the displacement of muscles do, sometimes, at length trouble their nutrition, and derange their action, these are effects which can only be effaced with the curvatures which have occasioned them. But we have not yet clearly made out either the influence of muscles on a curved spine, or their agency in producing it. These reasons have had their effect, and, in the present day, there are not many persons who seriously believe that we can cause the disappearance of a curvature by exercising the arm opposed to the convexity.

In the present day, when mechanical means are employed to remove curvature,

their use is based on a different principle to that we have considered; the principle now sought to be carried out is extension. It may be done by sustaining the trunk during station; it may be done while the patient is in the horizontal position, or it may be done by suspension. A great number of machines have been invented to raise and sustain the spine during station, some very complicated, others comparatively simple; all taking inferiorly a solid support upon the sacrum or the ilium, upon which they should be moulded so as exactly to be adapted to those parts, without compressing the abdomen. From this point one or many thin splints, placed along the spine, or at the side of the trunk, pass upwards above the head, or to the axilla; they should be capable of elongation at will. Those which extend along the trunk on the median line pass above the head, where they are curved, and from thence is suspended an apparatus to pass under and support the chin and the occiput. This machine used to be known formerly as the *Minerva*. In Heister's cross, improved by Bell and Shaw, as well as Chesher's, Stark's and Pfing's, the same principle is carried out. Those supports which do not extend beyond the axilla are more or less employed in the various stays used in the treatment of curvatures. These means have been adapted to chairs, couches, or other seats, upon which the patients rest. Those of Shaw and Bloemer are of this kind; and in many instances a short crutch, such as the following, is added (fig. 2.)

Fig. 2.

These various modes of supporting the trunk rarely completely counterbalance the tendency in the curvature to increase. They often painfully compress the soft parts around the pelvis. In some cases they press too hard on the lower jaw;

and the extreme mobility of the shoulders interferes with the usefulness of the axillary apparatus. The crutch support is unquestionably often useful; by it the inconvenience of compressing the pelvis is avoided, and it furnishes to the upper extremities a solid support.

The horizontal position has been much employed alone and associated with various mechanical contrivances, as a means of curing curvature. We usually refer to Darwin the idea of first suggesting it as a useful means of treatment. The Germans refer it to Wichmann. The French to Dauterney; certainly his suggestion was published in 1751. Wherever the first suggestion came from, so much must be admitted, that the plan was in general use in England long before it seems to have been employed in France. In 1788 Venel, of Lausanne, advised that mechanical means of extension should be associated with this position by day and by night. The horizontal extension was soon enthusiastically adopted in Germany, France, and England. I cannot, however, in this place enter into a description of the multitude of machines which have been invented for carrying out this principle; but the use of elastic means of extension, the credit of which belongs, I think, to Heyne, is a real improvement. Many persons, among others Shaw, Maisonneuve, and Pravaz, employed weights for the purpose of making the necessary extension, and in many cases they seem to act very happily. It is easy to understand the effect of the horizontal position in these cases; no other means so completely removes the pressure supported by the vertebræ. In a large number of cases we see, in a comparatively short time, a diminution of the deformity by position alone; but this attitude, long continued, has its inconveniences, and they were well pointed out by Shaw; but when the attitude is changed at proper intervals these inconveniences are much lessened; and this is the plan of treatment at present generally followed. You now understand that extending machines only serve to maintain the body in a certain position; they prevent that flexion of the trunk which would inevitably happen during sleep. Many reproaches have been attached to horizontal extension; among the many inconveniences attributed to it, some are purely imaginary, and others may be easily avoided by moderate care. When there is a single or predominant curvature, the extension may be made to act more immediately on this point, by bringing the extending power to act more directly upon it. In some instances, apparatuses for making pressure are associated with those

of extension in the horizontal position; such are the machines of Milli, Humbert, Heyne, and others. By this means a double indication is satisfied—they concur with extension to re-establish the form of the thorax; they contribute to straighten the spine. (fig. 3.)

Fig. 3.

We see that extension results from the incomplete suspension of the patient, either by the inclination of the plane on which he rests, or by contrivances which act upon the head or the axilla; but extension may be had by other means. At the latter end of the last century Lentin proposed

Fig. 4 and 5.

that the patient should suspend himself by the parts from a stick attached to a cord at a convenient height, or by climbing a pole; and this advice, long neglected, is become the basis of gymnastic treatment, which generally consists in a more or less complete active suspension of the body by the arms. The weight of the inferior parts of the body manifestly tends to straiten the spine, whether the patient be in the vertical or inclined position. Direct inspection of the curvature proves this; the large muscles of the trunk do not destroy this effect in sustaining the pelvis and the inferior part of the spine, because, although contracted, they are at the same time in a state of tension and manifest elongation. These things once understood, it is only to vary their application to accomplish particular indications. The Pestalozzian, Clasian, Amorosian, and other codes of gymnastic exercises, point out the appropriate means of attaining these results. These kinds of exercise do not simply act mechanically; they develop the muscular system; and employed alternately with those machines which require the horizontal position, they remedy the inconveniences of inaction which belong to the latter, while they in their turn relieve the fatigues of the gymnasium. All gymnastic exercises should be symmetrically employed, and if possible, simultaneously, right and left; not to establish an antagonism between the muscles of the spine, nor, as some authors believe, to give the feeble side a vigour which it has not lost, but simply to give the body the most complete rectitude, to prevent exaggerated flexion which will usually favour the extension of one or other curvature. Consequently we generally avoid constantly raising the depressed shoulder above the level of the other. The action of the extensors of the spine should be solicited by bending back the trunk. The lower limbs, which usually do little in these exercises, do most in those exercises where the body is maintained in a horizontal position. It is not one of the least of the advantages of swimming, that it gives activity to the lower limbs, as well as to the rest of the muscular system while vertical pressure is avoided; and, therefore, though no extension be made, it should be most strongly recommended in curvature of the spine. In Pravaz's and other beds a certain quantity of exercise of the limbs is given by various contrivances of drawing weights over pulleys, and so on, at the same time that we get all the good of extension and the horizontal position.

I do not propose to occupy your time by entering into a critical examination of the different machines, but shall content my-

self by stating generally, that those in which pressure and extension are combined, and can be associated with exercise, are the only means which should be employed; but that among the variety of agents in which this method can be more or less completely carried out, those should be preferred which take their support upon the pelvis, and which do not inconveniently compress the thorax. If these conditions be not accomplished, the evil increases, or, at least, time is lost which might have been beneficially employed.

The treatment of these affections is not so well directed any where else as in establishments specially directed to the purpose. It is true that in such institutions the treatment is often too mechanical, that permanent extension is too completely carried out, and that the confinement sometimes exercises a fatal influence upon the general health of the patient.

After passing in review so many remedial agents, it may be asked what is the general result of treatment. Well applied, it is, from the first moment, to elongate the body a few lines, and by the end of a month, if the curvature be a large one, from one to two inches. In the succeeding month, though less rapidly, yet equally steadfastly, the elongation continues until four, five, or six inches may be added to the height. At the same time we may have the happiness to see the curvature more or less completely effaced—the thorax resume its proper proportions; in a word, the conformation restored to nearly its proper character. The respiration, instead of being hurried, is tranquil; the circulation becomes less laboured, the digestion improved; the person more fleshy, the face more coloured, the muscular power increased—in fact, a marked improvement in the general health. But, however decided may be the good we accomplish, a curvature of the spine is scarcely ever completely effaced; a slight inclination will still remain. This extent of benefit being obtained, the spine should be still sustained and preserved from pressure until its constituent parts appear to be in a state to support the weight of the trunk, which should be gradually borne. We must never forget, that once curved the spine generally retains a tendency to reproduce it, especially in young persons; we must, therefore, remove every thing likely to renew it. Pregnancy requires great watchfulness, and, indeed, it is wise to recommend a persistence in the horizontal position during a part of every day, especially in the latter months.

OBSERVATIONS

ON

THE PREMONITORY SYMPTOMS OF INSANITY;

With Cases.

BY JOHN GRANTHAM, ESQ.

Surgeon.

[For the London Medical Gazette.]

In a former number of the MEDICAL GAZETTE (vide page 203, vol. I, N.S.) I endeavoured to set forth the importance of attending to the premonitory symptoms of insanity, and to awaken the attention of the profession to the neglected state of this subject, rendered still more imperative by the manifest ignorance betrayed in medical evidence relating to the phenomena of insanity. To render this inquiry as plain and useful as possible, I illustrated it with various cases in which both the moral and physical causes and effects of mania were considered. It is the object of this paper to detail still more minutely the premonitory symptoms of insanity, and especially such as present themselves in the generality of mental diseases.

The moral effects which demand attention may be classed under ten heads (and let me premise by asserting that all these moral effects may arise *pro tempore* without any fear of insanity; nevertheless I feel warranted in regarding them as worthy of attention in combination with the general history of a case:)

1. Undue suspicion,
2. Discontent,
3. Remorse,
4. Disaffection,
5. Revenge,
6. Indolence,
7. Excitement,
8. Unnatural activity in the pursuit of different objects,
9. Fearful apprehension,
10. Forgetfulness.

Not that I am intending to enter into any controversy on the merit or the demerit of phrenology; yet in this inquiry I feel it due to my own sense of justice to advocate the right use of the system in the investigation of moral causes. Phrenology teaches, first, that the brain is the organ of the mind, and is concerned in every mental operation, whether of emotion or intellect; secondly, that the brain does not act as a unit, but consists of a plurality of organs, each serving for the manifestation of an individual faculty of the mind;

thirdly, that the energy of function, or power of manifestation, is proportioned *ceteris paribus* to the size of the organ; or, in other words, that a large organ will, *all other conditions being equal*, enjoy a power of action proportioned to its size, and, consequently, manifest the corresponding faculty with greater energy than if it were small. Cuvier says, "Patanomie comparée en offre une autre confirmation dans la proportion constante du volume de ces lobes avec le degré d'intelligence des animaux;" thus admitting the influence of size of the cerebral organs upon the power of manifesting the mental faculties as distinctly as Dr. Gall himself could assert it. But, to prevent any misrepresentation, let it be observed that there is scarcely a phrenologist who does not utterly scout the notion of organic size being the only condition of functional energy. To demonstrate the evidence of organic size being *ceteris paribus* a measure of functional power, let any one look into the field of nature, and there examine the testimony of every anatomist and physiologist who treats of the relation between structure and function. The brain, in its functions, must be relatively studied in reference to the amount of muscular power in the body. Dr. Marshall Hall states, "That the cerebrum is, in its acts of volition, an exhauster of muscular irritability; that in muscles separated from their nervous connexion with the brain we have augmented irritability." It is admitted that insanity begins in the slightest departures from healthy feeling, and may be traced through every variety of shade to forms of severity, in which it is so evidently associated with an infirm, ill-judging, ill-reasoning, and perverted mind.

After examining the moral effects, the next step will be to ascertain the primary cause, and which will be found in the deranged function or diseased action of one or more of the various organs of the body. To descend to minutiae here would only be a tedious repetition of those pathological symptoms well known to the reader; yet it may be well just briefly to observe that the skin must be noticed with regard to its functions as an absorbent, exhalant, and regulator of the animal heat; the muscles, as to their action in reference to volition; the head, in reference to action and power; the blood, as to its condition and composition; the assimilative organs, in reference to diet and muscular power of the stomach and large intestines; and the glandular system, in reference to the supply of the nerves of organic life.

As far as I have prosecuted the diagnosis of the premonitory symptoms of insanity I have invariably found the exciting cause

to exist in the spino excito-motory system, and by sympathy to the brain. The primary cause or causes come under the appellation of depression, stimulation, and irritation. The fever that generally attends the early stages of insanity is of the congestive character. Congestion of the venous system is a state produced by the operation of common depressants, and marked by a diminution of the animal heat on the surface of the body, a diminution of the heart's action, and by a disturbance in the function of this or that organ which is the seat of congestion. The pathological inquiry must also be continued, first, in reference to predisposition; secondly, to disorder or deranged function; and, thirdly, to diseased action. The medical treatment called for in each case in which the mental disorder depends chiefly or entirely on some disordered condition of the heart, the liver, the stomach, the intestines, the uterus, &c., must, of course, vary in each particular case, and be conducted on general principles. In exemplification of the treatment it is my intention to publish those cases which may, in addition to the following, come under my observation.

CASE I.—S—l M—n consulted me March 31st, 1840; he was about twenty-six years old, of a middle stature, in temperament sanguineous. He complained of lowness of spirits, and inability to perform any of his usual duties; he lost all confidence in himself, and thought every one regarded him with distrust; his religious views became unsettled, and his confidence in the divine promises disturbed by the fears of his final perdition, which he thought must be his inevitable doom. He was a man of the strictest integrity, and esteemed as such by his employer, naturally of a lively and amiable temper, &c., &c. He left his business, which was that of a clerk in a notary's office, in London, in the month of November, 1839; he felt himself unwell, and consulted his medical adviser, who considering he had simple fever, made no restriction of diet or action: in a fortnight he resumed his employment, but the malady returned with increased severity: he a second time consulted his medical friend, who termed his case a nervous affection, and placed him under a tonic treatment of aromatics, camphor, &c., and wished him to leave the neighbourhood of London; before going away he was advised to have the opinion of another medical man, who approved of the plan pursued, and also stated it was necessary that he should leave town; he then went to the Island of Guernsey, and there sank into a state of deep melancholy: he there consulted a physician, who told

him to take much exercise, walk about, but ordered no medicine, stating it as useless. From thence he went to Jersey, where he suffered more depression of mind. After remaining some time in the latter place without benefit, he returned home, and a third time consulted his family medical attendant, who advised him to take a voyage to New York, but ordered no medical treatment: having a great reluctance to this advice, he came into the country to be under my direction. On examination he stated his inability to rest, with occasional dimness of vision, taste depraved, hearing good, the bowels inactive, urine pale, but unable to expel the last drops; muscular action defective, the skin dry, with occasional sensations of heat and cold, not general, but partial. On inquiring as to the original cause, I learned he had been washing his feet in cold water at night just before going to bed.

Treatment.—I ordered him to have the feet put into a hot bath at 100 degrees, composed of six table-spoonfuls of mustard in two gallons of boiling water, for fifteen minutes, at bed time; to use the flesh-brush to the skin in the morning; to remain quiet: the diet to consist of gruel for breakfast, mutton broth or beef tea, with bread, for dinner; no tea, and a gruel or arrow-root meal at seven o'clock in the evening; to abstain from fermented liquor and solid meat; to take twice a day Pil. Hydr. gr. v. and a Draught composed of Carbon. Sodæ, 5j.; Spt. Ammonia Co. 5j.; Pulv. Rhei, gr. vj.; Misturæ Camphoratæ, q. s.

April 2d.—He stated he had slept the whole night, such a circumstance as had not occurred during his illness. I requested him to continue the measures as stated—to take walking exercise, so as not to cause fatigue. I scarcely need observe that the partial paralysis of the muscles of the perineum were owing to defect in the internal pudendic nerve, which is supplied from the fasciculi of the fourth and fifth lumbar and three upper sacral nerves; this will lead to the exciting cause that the spino-excitomotor system was deficient in its supply of the power of organic life to the large intestines, kidneys, and, probably to the mesenteric glands, and through the medium of the muscular deficiency, exhausting the power of the cerebrum.

4th.—The animal heat more equally diffused; continues to sleep well; appetite improving, and feels less gloom of mind. Continue the medicine.

6th.—Improving; the evacuations becoming more healthy, and the skin inclined to perspiration towards the evening. Continue the medicine.

8th.—Still improving, especially as regards the mind, but feels great general debility; continue the pills until gentle ptyalism is produced; increase the diet: an egg with the breakfast. This system was continued so as not to produce prostration of the animal powers, increasing the diet as the mental faculties became natural, enjoining moderate exercise and mental quietude, avoiding excitement, until

May 14th.—The weakness now being confined to the back over the region of the fourth and fifth lumbar, and three upper sacral vertebræ, and legs, I requested him to use a cold shower-bath every morning, and resume his duties, which he has done, and is improving in strength up to the date of this paper, not having had a return of his melancholy feelings. The above case is an example of the good effect of the mercurial action combined with the alkali, (carbon. soda:) the former being an excitant and antiphlogistic, while the latter acts as an antiseptic.

July 7th.—I have heard he is deriving immense advantage from the cold shower bath as a tonic.

CASE II.—Wm. K—p, a painter and publican, applied to me in the year 1828: a stout, middle sized, dark complexioned man, he complained of pain and weight over the head, imperfect vision, loss of appetite, great debility, pulsatory sensation across the occiput, trembling of the hand, evidently from intemperance; his feelings were low and desponding; he wept on the slightest occasion; he wished for solitude, and yet feared to be alone, either suffering the most dreadful nervous irritability or sunk in the deepest despondency. The treatment consisted in enjoining an abstinence from fermented liquor, loss of about twelve ounces of blood taken in a full stream from the arm, and repeated mercurial aperients, which had the effect of restoring him to health of body and mind. From the above time to Dec. 28th, 1839, I lost sight of him, when I was sent for in haste, he having attempted suicide, and had divided a portion of the right parotid gland, and some arterial branches of a moderate size, so as to bleed rather profusely: since I saw him he had very much increased in flesh, from indolence of habit, as he had been out of work for some time, in consequence of an irritable disposition rendering him obnoxious to his employer; he had again drank freely of both beer and spirits. The membrana conjunctiva was inflamed; the pulse 120, and tremulous; pain in the hepatic region; distension of the stomach and large intestines; uneasy sensation over the whole of the dorsal vertebræ; paralysis of the right side of the tongue; neuralgic pains down the right side of the neck; urine scanty, high

coloured, depositing after standing a brownish sediment. After dressing the wound I ordered the patient to be kept on low diet, to remain in bed, and to take the following draught every four hours:—

R Magnesiæ Sulphatis, ʒiij.; Antimonii Tartarizati, gr. i.; Inf. Sennæ c. q. s. M. Haust. ʒiss.

Dec. 29th.—Had a restless night; very incoherent in his talk; pulse full. I took sixteen ounces of blood from the arm; ordered the aperient draught to be continued, with Pil. Hydr. gr. v. added to each dose.

30th.—Slept about two hours; bowels acting freely, the evacuations dark and very offensive; tongue white, and the edges uneven. Omit the Ant. Tart., and take a teacupful of beef tea in the day.

31st.—The pulse 90; more natural; the mind is becoming tranquillized; the vision still imperfect; complains of a noise in the ears, with tenderness in the right side. I now determined on continuing the mercury until gentle ptyalism ensued, with a spare diet, perfect quietude of mind and body, forbidding all conversation. The state of mental stupefaction in which he was when he committed the act was after a few days succeeded by feelings of the bitterest remorse and contrition; nothing could pacify his self-accusations for having attempted so horrible a deed, until I explained to him that his crime was itself an almost involuntary act, depending upon his deranged health, and that it was his previous ill conduct and intemperance which had induced the attempt: he said “he had not been well the last six or seven months past, frequently wandering he knew not where, until hunger or fatigue roused him to reflection; and at other times shunning the society of friends, and stupifying himself in the corner of some public-house-tap room, imagining that every one distrusted him, and regarded him as unworthy of their friendship.” My reasoning with him in endeavouring to convince him that health of mind was dependent on health of body, seemed to inspire him with hope, and allowed of my furthering the medical treatment, which was continued by attention to the sanguineous system and *prima viæ*, by removing the inflammatory condition of the membranes of the brain, with the mercurial and alterative treatment.

Feb. 14th, 1840.—I took my leave of him, after assuring me how gratefully he felt for his restoration to health of mind and body.

Crayford, Kent, August 20, 1840.

OBSERVATIONS

ON THE

DISEASE LETHARGUS:

WITH CASES AND PATHOLOGY.

BY ROBERT CLARKE, Esq.

Colonial Surgeon, Sierra Leone.

THE attention of the medical profession was, I believe, first directed by Dr. Winterbottom to the frequency and often fatal termination of the disease termed *lethargus* on the western coast of Africa; but the description given in his work, both of the symptoms and treatment, is much too meagre for practical purposes. As deductions leading to a sound and rational mode of treatment can alone be drawn from an attentive, patient, and minute investigation of the pathological appearances presented, the following observations, with cases and pathology of this most interesting disease, founded upon my own experience as Surgeon to the African Hospital at Kessy, in the colony of Sierra Leone, will not, I trust, be uninteresting, or deemed a work of supererogation.

Dr. Mason Good, in his work upon the Study of Medicine, has placed this disease among the class *Neurotica*; but, as developed in the cases which have come under my notice, I submit that it may be classed under the variety *Cataphora*, or short remissive lethargy.

Causes of disease.—Lost balance of circulation, inducing irregular distribution of blood, and venous congestion; depressing mental emotions; severe bodily labour; unwholesome, scanty diet; repelled eruptions; suppressed evacuations; perhaps functional derangement of the nervous system, producing insufficient action or energy to resist the approach of sleep, even without its concomitant existing causes.

Symptoms.—On first approach of the disease the patient is observed to become fat, the demand for food being inordinate. When the disease has, however, existed for some time, the appetite declines, and, in the latter stages of the complaint, the patient emaciates. Uncontrollable desire to sleep, the patient often falling asleep in the act of conveying food to his mouth. Sometimes squinting and convulsions may be observed. The glands

of the neck become tumefied; but this is by no means always present.

The negroes call this disease sleepy dropsy, and, after it has progressed, never attempt its cure, giving over the patient as incurable; but, in the first stages, they endeavour to cure it by inducing copious perspiration.

Some European doctors, conceiving the disease to be induced by debility, have administered various stimulants, such as camphor, musk, valerian, blisters, sternutatories, metallic tonics, as sulphate of zinc, &c. The powerful agent, galvanism, has been also employed. Others, I imagine with more propriety, have viewed the disease as originating from congestion of the brain, and have sought its cure in the employment of local depletory measures, and of keeping up an action of the bowels; but it appears to me that medical men have been deterred from the judicious employment of general bleeding by an unfounded apprehension of danger from debility; nor would it appear that the potent remedy mercury has ever been called in to exert its powerful influence in equalizing the circulation; indeed the practice I imagine to be novel. An esteemed and experienced friend of mine, holding the chief civil medical appointment in this colony, has informed me that he has repeatedly tried it with a view to induce ptyalism, but without effect. Another medical friend, of long standing and experience in the colony, told me that he had treated the disease repeatedly, using blisters and drastic purgatives; but neither of these gentlemen appears to me to have sufficiently appreciated this medicine (mercury). Dr. Bacon, a gentleman practising at Cape Mesurado, the American settlement on this coast, remarked to me that the disease is of frequent occurrence there, accompanied in its progress by a low type of typhoid fever; but this I have never observed in any of the cases which have come under my notice. Dr. Winterbottom observes, that the slaves from the Bight of Benin are the most subject to it, and that it prevails much among the Foulahs. I have observed it also equally to prevail among several other tribes inhabiting parts of the continent far inland. I have chiefly seen it among the liberated Africans, of whom there are sometimes from 400 to 500 at one time in the hospital under my charge; and I have

been informed that several cases have occurred even among the Creole inhabitants.

CASE I.—On the 7th April, 1839, Mary Coker, æt. 14, an apprentice from Waterloo Village, a native of Benin, was admitted to hospital. States that about three months ago she was attacked by sleepy dropsy, (country name), or lethargus, for which she was treated by the natives, but without mitigation or the slightest alleviation of the symptoms. She is of a stout plethoric habit of body; general appearance that of an individual roused from sleep, the face and eyes being devoid of animation—almost of expression; wears a besotted look; the skin is dry, and above natural temperature; pulse 108, and small; bowels costive; tongue clean about tip, but towards root and in middle coated with a greyish fur; during the day she continues drowsy, and will fall asleep while taking food.

℞ Emplast. Vesicator. 7 × 4 inches. Apply from occipital protuberance along the spine:

℞ Ext. Colocynth Comp.; Submur. Hydrarg. aa. gr. xij. Divide in pil. No. vj. One every two hours until the bowels are freely opened.

8th.—Bowels open; alvine evacuations natural; during night she removed the blister; it had partially risen; skin cooler.

Re-apply blister.

℞ Calomel ℥j.; Pulv. Ipecac. gr. x.; Opia. gr. ij. M. Divide in pil. No. vj. One of the pills every three hours.

April 9th.—Blister has risen well; bowels open once; a lumbricus about eight inches long discharged; the urine is secreted sparingly in quantity and is highly coloured; does not however coagulate on application of heat; skin of natural temperature.

10th.—The mouth has become affected with the mineral; her bowels have been twice opened; micturated once in the space of 36 hours: the same lethargy oppresses and weighs down both her physical and intellectual faculties: pulse 94, small and quiet.

Let the mouth be gargled with

℞ Solut. Chlorid. Sodæ, ℥i.; Aquæ font. ℥xv. M. Fiat solutio.

11th.—No change.

12th.—Considerable amendment in appearance, which is more lively than since her admission; bowels have been severely purged; appetite good; but it being desirable to keep up a brisk action from the intestinal tube, I gave

℞ Aloes Socot., Ext. Colocynth. comp. aa. gr. xij.; Calomel. gr. xij. M.

Divide in pil. No. vi. One every three hours.—Continue the wash for the mouth.

14th.—Vast quantities of fæces have been discharged by stool, dark coloured, highly offensive, and stringy, as if from the tenacity of intermixed bile. During the night she was buried in the most profound sleep. Pulse 112, small and quick; tongue much loaded at base; the secretion from kidneys sparing, and on application of heat a film of albuminous-like coagula floated on surface: about abdomen, particularly in epigastric region, there is some distension as if from flatus: appetite good.

R Bitart. Potassæ. ʒi.; Aquæ font. ℥ij.
M Ad libitum.

To discontinue pills, and the bowels to be kept kept open with

R Sulph. Magn. ʒij; Aquæ font. ℥ij.
M. A wine-glassful every four or five hours until the bowels are opened.

16th.—Bowels freely open; says she feels less inclination to sleep: about half a pint of slightly turbid urine passed in the course of the 24 hours.

18th.—Pulse 120, quick but small; appetite good; tongue clean round the edges and at tip, but base covered with grey sordes; her general appearance more lively than on previous days.

19th.—Bowels open, but evacuations sticky: during day she walks about the yard and ward, occasionally conversing with girls of her own age, but more frequently moves about without noticing surrounding objects. She has never been observed to laugh since her admission, and often drops asleep after very slight exertion. Urine sparingly secreted. She has continued to use the Solut. Bitart. Potassæ, and as a purgative a solution of Sulph. Mag.

Continue wash for mouth. The diet to consist of soup with arrow root, or well boiled sago and a small quantity of wine.

20th.—Several lumbrici, from eight to nine inches in length, were found in alvine evacuations.

R Ol. Ricini. Terebinth. aa. ʒss.; Sp. Piment, ʒi. M. Statim sumend.

21st.—She is greatly emaciated; bowels well opened by the medicine; pulse 118, small and quick.

R Sulph. Quininæ, gr. vi.; Infus Quassia, ʒij.; Sp. Vin. Rect. ʒi. M. A wine-glassful three times a day. The mouth and gums being still tender and spongy, continue wash for mouth.

22d.—A lumbricus came away this morning. The irresistible disposition to sleep cannot be better described than by noticing the fact of her dozing at the moment I was noting her case, although aroused the mo-

ment before to put some questions to her. The urine is still secreted very sparingly.

R Ol. Terebinth. ʒi.; Sol. Gum. Arabic, ʒi. M. Statim sumend.

26th.—On the 23d she passed a lumbricus; the bowels have been opened two or three times daily: tongue clean at tip and round edges, but towards the root loaded with greyish coating: pulse 100, small and quick: no improvement of lethargic symptoms. When dozing I have repeatedly held a candle close to the eye, the pupil remaining fixed and staring. About epigastrium there is distension, but no sense of pain is experienced on pressure: call to pass urine is seldom oftener than three times in the course of 36 hours.

R Emp. Lyttæ to epigastric region.
—Continue Infus. Quassia c. Sulph. Quininæ. To be used as formerly.

Her strength to be supported with light nourishing food.

27th.—She appears better. At the same time during the night she attends to the calls of nature, while formerly they frequently passed involuntarily. Quantity of urine is now very considerably increased, amounting to eleven ounces in three hours.

28th.—Has removed blister from abdomen; appears lively. The bowels to be kept open by

R Submur. Hydrarg. Ext. Colocynth. comp. aa. gr. iv. M. Divide in pil. No. ij. One to be taken immediately, and the other six hours thereafter, if the bowels are not previously acted upon. Let the blister be reapplied.

29th.—Blister has risen well; pulse small, 116.

Continue Infus. Quassia c. Sulph. Quinin.

May 2d.—Alvine evacuations more natural: the feet and legs slightly œdematous.

R Liniment. Sapon. ʒij. The feet and legs to be embrocated, and to be then bandaged from toes to knees.

4th.—General appearance bad: alvine evacuations bilious, mixed with frothy-like mucus; quantities of undigested food contained therein; drowsiness evidently on the increase.

5th.—To-day she was asleep when I entered the ward. On light being brought close to pupil it remained uncontracted.

6th.—No change.

7th.—Pulse full, 106; breath is highly fœtid; general aspect improved; has, however, slight dyspnœa, attended with cough, and complains of pain under left breast. On applying the ear to chest the respiratory murmur was distinctly crepitous: feeling of hardness about epigastrium has disappeared.

R Emplast. Lyttæ. 4 × 4 to chest.
 R Tinct. Camph. Comp., ℥iv.; Antim.
 Tart., gr. ij.; Aquæ Font., ℥viii. M.
 A table spoonful every three hours.

8th.—To day the blister has risen well: she appears, however, weak. No expectoration; breath extremely fetid; pulse 100.

9th.—Before visiting hour was told by matron that she was dying. At 7 A.M. she expired.

Autopsia, two and a half hours after death.—

Body not much emaciated. *Head*: Arachnoid membrane thickened, firm, and opaque. Substance of brain, when cut into, was closely dotted over with blood-vessels. About one dram of serum present in lateral ventricles, and at base of brain half an ounce of same fluid was effused.

Thorax: Some effusion between pleura of right side, which was thickened and highly vascular. Lung of same side had a dark and florid aspect: a gangrenously fetid and melanotic-like fluid covered a great portion of inferior and middle lobes: the inferior lobes slightly adhered to diaphragm. A pretty copious secretion of purulent matter, intolerably offensive, has poured out on that portion of diaphragm where adhesion existed, which being removed it was found roughened. Corresponding surface, to the extent of an inch and a half, was of a dark colour, evidently from infiltration and inflammation. *Heart*: Heart of natural size: on laying open its cavities large portions of coagulated lymph were found filling up the ventricles and passing into arterial tubes. There was considerable deposition of fat on parietes.

Abdomen: Peritoneum pulpy, and crowded with small blood vessels holding florid blood. Omentum contracted, having a considerable accumulation of adipose tissue. Stomach at its greatest curvature had a blush of redness. A lumbricus* was found in cavity measuring eleven inches in length. The contents of upper portions of intestines were dark coloured and semi-fluid: fæcal matters of similar colour were found in colon. Patches of ulceration were discovered in both great and small portions of tube. Lumbrici, varying from two and a half to eleven inches in length, occupied the canal, and were situated both in duodenum, ileum, and colon. *Liver*: Gall bladder green externally, and impacted with very green ropy bile, otherwise healthy. Weight of liver two pounds two ounces. *Kidneys*: Kidneys healthy. Coats of bladder thickened and contracted.

On laying open the spinal canal a good deal of blood was found diffused at inferior cervical and dorsal regions; the neuro-

lemma of cord had a yellowish-like lymph deposited on surface, which appearance could be observed more especially towards its termination. On carefully removing the sheath a beautiful network of vessels was seen ramified throughout the whole length of cord.

CASE II.—Sara, a fine intelligent and lively boy, ætat. 10, a native of the Soosoo Nation, was received into hospital on the 17th of April, 1839, from on board the Portuguese schooner, "Labrador," affected with glandular swellings of both sides of neck, for which he was treated with iodine ointment, to which treatment they yielded. Bowels regulated by gentle purgatives. A few weeks thereafter he began to lose flesh, his appetite at same time declining. On the 2nd of May he was first observed to drop asleep while eating: on being roused he was seized with a universal tremor, the motions of his head resembling the symptoms produced by inebriation, the eyes bloodshot, pupils staring, look meagre and emaciated. Bowels costive, tongue white and loaded, pulse 84, skin below natural temperature.

Applicentur Hirud., No. xxx. temporibus. Bleeding to be encouraged as much as possible by flannel cloths dipped in warm water, then wrung, and applied as hot as possible, which are to be renewed at intervals.

R Spir. Vini. Rect. ℥ij., Aquæ Font. lb. ij. The head to be kept constantly wetted by means of pledgets moistened with the lotion.

R Emplast. Vesicator. from occipital protuberance along the spine.

R Pulv. Jalapæ, gr. x., Calomel, gr. iv. M. Statim sumend.

These active measures, with repeated large doses of oil of turpentine (which certainly brought several worms away) conjoined, and the production of salivation, with the occasional use of the sulphate of quinine, combined with infusion of quassia, alleviated, although they failed to arrest, the progress of the malady, which terminated fatally on the 2nd of June.

Post mortem Examination two hours after death.—Body much emaciated. *Head*: Skull cap with great difficulty torn from dura mater, to which it firmly adhered round the corona: about four ounces of blood, mixed with serous fluid, escaped on its removal: the skull itself appeared more than usually dense: minute injection of the arachnoid membrane; great engorgement of the vessels distributed over the convolutions; grey substance of brain of a rather paler colour than natural; choroid plexus pale: serosity between the convolutions. The ganglions of grey substance, corpora striata, and optic thalami, were

* These parasitical intruders were found alive after removal from body.

softened. In the ventricles a small quantity of fluid was present: the principal arteries at base were enlarged and turgid. *Thorax*: A good deal of serum was found between pleura on opening thorax: the inferior lobe of left lung was found to cohere to superior surface of diaphragm to the extent of a half crown piece, where a yellowish exudation was abundantly poured out, and which was discovered to exist in considerable quantity about root of lung. Surface of lung was rose-coloured, from excessive congestion; on being cut into a reddish-like fluid oozed from every part. Right lung was also much engorged; pericardium collapsed; heart much loaded with fatty deposit, but of natural size. *Abdomen*: Stomach highly vascular between its great curvature and pylorus: intestines presented very considerable traces of inflammation in some points; spleen slightly enlarged; several lumbrici were present in small intestines; liver healthy; gall bladder filled with dark green bile; peritoneum exceedingly vascular; cortical substance of kidneys highly injected.

On sawing and chiselling out the vertical column to its termination, a considerable quantity of blood was found effused over cervical and dorsal aspects. Blood-vessels filled with blood were seen everywhere ramified in an exceedingly beautiful congeries of network over structure of cord.

CASE III.—John Silver, a liberated African of the Ackoo Tribe, ætat. 14, was sent to hospital on the 9th June, 1839, affected with lethargus, by which he was first attacked about three months previous to admission. When seen by me he lay upon his back in a state of stupor; pulse 90 and full; on application of light to pupil it remained uncontracted: on being roused he articulates with difficulty: he complained that he felt pain at lumbar sacral junction; expression of countenance stupid and vacant; the eye is bloodshot and listless; bowels open; tongue moist, clean at tip, but at base covered with green sordes; respiration natural; skin of natural temperature; slight rigidity of muscles of arm, accompanied by spasmodic motion of the fingers, with occasional slight jactitatory motion of the body; feet cold; says he passed several lumbrici prior to admission; states that he has not made water for many hours previous to admission.

Applicetur Cucurbitula to portion of spine complained of. Head to be shaved, and then apply thereto, so as to cover the scalp—

R Emplast. Lytta 6 × 4.

R Pulv. Jalapæ. gr. x., Calomel, gr. v. M. Fiat Pulv. No. i. statim

sumend. Let his strength be supported with thin soup, arrow root, and aggidu, to which he is extremely partial.

Vespere.—In the same profound coma. Pulse 104, and full; skin hot; medicine has not operated. Flannel cloths to be immersed in boiling water and applied to feet and around ankles; but although the application had the immediate effect of rousing him, the relief was not permanent. The skin was slightly vesicated by the high temperature.

R Ol. Terebinth. ʒj., Mucil. Gum Arabic. ʒss. M. Fiat haustus. Statim sumend.

June 10th.—During the night he lay on his back, from which posture he did not move. Blister applied to head has risen well; seven lumbrici, varying in length from four and three quarters to eleven inches, were evacuated: the fæces were of a dark green colour, being intermixed with a considerable quantity of mucus; in the course of twelve hours ʒv. of urine of a very high colour was passed; pain in back gone; complains of pain about left trochanter major, where there is some slight swelling.

R Submur. Hydrarg., ʒi., Pulv. Opii, gr. iss. M. Divide in Pil. No. vj. One of the pills every hour.

R Tinct. Sapon., ʒi. Embrocation to thigh.

Vespere.—Pulse 120, and full; skin hot; ʒiv. of urine of a pale yellow colour passed in the course of eight hours: during the day he would occasionally awake and converse with boys of the same age in the ward.

R Subcarb. Potassæ, ʒij.; Mist. Camphor. ʒij.; Antim. Tart. gr. ij.; Aq. Font. ʒviij. M. Fiat mistura; ejus sumat cochleare magnum quaque tertiâ horâ. The skin to be sponged with vinegar and water; pledgets, moistened with water, to be constantly applied to head; bottles of warm water to feet.

11th.—Pulse 80; skin cool; tongue clean at tip, but loaded with a grey fur towards base; gums swollen and tender; countenance mild; articulates with difficulty, but returns appropriate answers to interpreter; appetite improved; does not complain of pain; respiration natural. On applying ear to chest, the action of heart was violent, the impulse being extended over a considerable portion.

Pills to be discontinued.

R Solut. Chlorid. Sodæ, ʒj.; Aquæ Font. ʒxv. M. Fiat Solutio, with which the mouth is to be repeatedly gargled. A large blister to the calf of

each leg. The application of cold water to the head to be persevered in. Cold water also to be poured on the head from a tea kettle. Continue Mist. Diaphor.

12th.—Pulse 120; skin bedewed with a copious perspiration; blisters have risen well. At the evening visit the countenance was natural, and more lively: during the day he ate some fish, which he appeared to relish.

13th.—Makes no complaint; pulse natural and soft; tongue white and moist; extremities cold.

Apply bottles of warm water to feet; cold application to head to be continued; discontinue Mist. Diaphor.

14th.—Skin cool; pulse, although quick, is regular; bowels costive.

R Ol. Terebinth. ʒi.; Mucil. Gum Arabic, ʒss. M. Fiat haustus.

15th.—Bowels open; evacuated several lumbrici: the discharge consisted of pure bile: the bedding has a urinous smell, from the involuntary discharge of urine.

16th.—Urine and fæces passed involuntarily; wine ordered ad libitum, but he continued to sink, and died at 2 o'clock A.M. of the 17th.

Post-mortem examination five hours after death.—Emaciation considerable. *Head:* The calvarium and dura mater being removed, the blood-vessels passing between dura mater and brain were found enlarged to the size of a crow's quill; retiform injection of the pia mater; a little serosity between membranes. On slicing the brain, many bloody points were discovered, closely congregated, both on medullary and cortical substances; investing membranes of ventricles highly vascular. Nothing particular in the cerebellum. Spinal marrow not examined. *Thorax:* The lungs were slightly congested, and of a rose colour. Deposited on inner and inferior aspect of left lung there was considerable effusion of yellowish lymph; heart enlarged, having its walls thickened; fibrinous clots were found in auricular and ventricular cavities; its parietes were loaded with fat. *Abdomen:* Stomach, at upper curvature, highly vascular; omentum loaded with fat, having its vessels highly injected with blood; liver, on being cut into, was found turgid with blood; gall-bladder loaded with dark green bile similar to what had passed by stool; intestinal canal contained the same coloured fluid, with here and there hardened scybala; four worms, from four to twelve inches in length, were also found; spleen of middling consistence, between the state of health and degeneration; blood-vessels of kidneys completely gorged with blood; bladder contracted.

CASE 4.—Thomas Caperhill, a Creole boy, æt. 14, was admitted into Hospital on the evening of the 6th July 1839, affected with the decided and far advanced symptoms of lethargus. I was informed by the person who brought him to hospital that he was an orphan, his parents having died about six years ago, leaving him to the tender mercies of an individual residing at the village of Wellington, by whom he had been employed to cultivate his farm on the banks of the Quia River, at a distance from the residence of his assumed protector. From the same source I learnt that he had been attacked by the disease about five weeks prior to admission, and that no remedial means had been employed to check its progress. When seen by me he lay upon his back steeped in deep lethargic sleep; expression of countenance fatuous; skin rather hot; pulse small and irregular: tongue (which he had difficulty to protrude) covered at its base with grey sordes; bowels costive; respiration slightly crepitous; impulse of heart heard over a large space; pupils contracted: articulation indistinct and hesitating; spasmodic rigidity of upper extremities; feet cold.

Let the head be immediately shaved, and kept constantly wetted with cold lotion, pouring at intervals a stream of cold water over the head. Blisters to calves of legs. Apply boiling water by means of flannel cloths to feet and round ankles.

This application roused him, but the benefit was not permanent.

R Ol. Tiglii, gtt. i.; Calomel, gr. iv. M. Mor. sol. Fiat pil. No. i. Stat. sumend. Bottles of hot water to feet and legs. Let his strength be supported with arrowroot given at short intervals.

July 7th.—Blisters have risen well; bowels open, stools consisting of hard and dark coloured fæces; reclines on his back; pulse small, weak, and intermitting; urine discharged involuntarily; the skin around feet and ankles is slightly vesicated, the result of application of hot flannel; extremities cold.

Let the feet and ankles be dressed with

R Ol. Lini. Aquæ Calcis. aa. ʒiij. M. Continue cold lotion to head. Apply warmth to extremities by means of bottles of hot water. Wine to be allowed at short intervals.

During the night he expired.

Post-mortem examination two hours and a half after death.—*Head:* Skull cap with much difficulty separated from dura mater; a very large portion adhered very firmly to calvarium, so as to be removed along with it. Engorgement of the vessels which ra-

mify in convolutions; general injection of the arachnoid, which was red and thicker than natural. Both cortical and concretious substances very red. To choroid plexus of left side there was a small hard tumor attached, of an oval shape and of a dark ash colour. Several ecchymotic spots on lateral parts of middle lobes. On the internal and external sides of olfactory groove of left hemisphere there was considerable ramollissement. Vessels ramifying on circunvolutions of cerebellum engorged. Spinal cord much congested; investing membrane of a rose colour. *Thorax*: Lungs were of a light rose colour, and congested every where with dark blood. Heart filled with very dark coloured blood. *Abdomen*: Omentum loaded with fat; minute injection of peritoneum; liver much gorged; gall bladder filled with very dark tarry-like bile; intestines filled with matter of a very dark green colour, being mixed at lower portion with hardened scybalæ; several lumbrici were also found among their contents. At upper third of jejunum there was an ecchymotic spot about the size of a half-crown piece; kidneys much loaded with fat, the cortical substance being engorged.

Autopsia of a boy of the Bacongo tribe, æt. 16, who died 14 days after admission to hospital, but whose case I did not note down.

Head: Calvarium being removed, a great quantity of very dark coloured blood escaped. The dura mater was infiltrated with some fluid, which ablution failed to remove; glandulæ pacchioni enlarged; effusion of lymph over arachnoid membrane. On slicing the brain streaks of blood were observable; the ventricles were filled with bloody serum; choroid plexuses were turgid, small vesicles appearing on their structure. Over the corpora striata blood-vessels ramified in arborescent form: the circle of Willis was well marked, from the great turgidity of vessels; a netting of blood-vessels stretched over the pons varolii; the cerebellum and its coverings were equally congested. *Thorax*: On opening the thorax both lungs were found engorged; considerable adhesions to pleura costalis; pericardium collapsed; the heart was enlarged, its walls being thickened. On making a section through right ventricle, fibrinous clots three inches and a half in length were discovered, of very dark coloured blood; coagula filled the auricles. *Abdomen*: On opening the abdomen, the liver was found enlarged and of a purple tint, some parts of its structure being infiltrated with bile. The gall bladder was distended with bile of a tar-like consistence and colour. The omentum was contracted and thickened, tinged of a yellowish hue; the stomach contained a glairy fluid, the mucus being dotted over with grumous coa-

gula; the duodenum was also much studied; intestines being removed from body, washed, and slit open were found filled with lumbrici and hardened scybalæ; spleen softened; kidneys were normal; bladder thickened, and distended with urine.

In the case of a boy, æt. 14, of Akoo tribe, who was admitted to hospital on 2d September, 1839, and who had been ill for six weeks prior to admission, dissection revealed sanguineous infiltration of cerebral substance, thickening of dura mater, and several spots of a black colour scattered over its structure. Along the course of longitudinal sinus it was marked of a brownish blue colour. Lungs were found with tubercles in first stage; hypertrophy of walls of heart. Several lumbrici were found in the intestinal canal, at its upper portion.

Dr. Copland, in Part II., section 25, page 345, of his valuable Dictionary, observes that in the dark races of man, worms, especially lumbrici, in the intestinal canal, are frequently connected with the origin of many maladies of remote but related organs; affections of the stomach, diarrhœa, colicky pains, &c. &c. very often arising from this cause. Those parasites, it will be noticed, were found in great numbers to be present, both during and after life in those cases.

In conclusion, I hope it will be conceded, that if the practice pursued in those cases proved unsuccessful, that circumstance may with propriety be accounted for from the advanced stage to which the disease had arrived prior to admission, or to its being subjected to medical treatment.

In Mary Coker's case the right lung weighed 14½ oz.; left lung, 5 oz.

In the case here alluded to the weight of brain was 3 lb. avoirdupois; liver, 2½ lb.; spleen, 9 oz.

AN INQUIRY INTO SOME OF THE CONSEQUENCES AND CAUSES OF FAILURE
OF THE
NEW OPERATION FOR THE CURE
OF STRABISMUS OR SQUINTING.

By E. W. DUFFIN, Esq.
Surgeon.

[For the London Medical Gazette.]

[Continued from page 943.]

Much diversity of opinion certainly prevails in regard to the functions of the oblique muscles of the eye; but if

we dissect them with very great care to their insertions, we must admit, whatever else we may call in question, that the direction of their fibres, as well as their ultimate attachments, warrant the conclusion that the function of the superior oblique is to roll the eye inwards and downwards, and that that of the inferior is to rotate the organ in the opposite direction. When both muscles contract at the same time, the effect will be to bring the eye forwards, and render it a little more prominent; thence proceeds one of the common results—increased fulness of the eye, when the adductor is divided.

But in what manner the superior oblique can assist in rotating the globe upwards and inwards, as Sir Charles Bell, Dr. Franz, and others have imagined, I am at a loss to comprehend. Were it indubitable that Dr. F. divided the tendon of the superior oblique in his operation, the result he relates would, of course, be conclusive that this muscle does by some means or other contribute to the performance of the movement in question.

The following case, an exceedingly instructive one, affords ground for believing that the only muscles requisite to enable the eye-ball to move diagonally upwards and inwards, *i. e.*, towards the nasal process of the frontal bone, are the superior rectus and the adductor; although it is possible that the superior oblique, by rolling the globe downwards and inwards, may contribute slightly, in some individuals, in causing the pupil to approximate the inner canthus, but certainly not in directing it upwards. A man presented himself for operation who squinted in a most remarkable degree with the right eye, in the manner we have been discussing, *viz.*, upwards and inwards; so much so, indeed, that, when the eye was at rest, fully a fourth part of the cornea was concealed from view. The gentlemen who examined this case previous to operation, *viz.*, Dr. J. C. Williams, Mr. J. N. Thompson, of Nottingham, and Messrs. Smith and Walker, surgeons in the immediate neighbourhood of that town, were all convinced that either the superior or inferior oblique muscle was implicated in producing the deformity. From what I had experienced in similar cases, I was of opinion that the position of the eye proceeded from the conjoint operation of the superior rectus and adductor only,

the former pulling the globe upwards, whilst it was unnaturally tethered or bound down by the latter. On dividing the tendon of the adductor, and completely liberating the eye from all confinement on its inner aspect, it immediately darted directly upwards, so that one-third of the cornea was concealed under the superior palpebra, and the pupil was restored to the natural central line, but, of course, much above its proper situation. In this position the eye remained fixed, unless the patient made an unusual effort to look downwards, which he could never so effectually accomplish as to make the axis of the two eyes correspond, and obviate double vision. On the third day after the first operation I divided the tendon of the superior rectus by cutting down upon it anterior to where that of the superior oblique passes under it. This I did in the manner that I usually perform the operation on the adductor, by inserting a flat blunt hook underneath, and then snipping it across with a pair of scissors. The pupil immediately afterwards descended to its proper position in the centre of the orbit, vision became single, and the case went on satisfactorily in every respect afterwards. I have met with numerous other instances of precisely the same description, as regards the direction of the pupil upwards and inwards, but never in any other case found it necessary to divide any thing but the tendon of the adductor, and to liberate the eye from such abnormal connections as I have described, that tended to confine its inner aspect. When in the course of an operation, after cutting across the band of tendinous fibres by which the adductor muscle is inserted, the eye has been turned upwards and inwards, or in the contrary direction downwards, and towards the nasal canthus, I have always found some adventitious adhesion to be the sole cause of the movement, the contraction of the superior or inferior rectus not exceeding that which was natural to them, but productive of an irregular effect because exerted on a tethered globe.

We have stated that one of the immediate effects of the operation is a trifling projection of the eyeball; the extent, however, to which this occurs is very variable, and depends, I conceive, much upon the manner in which the division of the tendon has been accomplished.

When the operation has been performed without injuring the conjunctival and other coverings more than is absolutely essential, the increased prominence of the eye that results is scarcely appreciable, and, in some instances, cannot be at all detected.

If, on the contrary, the eye has been liberated by submitting the sclerotic to a clean dissection by means of the forceps and scissors, and the investing membranes have been removed to an unnecessary extent, the globe is much more liable to start forward than when attention is paid to preserve the appendages and unoffending textures entire.

If, as frequently happens, the faulty eye is of somewhat less dimensions than its fellow, this mode of performing the operation merits, perhaps, a preference. But if, on the other hand, the faulty eye be the largest of the two, a circumstance of equally frequent occurrence, then it is of the utmost importance to perform the operation in such a manner that all the natural attachments not concerned in the production of the deformity shall remain uninjured. This mode of proceeding, moreover, is in general too severe, and, when no attention is paid to preserve the semilunar fold of the conjunctiva, destroys the natural beauty and finish of the nasal canthus, substituting in its stead a gaping cavity, and a widened state of the inner angle, often so unsightly in appearance as to attract the notice of even a casual observer. When the circumstances of the case, then, lead us to select the operation by the forceps and scissors, care should be taken to preserve all those natural appendages of the eye on which its elegance and symmetry depend.

Another objection that I have found to proceed from removing more of the conjunctival covering than was essential to admit of a perfect division of the structures which hold the eye bound in its unnatural position, is the protracted manner in which the work of restoration is afterwards carried on, and the difficulty of restraining the exuberant growth of the reparative granulations. Indeed, this is such that they occasionally withstand the application of escharotics, and require to be removed with the forceps and scissors, a measure which, though productive of very trifling pain, always creates dissatisfaction. In a surgical point of view, perhaps, this

may not be a matter of very great import; but children and nervous timid persons are with difficulty persuaded to submit again to what has to them the appearance of a second or third operation. Another objection to this mode of operating is the necessity of fixing the eyeball by means of a sharp hook passed through the tunica albuginea, which not only gives considerable pain, but, in refractory patients, is liable to pierce and lacerate the sclerotic, or even to injure the retina.

But these are minor evils compared with sloughing of the eyeball and total loss of vision, an occurrence which I know has happened when a clean dissection has been rather too extensively made of the sclerotic. Under all these points of view it appears to me a matter of great importance to separate or destroy the conjunctiva and other membranous attachments as little as possible, and to confine the operation, when practicable, to a simple free slit through the conjunctiva and subjacent coverings down to the tendon, and to separate this latter by means of a blunt hook underneath, passed as first recommended by Mr. Bennett Lucas, previous to cutting it across with a pair of scissors inserted between the convexity of the hook and the sclerotic coat. I can produce abundant proof that the fullest benefit the operation can confer may be easily obtained by this mode of performing it, and that a week or ten days are in general sufficient for recovery, without any subsequent application of scissors or escharotics; and, as before observed, when thus performed, undue prominence of the eye will be a very rare consequence of the operation.

Another unfortunate result, but by no means the fault of the surgeon, is the undue influence which the external rectus occasionally exerts after the eye has been freed internally. For the most part this effect does not continue beyond a few days, and never occurs at all if a slight obliquity remain in the other eye. A very remarkable case of this description presented itself to my friend, Mr. J. N. Thompson, of Nottingham, which I had an opportunity of examining when in that town. A girl of 13 years of age, of an irritable delicate habit, squinted inwards and downwards with the left eye. On dividing the tendon of the adductor, the pupil was instantly everted in an unu-

sual manner, that of the right eye occupying its normal site, and vision became double. It was now found that, on looking at any object placed immediately before her, she had the power of directing the axes of both eyes correctly, so that no obliquity could be detected in either, and vision was single. If, however, without turning her head, she regarded any object placed a little at one side, the eye of that side was instantly turned outwards to a very considerable extent; but when the object was placed on the left side, the globe turned so completely round, that a considerable portion of the cornea was concealed in the outer angle of the orbit, the opposite pupil occupying its proper position. The most singular circumstance in this case is, that the external rectus of the sound eye should obey the same impulse, though in a somewhat less degree, as the eye which had been subjected to operation. But I think the fact is easily explained, and I shall attempt its solution when I have detailed another case that happened in my own practice of a similar nature.

A lady had the operation performed on the left eye, that in which the obliquity was the worst, and the vision most imperfect; the result was in every respect satisfactory. At the expiration of three weeks, as the defect in the right eye continued very marked, she was desirous of having the tendon divided in it likewise, having seen the double operation highly successful in a young person similarly situated a short time previously. The tendon of the right eye was therefore divided; immediately the external rectus of the left eye exerted an undue influence, and turned the pupil so much outwards, that vision became double, and a very unpleasant leer supplanted the original squint. It was afterwards found that she could direct both pupils with the utmost precision, when the object she looked at was placed immediately before her; but that if it were removed only a few inches to either side, if she continued to look at it without turning her head, the external rectus of the eye, on the side to which the object was moved, immediately exerted an undue ascendancy, and drew the pupil so much to the outer angle, that vision instantly became double, and a most ungainly cast to that side supplanted the original evil. This untoward symptom has con-

tinued for some length of time; but as it is now confined to the left eye, and does not appear to be so marked as it was at first, I am in hopes that it will ultimately be overcome when a reparation of the nerves which preserve the sympathy between the eyes is sufficiently established. Still it is possible that, in some instances, this overaction of the abductor may remain a permanent imperfection. This case not only shews the propriety of very maturely weighing the possible consequences of the double operation before having recourse to it, but suggests some points deserving consideration in the mode of performing it.

14, Langham Place, Regent St.
September 10, 1840.

ON THE CURE OF STRABISMUS.

By D. HENRY WALNE, Esq.

[For the Medical Gazette.]

So many surgeons have already communicated to the profession their opinions and experience respecting the new operation for the cure of squinting, that I should be unwilling to add to the number, but that it appears to me very evident that much remains to be learned by those even who have written on the subject.

I could not myself have believed, had not the pages of the medical periodicals proved it, that any surgeon in or out of London would have been at present found ready to declare that in all cases it is necessary, in performing this operation, to employ a sharp hook to draw the eye outwards, especially after the publication of the clear account of Mr. Lucas's simple and effectual, as well as numerous, operations performed without any such contrivance.

Conversation with a surgeon of some eminence, held some weeks ago, had shewn me that a prejudice in favour of force, in preference to address, at that time existed in some minds; but I thought that the superiority of the latter had been since made so evident, not merely by Mr. Lucas's reports, but by those of several other distant and unconnected professional witnesses, that ere this such a prejudice must have been removed. Finding, however, that this is not the case, and that the violent, not to say unsurgical, method of dragging the eye outwards by a sharp hook,

however delicate its construction, is still continued, and that by gentlemen accustomed to operate and witness operations on the eye, I feel that the subject deserves and requires further attention.

When the operation for the cure of strabismus, by division of the muscle causing the disfigurement, was first introduced, it naturally occurred to surgeons, especially those unaccustomed to operations on the eye*, that one principal difficulty would be to keep the eye steady whilst the division of the muscle was effected, and some contrivance for the purpose being deemed necessary, a double hook was suggested and employed by the early operators. But when for the purpose of raising and dividing the muscle itself, after the division of the conjunctiva, a bent probe or blunt hook had been used, it was soon found that, by the same means, the eye was also effectually secured, and its recession from the operator sufficiently prevented, or the effects of such recession speedily corrected. Once this was discovered, the sharp double hook to draw out the eye ceased to be necessary, in the employment of which some address in the fixing it is required, and still more care lest it should tear the sclerotic or the cornea. The same amount of address, and the same opportunity for using it, will suffice to enable a dexterous surgeon to raise gently, either by a hook, or, as I prefer, by forceps not too sharp-pointed, enough of the conjunctiva covering the globe of the eye to allow him to open that loose tunic with scissors or a knife, and divide it to the extent he may think requisite. This being accomplished, there is no difficulty in passing the blunt hook or bent probe beneath the muscle, none of these steps of the operation being in any considerable degree painful. When the hook is beneath the muscle, the operator has complete command of the eye, and with this advantage, over all the fixings by sharp hooks of whatever kind, that it is scarcely possible for him to do any mischief by the means, whereas, with the sharp hooks, he is in constant apprehension that his assistant may do serious injury.

It is not, I think, of much conse-

quence how inconsiderable the opening into the conjunctiva may be, or the direction of it, provided it begins a little below the lower edge of the muscle intended to be divided, if either internal or external rectus, and be capable of readily admitting the end of the blunt hook. If scissors be used for dividing the muscle, the conjunctiva remaining over it will, of course, be liable to be severed at the same moment; if a knife, it is possible to limit more the division of the membrane, and this, it seems to me, constitutes the chief advantage of a knife; but I am by no means satisfied that scissors are not in all cases preferable. When scissors have been employed the surgeon can satisfy himself most fully that every fibre of the muscle, to whose action principally the deformity has been owing, has been cleanly divided, and he can readily remove, if he should wish to do so, the little portion of tendon attached to the sclerotica.

I have not seen any necessity for the artery forceps, employed by some surgeons for the purpose of keeping down the lower eyelid, nor can I fancy any surgeon accustomed to operate on the eye persisting in their use. Nor is there any occasion for a speculum, unless it be in very young children. The fingers or thumbs of an intelligent and practised assistant answer the purpose of separating the lids and keeping them apart sufficiently well. By discarding so much apparatus, at first thought requisite, and only by experience shown to be otherwise, the operation is admirably simplified, and loses, in a great degree, its formidable and painful character. It is reduced to a few simple steps, which, if practised with gentleness and address, leave the patient comfortable, satisfied and surprised at the ease and readiness with which the result he so much desired has been attained. To recount these steps: In the case of inversion, let the patient be seated in a chair, or recline with the head resting on the scroll end of a couch. In the former case the head rests against the breast of the assistant in the first stage, if not in both stages of the operation. The eye not to be operated on must be covered, for on its being so depends the power of the patient to direct outwards the pupil of that which is to be the subject of operation, and so afford to the operator the

* In extraction of the cataract, the most difficult and delicate operation on the eye, the surgeon dare not attempt to fix the ball by any pressure, lest he should squeeze out the vitreous humour. This operation is not, however, admissible in the case of children.

greatest facility of proceeding. If at first this is not done effectually and steadily, a short delay, and perhaps touching the eye once or twice gently, strengthens the patient's resolution. A formidable apparatus, on the contrary, causes alarm, and creates a necessity for its use. When the eye is pretty steadily directed outwards, a pair of forceps, or a fine hook, gently raises a little fold of the conjunctiva, which is penetrated by the very fine point of a pair of scissors, having one of its points as fine as a needle for the purpose, and a section of small extent is made. The eye may now rest, with the lids closed, and the few drops of blood shed by this section be wiped away by the assistant, whilst the surgeon takes the blunt hook and a pair of curved scissors, should he, as I do, prefer them, or if he prefer the scissors already in his hand, it will be well, by turning them, to keep the sharp point away* from the globe of the eye in dividing the muscle, which he proceeds to do as soon as, with the lids again separated, and the use of the blunt hook, he has caught it from below. Having divided the muscle, he carefully examines with the blunt hook, by drawing it over the sclerotic, across the natural direction of the muscular fibres, to ascertain if they are all divided, and being satisfied of this the operation is at an end; but he convinces himself completely by its effect upon the eye. Finding it most convenient myself always to stand on the right or in front of my patient, so as to use my scissors with my right hand, directing their points upwards, which prevents their handles being interfered with by the upper ridge of the orbit, I have my assistant placed on the patient's left, except in the case of outward squint of the left eye, when he stands on the right and I in front. If the left eye be operated on in internal squint, the assistant applies his fingers or thumbs to the lids, towards the external canthus; if the right eye, towards the internal. This is reversed in external squint.

The surgeon will of course select his scissors, as any kind may best suit his manual habits. For dividing the adductor muscle of the left eye, I prefer scissors which are curved in the flat; for that of the right eye such as are

angular, having probe points; but straight will do for either eye, though, I think, less conveniently.

The ground of the preference which I give to forceps over a hook, for raising the conjunctiva, is akin to that which induces every anatomist to prefer them in dissecting loose cellular substance. They are equally ready in catching it up, and, particularly if not too sharp-pointed, more secure of retaining their hold. They are also much less liable to cause the patient to start by the sensation they produce.

We are told strange things as to the necessity of sharp hooks to hold the eyeball in a right direction during the steps of this operation, and those who do not use them have reflections cast upon their experience. What amount of experience would entitle an operator to deem a painful expedient necessary, which even the inexperienced, according to his estimate of the matter, find they can dispense with, I cannot conjecture.

Those operators who still advocate the employment of sharp double hooks for holding the eye, must be divisible into two classes; such as have tried the simpler method, and failed in its execution, and such as have not yet tried it. Let the former publish an account of their attempts, that an opinion may be formed of the cause of their failure; and let the latter make trial of the improved operation. In confirmation of its efficacy and practicability, I will, in the briefest manner, give a few examples, selecting one instance only of each of those varieties of the deformity which are of most frequent occurrence. In all these cases, as well as upon several other occasions, I am indebted to my intelligent friend, Mr. Beale, for his able and judicious assistance.

Single inward squint—left eye.

Mrs. M., æt. 26.—To her own knowledge was affected with squinting before 7 years old. At 13, the sound eye was kept covered, almost constantly, for two years, with great benefit, but she had not further patience. Disease not very strongly marked now, except when aggravated by emotion; but the eye cannot be turned fully outwards. Sight of it very imperfect.

Aug. 24th.—Operation done as above described. Immediate result: the eye could move outwardly to the fullest extent; cure completed in ten

* It is best, however, to use strong scissors, cutting well to a somewhat blunted point, as the fine point above alluded to would be soon destroyed in dividing the muscle.

days, except a little remaining enlargement of the conjunctival vessels, near the wound.

Single internal squint—right eye.

W. N., Esq., æt. 32.—Disease noticed by his friends at the age of about three years. Hearing their remarks, induced him to practise the manner of looking, which, he believes, confirmed it. Deformity strongly marked, and the motion outwardly much limited.

Aug. 23d.—With the head resting on the end of a couch, the patient reclining, on account of being faint with mental feeling, I operated in the above manner. The chief uneasiness he felt was from the restraint on the lids. When it was finished, he would hardly believe that the operation could have been done, and said it had given him no actual pain. Immediate result: total cessation of the strong squint. In this case a slight rounded fungous growth appeared at the corneal edge of the wound. In all other respects success complete.

Double inward squint.

Wm. Goulden, æt. 30.—Disease attributed to convulsions in teething. It is strongly marked in each eye, but he sees very well with either.

Aug. 15th.—Operated on the left eye. Aug. 22d, operated on the right. Direction of the eyes rendered natural in each case. In the former operation, the conjunctiva was more freely divided, and the stump of the tendon carefully stripped off, yet fungous growths appeared at both edges of the wound, shewing that the remnant of tendon is not the cause. The eye last operated on was quite well in ten days. The first, from the occurrence of these growths, requires attention still.

Single external squint—left eye.

Mr. A., æt. 55.—Thirty years ago was twice operated upon for cataract of this eye, the effect of a punctured wound of the eye, but the nerve and other textures having sustained injury, as well as the lens and its capsule, sight remained very much impaired. The squint seems to have been the consequence of this imperfect vision.

Sept. 3d.—With the modification required for dividing the abductor oculi, being little beyond the choice of different positions, for Mr. Beale and myself. Operation as before. Effect: immedi-

ate and complete restoration; case still under treatment, but proceeding very satisfactorily.

Internal squint in a child.

—Brown, æt. 8 years, a rather timid girl. She was placed on a chair, and her father, kneeling before her, asked her to take his hands. By this artifice he took her's, without alarming her. She had the other eye covered, and I proceeded to operate on the left, which she directed outwardly with steadiness. She did not mind the division of the conjunctiva. The blunt hook, in passing beneath the muscle, unfortunately was raised at its point a little too soon, and allowed a few fibres of the muscle to remain undivided, which making it necessary to pass the hook again, some time was lost in prevailing on her to submit. A little patience, however, sufficed, and the operation was then easily completed.

This is the only troublesome case I have had, and shews that the timidity or obstinacy of children might render this gentle operation unavailable in their cases. The result of the operation is, in all respects, such as could be wished, even in this least favourable of the examples which have occurred in my experience.

MEDICAL GAZETTE.

Friday, September 18, 1840.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

CONCLUSION OF THE VOLUME.

ANOTHER volume is now terminated, and another medical year is nearly over. So short a time has elapsed since we gave a general summary of our career, that we need not here repeat it*.

We trust that the volumes of the MEDICAL GAZETTE which have since appeared, have not belied our former reputation, nor given cause for the maintainers of professional honour to blush for us. To diffuse useful informa-

* Medical Gazette, vol. xxi. p. 19, art. A Prospect and a Retrospect.

tion, and to raise the tone of professional feeling, have now, as ever, been our aims. Careless of the hostility of the ignorant or the fraudulent, we have rarely turned aside to notice their clamour, but have been content to live it down. Unfounded calumny, says an ingenious writer, is like a fish on dry land; however violent may be its contortions, you need not meddle with it, for it expires of itself.

Amid the turmoil of party disputes and professional controversies, Science continues her quiet victories, and Medicine follows in her path with slow but sure steps. The increased attention paid to hygiene is one of the best signs of the times; nor do medical works alone give evidence of this improvement, but legislators are beginning to consecrate a larger portion of their time to the health of the people. Some months ago, we commented on Mr. Slaney's motion in the House of Commons, for an inquiry into the health of great towns. The Select Committee, appointed at his instance, have made their report, and we trust that we shall soon be able to present its substance to our readers.

Of the prospects of the medical profession, as far as regards its internal economy, it is difficult to speak with probability, much more with certainty. We doubt whether any great change will be effected, and we are quite sure that opinion is very much divided as to what ought to be done. Even if it were within the bounds of improbable possibility, that Messrs. Wakley and Warburton succeeded in adding another to the seventeen licensing bodies, whose number is so often lamented, the reform would be but slight; and it is monstrous to suppose that the legislature would sweep away improved and improving establishments, such as some of our medical corporations undoubtedly are, in favour of some fantastic novelty. Let us enter on the new medical year with better hopes.

ON THE NECESSITY OF STUDYING RARE CASES,

BEING THE INTRODUCTORY LECTURE TO A
COURSE OF PHYSIOLOGY, BY M. LORDAT.*

WHEN the old University of Paris was suppressed, and the republican government substituted the *Ecole de Santé* for the *Faculté de Médecine*, the director, besides his official duties, was appointed to explain the doctrines of Hippocrates, and the history of rare cases; that is to say, the history of the extraordinary phenomena which have been observed at various periods in some individuals, whether belonging to anatomy or physiology. It appears, however, that he did not give a single lecture on the latter subject; and in the catalogue of professors in the Parisian faculty of medicine, we no longer find one whose office it is to explain rare cases. I am surprised that this part of the study of physic should have fallen into oblivion, indifference, or discredit.

On examining the question more nearly, however, it seems to me that all parts of the history of rare cases are not equally neglected; cases belonging to anatomy are studied, but those appertaining to physiology are passed over. Monstrosities, anomalies in the distribution of the blood-vessels, club-feet, imperforations, and remarkable pathological phenomena belonging to surgery, are carefully collected. If they are not the subject of a special lectureship, they do not lack celebrity; they re-echo in the Academies; they are described at length and commented on in the journals; and they have been long mentioned in lectures on surgery and anatomy, with which they have more or less connection. But it is not so with the singularities observed in the exercise of the vital force of man, without material alteration. The facts formerly taught in the schools, and published under the names of *casus rariores*, *historia medica admiranda*, or *praxis miranda*, are now unknown; and those which are still presented to us by nature are unnoted, disdained, and rejected with derision.

Why are two kinds of facts, which are equally singular, treated so differently? We see, on reflection, that they are derived from the same source; that congenital deformities or monstrosities are the effects of the same cause which produces the most singular transitory phenomena, namely, the variations which happen in human *dynamism*. How is it possible to think so

* Abridged from the *Gazette Médicale* of July 18, 1840.

much of one kind, and so entirely to undervalue the other?

The immediate or proximate cause of this general disposition is to be found in the preference given by the majority to material knowledge over intellectual notions. The presence of a permanent fact which strikes the senses absorbs the whole attention: its origin and cause are forgotten, while the observer is occupied in classing it, or employing it for some mechanical purpose. But a vital, fugitive, and extraordinary phenomenon is often noted by the skilful alone; it vanishes before a sufficient number of witnesses have been able to satisfy themselves of its reality, and make it sufficiently notorious. Since nothing visible remains of it, we can only investigate its relations, affinities, and causes; an intellectual labour which is very difficult, and is no longer the mode of the day.

The disregard of this study proceeds from the prevailing error of neglecting the theory of physic, and believing that the causes which we have seen are sufficient to form a complete nosology. The majority of physicians have forgotten the necessary truth, that the number of things which the most busy practitioner has seen is infinitely smaller than the number of those which he has not seen. From this forgetfulness proceed the disuse of many doctrinal principles of a high order, the ignorance of many vital facts necessary to be known, contempt for the past in medicine, profound indifference for anthropologic erudition, a great desire to appear well informed in rare cases of the anatomical kind, and an extreme wish to show oneself an *esprit fort* (incredulous) with respect to these singular phenomena in the domain of physiology, which we have not witnessed ourselves. Nay more, we now actually see men, otherwise estimable, who after applying the test of their senses, quite at their ease, to physiological phenomena differing from those with which they are familiar, seriously repeat what Fontenelle uttered as an epigram: "*Je l'ai vu, et je ne le crois pas.*"

This last caprice, which has been seen sporadically in all ages, from the effect of individual ignorance, and which has now become epidemic, from the fault in teaching which I have mentioned, might be injurious to your progress if you were affected by it.

You do not suppose, I hope, that I declare myself the general champion of all the writers of wonders, of all the historians who have accumulated marvellous narratives, such as Herodotus, Pliny, and Livy. What I wish is that you should distinguish judicious and observing physicians from other narrators; that you should not be

armed with prejudices against extraordinary facts, either when it depends on you to verify them, or when you are able to calculate on their credibility, whether from their relations to the knowledge you have of human nature, or from the rules of evidence.

I have endeavoured to find out what are the accusations by which the enemies of rare or new cases deery their study; but I have listened in vain, and have heard nothing but repugnance, obstinate and unreasoning incredulity, and indirect arguments; but never what the logicians call an argument *ad judicium*.

The following is what the incredulous allege:—

1. That novel cases of the physiological kind are unworthy of confidence, and consequently do not deserve any attention.

2. That rare cases, in general, are useless in the practice of physic, for it is an axiom that *rara non sunt artis*.

3. That they have been collected to entertain, and not to instruct; they are æsthetic and not philosophical.

4. The physician cannot employ them, as the public does not believe them, and even laughs at them.

1. *Novel cases of a physiological kind are unworthy of attention.*

When I wished to analyse this important assertion, and reduce it to clearer terms, some of these cases were declared to be impossible, others incontrovertibly uncertain, and others anomalies.

But when I asked for a demonstration *à priori* of the impossibility of the most extraordinary cases, I did not find a man capable of giving it. Those who consider the rare cases narrated in the writings of physicians as absurdities, are excellent *savans*, naturalists, or mathematicians; but they are unversed in the knowledge of human dynamism, and, consequently, unable to conceive the extent and limits of this power; so that they employ the word absurdity without reflecting on its meaning, and with the exaggeration of our men of fashion and pretty women.

Do not misuse this term, or confound the impossible with the incredible. The impossible is an absolute and demonstrable thing. The incredible depends on a relative mental disposition, which differs in each individual, according to the quality and number of the ideas which he possesses concerning the thing in question. This disposition is not composed merely of the distance which separates the fact examined from the knowledge with which the mind is furnished, but it also depends on the probability of the testimony by which the fact is accompanied.

PRACTICAL OBSERVATIONS
ON
PECULIAR AFFECTIONS OF THE
THROAT,

ARISING FROM ABSCESS BETWEEN THE
PHARYNX AND SPINE, AND OCCURRING IN
CHILDREN AND ADULTS ;

Exemplified by Cases.

By CHRISTOPHER FLEMING, M.D.,

Member of the Royal College of Surgeons, Ire-
land ; Member of the Court of Assistants ;
Lecturer on Surgery, &c. &c.

[Concluded from p. 969]

LET us now inquire into those circumstances which will best explain the nature of the affection, its progress, and the treatment calculated to remedy it.

From the report of the cases, and the details of the attendant symptoms (given perhaps with unnecessary minuteness), a particular description of this affection may in a great measure be dispensed with. It is evidently one of an inflammatory character, and, like the majority of such, may be acute or chronic, circumscribed or diffused, as appears from the following extract from the "Elements of the Practice of Medicine," by Drs. Bright and Addison: "Acute idiopathic pharyngitis, or that in which the inflammation is limited to the pharynx, is of extremely rare occurrence. We have only seen two instances of the kind. One occurred in a female beyond the middle period of life, the other in a man between forty and fifty years of age. The female, after exposure to cold, was attacked with pain in the throat, and great pain and difficulty in swallowing, speedily followed by the ordinary signs of febrile excitement. The pain and difficulty in swallowing rapidly increased, till at length the smallest particle of food or drink could not be taken. *The voice was distinct, but the articulation imperfect, as if the patient were unable or unwilling to exert the laryngeal muscles.* On making a careful inspection, scarcely the slightest trace of inflammation could be detected in the throat, nor could the epiglottis be distinguished; but on making pressure on one spot externally on the right side, and at the posterior part of the thyroid cartilage, the patient complained of acute pain. She was bled from the arm, and had leeches applied to the neck, followed by a large warm poultice, and the inhalation of warm water vapour. Under such treatment the disease yielded in a few days to such an extent that she was again able to swallow; but acute pleurisy now supervened, which, in her reduced state and bad constitution, speedily proved fatal. On examining the parts

after death, unequivocal marks of acute inflammation were found at the lower part of the pharynx, the inferior portion of the epiglottis, and posterior surface of the arytenoid cartilages, together with such a degree of purulent infiltration into the submucous cellular tissue in the latter situation, as almost to present the appearance of an abscess, although the cellular structure itself was not broken down. Had not the disease been subdued, this might have undoubtedly passed into a state of abscess, which, by its increase of size and consequent pressure upon the larynx, would probably have seriously interfered with the process of respiration, or even have proved fatal by producing suffocation. The symptoms of the other case bore an exact resemblance to the above, with the exception of the pain on making pressure externally, which was not present in that instance."

Here are evidently recognizable the local phenomena of diffuse inflammation, confirmed by the transfer of disease to the thoracic organs, so frequent in similar cases.

For my own part, I am disposed to the opinion, that, with very few exceptions, this particular affection of the throat is always symptomatic, in some cases, of direct injury, as in that cited from Sir Astley Cooper's Lectures; but, in by far the greater majority of cases, symptomatic of some constitutional derangement, general or specific; general, as the result of fever, and particularly of that form of fever termed by the French pathologists "gastro-encéphalite," or specific, in the two-fold sense in which that term is applied by practical authors, namely, specific as to the exciting cause, or specific as to modification by constitutional peculiarity.

These considerations appear to me of great importance in influencing the character and progress of the attack; in the one, stamping it with an acuteness and rapidity of supervention alarmingly deceptive, and in the other, with a chronic tediousness not likely to escape detection.

Its seat is unquestionably between the back of the pharynx and the muscles on the anterior part of the spine, in the loose cellular, or rather reticular texture, there to be found intervening. It is nothing more or less than inflammation in this region, terminating in suppuration; and, to have an accurate knowledge of the pathological conditions present, as well as of the symptoms attendant on them, and the requisite treatment, it is absolutely necessary to bear in recollection both the structural and relative anatomy of the pharynx. Perhaps in few other lesions can we more satisfactorily exemplify the relations be-

tween cause and effect. For example, the extreme tension, and almost unyielding hardness of those tumors on pressure, stated in the report of the cases, will be accounted for by the very strong, though apparently diaphanous membrane, upon which its superior constrictor is expanded at its posterior and upper part; and the locked state of the jaws will be partially accounted for, at all events, by the attachment of a portion of that muscle in its lateral aspect. The facility of opening the mouth in some cases, and the impossibility in others, may be referrible either to the amount of matter collected, and hence greater tension, or perhaps to the formation of the lower jaw in the child, as it was in the youngest that this freedom of separation existed most. Again, the cerebral symptoms, and those affecting the respiratory organs, are easily attributable to the mechanical pressure on the nerves and important vessels, on the one hand, and to the presence of impure blood in the nervous centre, on the other; while the peculiar position of the head, the inability to elevate it, the rigid state of the muscles at the back of the neck, and the supervention of the almost apoplectic interval when in the recumbent posture, may be referred to the varying pressure exercised on the glottis from the projection of the abscess opposite that opening, necessarily influencing more or less the free entrance of air to the lungs.

In childhood these effects on the brain are of the greatest moment; all practitioners are aware of the great predisposition which exists at that period of life to cerebral disease; that it is induced by the most trifling, sometimes the most opposite, causes, and that none more frequently give rise to it than those which create any derangement in the circulating capillary system, already so necessarily active in the immediate vicinity of this organ; that the several cutaneous diseases incidental to this period of life often terminate fatally in it, or are complicated with it, and none perhaps more than those which are accompanied with affections of the throat; for instance, variola or scarlatina. How awfully fatal are not those diseases in childhood; and in the most alarming cases, is not the throat seriously engaged? Nay more, may it not be one of the causes of the cerebral affection? These considerations have led me to an opinion which I am strongly induced to entertain, from reflections both anatomical and practical; namely, that the more close investigation of the causes and symptoms of this affection in its *acute* form may tend to limit the fatal results of those diseases, inasmuch as in them we know it to be a fact, that the glands in the neighbourhood

of the throat are constantly and extensively implicated in its inflammatory affections; and that if, as I at present feel satisfied from the examinations I have made, some of those glands are to be found in the loose reticular texture between the pharynx and the spine, more frequently in the earlier than the advanced periods of life, we have an additional point, at all events, to direct our attention and treatment to, which may assist materially the operation of remedies. That this affection which I bring under the consideration of the profession is not unfrequently an acute inflammation of one of those glands, particularly in childhood, I am strongly disposed to think, and I am confirmed in the opinion even by the history of the very cases which I have adduced. That those glands are only occasionally found in this situation I admit, and hence probably the rare occurrence of this particular form of disease; but that they do exist more frequently than is generally imagined I am equally certain; and I also believe that those affections of the throat termed *scrofulous*, when engaging the back of the pharynx, and presenting deep ulcerations, are often no more than chronic suppuration and ulceration of them.

To sum up then I would say, that I consider this affection of the throat in children, when *acute* in its progress, as, often, an inflammation of a lymphatic gland situated at the back of the pharynx; an inflammation extremely rapid in its progress to suppuration from its particular position; that I would watch for it during the period of difficult dentition, and in the several cutaneous affections or diseases of the gastro-intestinal mucous membrane to which children are liable; and that I would consider as strongly pathognomic of its presence the following symptoms:—

Fever, more or less *sthenic* in its character, according to the peculiarity of constitution of the child, is always present, and, I think, precedes the development of the local symptoms.

These local symptoms are premonitory and essential.

The *premonitory*, indicative of local uneasiness, but yet common to all affections of the throat; complained of, or otherwise, according to the age of the child, and on examination not accompanied with proportionate visible lesion. The *essential*, often very suddenly supervening, and indicated by derangement of the cerebral, circulating, and respiratory systems, alternating with the comparatively healthy condition of those systems, according to the alteration in the position of the individual. Fixed and retracted state of the head, with rigidity of the muscles at the back of the neck, and more or less locked state of the jaws. Painful deglutition,

impossibility of swallowing solids, and fluids convulsively darted forward through the mouth and nose.—Repeated acts of deglutition without the presence of any fluid in the mouth, and on examination of the fauces, a firm, projecting tumor felt beyond the base of the tongue, and if seen, presenting a smooth, rounded, highly vascular appearance behind the soft palate, usually occupying the median line, but occasionally inclining to either side. These essential symptoms accompanied with the ordinary characteristics of suppurative fever.

The presence of those symptoms appears to me so conclusive of a collection of matter at the back of the pharynx, that I would not for a moment hesitate to decide on its nature, and proceed to open it. In such cases I think the interference of the surgeon absolutely necessary, not alone from the fact of certain fatal results from mechanical pressure on, and interference with, vital organs, but also from the situation of the abscess being particularly favourable to extensive diffusion. In opening it, great caution must be observed, and a careful assistant be at hand to steady the head, and throw it forward the moment the abscess is punctured.

I am disposed to recommend an instrument much on the construction I have alluded to. I think it a manageable instrument, and fully within control, and I think the triangular wound made with it less likely to heal by adhesion, than one made with a lancet or bistoury. Another advantage also arises from the valvular shape of the opening, whereby a too copious or sudden discharge of matter is prevented, and a greater or less extent of subsequent ulceration secured, by which the opening becomes gradually proportioned to the contracting walls of the cavity, and hence is placed in a position more favourable to permanent healing.

The necessity for caution will be proportioned to the situation of the abscess, being more called for where it deviates from the median line, or exists below the level of the tongue. I have seen one instance, referrible, I think, to this class of disease, in which a spontaneous opening took place, and here the situation of the abscess was very high up, and the discharge was principally through the nose.

It occurred in a boy not more than *four weeks* old, who had a well-marked attack of erysipelas of the face and scalp, ushered in by a severe fit of convulsions. He was under the care of my friend Dr. Fitzpatrick, with whom I was in attendance. Independent of the age of the child, the case was most unpromising, from his extreme delicacy of constitution. Every, the most

unfavourable symptoms, were present. In fact, we thought the child almost in *articulo mortis*,—when a *sudden and profuse* purulent discharge took place from the nostrils. The features of the case rapidly altered, and the child got well. At that time I was unacquainted with the form of disease in question; but I think it more than probable, that it was one of those critical depôts behind the pharynx; at all events the case is, worth recording, from the occurrence of erysipelas in the situation mentioned, at that very early period of life, and from its successful issue.

It is unnecessary to dwell on the diagnosis of this affection of the throat, or allude to those diseases, with which it may be confounded, their respective descriptions being so extremely accurate, as merely to require reference to the authors who treat on them. Unquestionably, in the advanced stage of it, where the tumor is considerable, and the symptoms of cerebral compression intense, particularly where much debility and emaciation are present, (not unlikely concomitants,) it is more than probable that it may be overlooked, and the fatal result attributed to other causes,—and in the earlier stage many symptoms exist not unlike those attendant on spinal disease in this portion of the cervical region. Attention, however, to the history of the case, to the presence of fever, and to those features which have been noted as *essential*, will at once remove any difficulty.

Chronic abscesses, single or otherwise, are also occasionally found in this situation during the earlier periods of life. They are often actually formed of some size before detected, and this, probably, from the little inconvenience they occasion. They are connected more or less with that state of constitution termed scrofulous, and I am satisfied they will be found of the same nature with similiar degenerations (if I may use the expression) of the cervical glands, so common in those constitutions.

The symptoms attendant upon them are in a much milder degree of the same character with the acute, and perhaps, the most prominent are, the remarkable effect produced on the respiration by change to the recumbent posture. There is absence of fever, and throughout the day the child is free from any obvious illness,—able to play, and join in the amusements of other children; I have known them not to complain of any uneasiness in the throat, and attention to be directed to it, from the raucous breathing during sleep. In fact, the symptoms much resemble those of common scrofulous induration of the tonsil. They are hence cases of comparatively minor importance; there is time to investigate them. Indeed, with them may be compli-

cated chronic enlargement of the tonsils. I have met with them after scarlatina, after variola, and after measles. In fact, they are some of the sequelæ of those cutaneous diseases, and like them may be accompanied with suppuration of the internal or external ear, and so come under the description of similiar cases already alluded to, as described by Petit. They possibly may require surgical interference, and always are benefited by those local and general remedies suited to their peculiar nature. At the same time, it is perfectly intelligible that they may undergo a spontaneous cure, and altogether escape observation.

The remarks which I have as yet made are principally in reference to this affection, as an occurrence in childhood. From them the following conclusions are, I think, justly deducible.

First,—That a new cause of obstruction in the throats of children exists independent of those noted by authors who treat on their respective diseases.

Secondly,—That the presence of the obstruction is indicated by symptoms peculiarly characteristic, although extremely equivocal in their nature, if not accurately investigated. And

Thirdly,—That its removal is effected by an operation, simple in performance, and, as far as can at present be ascertained, certain in its results.

With respect to this affection in *adults* I have already stated that I have not had an opportunity of witnessing an instance. I cannot, however, imagine otherwise, than that the attendant symptoms, in the incipient and advanced stages of the inflammation, must very much resemble those as detailed in the child, with the great additional advantage of the history from the patient, and yet, how extremely anomalous and deceptive must they not be, when we reflect on the cases which I have brought forward and reported. In all, the *premonitory* symptoms did not attract attention, and even in those which were recognized, and terminated favourably, the *essential* were too characteristic, from the extreme development and mechanical operation, to escape notice. That they occur, however, cannot be questioned, and that they are, with certain restrictions, attributable to similar causes, is more than probable.

The case I have alluded to in the "Dictionnaire de Chirurgie, &c." is conclusive as to the occasional supervention of abscess behind the pharynx during or after fever, in the *adult*, just as the first case I have detailed, is, in the *child*.

"Il est assez rare que l'on soit obligé de porter l'instrument tranchant dans le pharynx, soit afin de donner issue à des collections purulentes formées à son voi-

sinage, ou dans son épaisseur, soit pour dégager et extraire des corps étrangers arrêtées dans sa cavité. J'ai vu, cependant, il y a peu d'années, un malade qui, à la suite d'une gastro-encéphalite grave, avait eu un *abcès critique volumineux* à la partie postérieure du pharynx. La bouche étant largement ouverte, et la langue abaissée avec le doigt, ou le manche d'une cuiller, la tumeur se présentait rouge, tendue, luisante et lisse à sa surface, faisant dans le pharynx une saillie considérable, qui obstruait cette cavité, rendait la respiration difficile, s'opposait au libre passage des substances alimentaires, et alterait beaucoup l'articulation des sons. La tumeur s'étant développée dans la paroi cervicale du pharynx, directement en arrière de l'isthme guttural, l'incision qui en fut pratiquée donna issue à une grande quantité de pus, que le malade rejeta au moyen d'efforts d'expulsion peu considérables, et la guérison eut lieu en peu de jours."

In this case and that given by Sir Astley Cooper, it is remarkable with what facility the mouth was opened, and the tongue depressed, as it forms a strong contrast with the almost utter impossibility of accomplishing the one, and the excessive pain induced on attempting the other, in those cases I have met with. It may perhaps be attributable to the greater powers of accommodation of the structures engaged, to their new position, at the former period of life than in the latter; but I am inclined to refer it more to the very rapid progress of the acute form of the disease in children, and the accompanying fever, a circumstance not noted in the other cases. They are, in fact, more of a chronic character. Indeed no account is given of the constitutional symptoms, or whether any existed; and it is almost certain that such would not have escaped the accurate research of those who witnessed and reported them, did they present any peculiarity beyond that arising from their local effects. Hence an additional circumstance in favour of their *chronic* nature.

It would certainly be a most interesting fact to be enabled to adduce an instance of the occurrence of such an affection, *acute* in its progress in the adult. Possibly some of the suddenly fatal cases in tonsillitis are confounded with them.

Allan Burns, in his "Surgical Anatomy of the Head and Neck," thus expresses himself when on the subject of suppuration in the tonsil.*

"When the collection of matter is large before the abscess bursts, the patient is in a more dangerous situation than is generally

* Surgical Anatomy of the Head and Neck, by Allan Burns. Glasgow Edition, 1824.

imagined. His breathing is obstructed and gasping; he feels much anxiety in the chest; his face is dark and bloated; his eyes are painted with vessels containing purple coloured blood, they are prominent, and seem ready to start from their sockets. We cannot be deceived in regard to the origin of those symptoms, which decidedly show that the lungs are imperfectly supplied with impure air. Whenever the abscess bursts, the mouth and fauces are filled by a gush of matter, every obstruction to the free entrance of air is suddenly removed, the patient fetches an involuntary and deep inspiration, air and matter rush together into the trachea, and death from suffocation is almost the inevitable consequence.

"This, to some, may have the appearance of a fanciful description, or, at all events, an overcharged picture; but its fidelity will be admitted, when I inform them, that in this very way a strong, active young man lately lost his life. He had been complaining for a few days of a sore throat, for which he had consulted his surgeon, who had employed the usual remedies. The inflammation terminated in suppuration: the abscess enlarged until the tumor occupied the entire fauces; yet *ten minutes before his death*, he was walking about the house, restless indeed, anxious, and gasping for breath. The bursting of the abscess, and death, followed each other so rapidly, that no measures could be taken to prevent the latter event.

"The cause of death was not conjectured in this instance: the body was examined, and the trachea found deluged with purulent matter."

It is much to be regretted that the condition of the larynx is not particularly noted, as the history of the case is by no means conclusive of the actual nature of the affection of the throat; it merely states, "sore throat"—a very equivocal expression.

Is it not a fact, that in the most severe cases of acute cynanche tonsillaris, the inflammation occupies a greater or less portion of the soft palate and its pillars? That the tongue can be hardly protruded, and that the jaws are separated with difficulty; and in this condition is not the base of the tongue so circumstanced as rather to favour the protection of the glottis; an office in which it is not unlikely assisted by the effusion of serum, or lymph mixed with serum, to a greater or less amount, on the anterior aspect of the base of the epiglottis? Here is it likely that an abscess of the tonsil would burst into the trachea? or rather that the glottis would admit the matter? I think not. I think in such severe cases death is much more attributable to the surrounding serous effusion producing œdema of the glottis, and its consequences;

or to the extension of a bad character of inflammation producing a similar effect on the glottis, from sub-mucous purulent infiltration.

It may be said that among the symptoms I have enumerated as pathognomonic of abscess behind the pharynx, the peculiar state of the jaws now noted, existed, and that it equally favours the same position of the tongue, and the same condition of the glottis; but here it must be borne in recollection that the situation of the abscess (when of a *phlegmonous* character, perfectly *circumscribed*) would above all others oppose this effect of the epiglottis. It acts from *behind forwards*, and so far forms an obstacle to otherwise perhaps fatal results, an obstacle assisted within certain limits by the posture selected by the patient. But on the other hand, how is this effect circumstanced as far as regards the glottis, should this abscess give way? or should the surgeon be incautious in opening it? Surely the passage of the matter into the trachea is almost inevitable. May such results not have occurred without detection? may it not have been the case here? The only provision against such a termination is the extreme laxity of connexion between the spine and the posterior part of the pharynx favouring its descent, and the more dense nature of the aponeurotic expansion already alluded to in the *median line*, being unfavourable to its pointing in that situation.

When we recollect, however, the laws adopted by nature to direct the progress of abscesses situated near mucous membranes, and that those laws are more strictly adhered to, the more *acute* the nature of the abscess, and the more distant from a *cutaneous* surface, we can reconcile to ourselves the opinion that such provisions would not prevent the *direct* bursting of the abscess, notwithstanding their presence. The same remarks are not applicable to *chronic* abscess; and hence the extended route they take may be accounted for, as instanced in two cases reported in the Transactions of the Association of the College of Physicians, on abscesses between the *œsophagus* and *spine*, which at their commencement were most probably situated behind the upper part of the pharynx, and there recognizable by sight or touch.

In the adult then as in the child the acute abscess behind the pharynx imperatively calls for the early and prompt interference of the surgeon, who must necessarily observe the same caution already alluded to in reference to its treatment. The selection of the trochar is perhaps still more advisable, from the great probability of a considerable accumulation of matter. The constitutional treatment here, as in that of

the child, includes, of course, those restorative means generally adopted under similar circumstances.

Chronic abscess in this situation is, in the adult, I would say, always symptomatic of some constitutional derangement resulting from a specific taint.

It may be scrofulous, and decidedly it may be connected with those anomalous affections occurring in the progress of cases of a pseudo-syphilitic character. As, in such affections elsewhere, our principal aid must be derived from constitutional treatment, which it is unnecessary here to particularize. The local treatment may vary in each individual case as to time of interference, but in all I believe the slow evacuation of the contents of the abscess is prudent. The complication of an abscess in this region of the spine with disease of any of the cervical vertebrae, will of course materially modify its character and progress, but not having met with such I merely allude to their possibility of occurrence.

The diagnosis of this affection in the adult is to a certain extent unattended with much of difficulty, and principally, perhaps, as in the child, escapes detection, from the little local distress induced by its presence. Some caution, however, is called for notwithstanding, as in the situation in which it occurs other affections of a chronic character are met with, with which it may be confounded. Allan Burns, for example, mentions a case where a *polypus* was mistaken for an abscess of the tonsil. Is it not equally probable, that a similar mistake may be made in the case of chronic abscess behind the pharynx; or, might not a chronic tumor, malignant or otherwise, in the same situation, lead to a similar mistake? These considerations, however, are not exactly relevant, or if so, are unnecessary, as they imply more than unusual carelessness on the part of the practitioner.

Enough, then, has been advanced, confirmatory of the presence of this form of disease in children, and in adults, and explanatory of those most prominent symptoms attendant upon its progress and full development. It most certainly is to be met with at *both epochs* of childhood, as an *acute and chronic* affection, and more than probably is similarly so in adult life. In both it requires on the part of the surgeon, promptness and extreme accuracy of diagnosis, and in both the most circumspect caution and decision as to treatment. Attributable to causes already specified as generally applicable, the chronic form in the adult may be complicated with constitutional lesions somewhat peculiar, arising from diseases to which he is more liable.

QUERY REGARDING SQUINT-CURING.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged to any of the readers of the MEDICAL GAZETTE, who have had opportunities of judging of the ultimate effects of the operation of dividing the rectus internus in cases of strabismus convergens, if they would state the result of their observations.

The story with which we were at first entertained, that instantly on dividing the muscle the eye flew like lightning towards the temporal side of the orbit, seems to be dropped. The eye comes soberly now, and sometimes not for a day or two, into the central position. It keeps there, sure enough, so long as the wound near the inner canthus is open, and the conjunctiva swollen; but as the swelling falls, and the pain subsides, does not the squint begin again to appear? and by the end of six weeks or two months, is it not generally found to be the case that the squint has not been cured, but is nearly, if not quite, as bad as ever?—I am, sir,

Your obedient servant.

SOLOMON SINGLE-EYE.

September 9, 1840.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Sept 10, 1840.

John Hill.—J. T. Porter. Sheffield, Yorkshire.
—O. L. Donnell, Falmouth, Cornwall.

METEOROLOGICAL JOURNAL.

Kept at EDMONTON, Latitude 51° 37' 32" N.
Longitude 0° 3' 51" W. of Greenwich.

Sept.	Thermometer	Barometer
Wednesday 9	from 52 to 71	29.97 to 29.91

INDEX to VOL. XXVI.

(VOL. II. FOR THE SESSION 1839-40.)

A.

ABDOMEN, Mr. M'Whinnie's case of transposition of the viscera of the, accompanied with an unusual variety in the venous system, 31.

Abortion of five fœtuses in the third month, Dr. Kennedy's case of, 528.

Abscess, mammary, Mr. Ferrall's clinical lecture on, 253.

Acetate of lead, Dr. Henderson on the employment of, in bronchitis, 263.

Acid, muriatic, Dr. R. D. Thomson on the proofs of the presence of, in the stomach, during digestion, 24.

Adams, Mr. J. A. on an improved hook for steadying the eye during the operation for strabismus, 839.

——— on the use of the blunt hook during the operation for strabismus, 866.

——— description of a knife which he has found well adapted for operating with in strabismus, 910.

Aikin, Mr. further remarks by, on the renewal of the vaccine virus, 139.

Albuminuria, Dr. Hughes' report on, 499.

Alcock, Mr. Rutherford, the Jacksonian prize for 1840 awarded to, for an essay on injuries of the brain, 160; on severe injuries of joints and their treatment, 282; note from, in reply to a suggestion for some improvement in the mode of delivering the prizes at the College of Surgeons, 607.

———'s, Mr. Benjamin, remarks on the Irish College of Surgeons, 806.

Alexander, Dr. on the Horley Green chalybeate, 309.

Alison, Dr. on the management of the poor in Scotland, 280.

———'s observations on the management of the poor in Scotland, reviewed, 664.

Alkaloids, Mr. Kemp on re-agents for the, 185.

Allium ursinum, on the employment of, in scurvy, 425.

Anasarca after scarlatina, Dr. Hughes' report on, 418.

Anatomist's vade-mecum, by Mr. Erasmus Wilson, reviewed, 303.

Andral's, M. lectures on the alterations of the blood, 171, 217, 297.

Aneurism, popliteal, Mr. Bullock's case of, 266.

——— Dr. Theophilus Thompson's case of, supposed to have opened into the pericardium a considerable time before death, 517, 906.

Aneurisms, Mr. Thurnam on, 360.

Announcement, an alarming, 473.

Antrum, fungus of the, clinical remarks on, by Mr. Ferrall, 256.

Ants, living, Dr. Schreiber on the use of, 474.

Aorta, Dr. Osborne on diseases of the valves of the, 601.

Apoplexy (meningeal hæmorrhage) of newborn infants, Dr. Burgess on the, 492.

Apothecaries' Hall, lists of gentlemen who have received certificates from, 80, 160, 240, 287, 400, 480, 528, 560, 672, 704, 816, 848, 880, 928, 960, 992.

Aquo-capsulitis, Mr. Hocken's case of, with hypopion and ulcer of cornea, 460.

Arm presentation, Mr. J. F. Kennedy's case of, 34.

Armies, the French and English, mortality of the, 155.

Armstrong, Mr. on tapping the head in cases of congenital hydrocephalus, 226.

Arnott's, Mr. case of contused artery, 76; case of large osseous tumor of the uterus, nearly filling the true pelvis, and occupying part of the left iliac region, 120; case of medullary tumors affecting the diploe and cancellated structure, in numerous distinct bones of the skeleton, 201; case of ununited fracture through a node on the tibia, 447; case of fatty tumor lodged under the tongue, at the side of the frænum, 558.

Arsenic, Mr. Jones on pytalism from the medicinal use of, 266.

- Artery, middle meningeal; Mr. Craig on a case of rupture of the, 206; the brachial, Mr. Barrett's case of puncture of, 229.
- Ascites, Mr. Ayres on the nature of the fluid in, 224; on a case of, 864.
- Association of Physicians, Dublin, papers read at the:—Dr. Thomas Brady on murder by drowning, 365; Dr. Law on the concurrence of empyema and phlegmasia dolens, 366; Dr. Osborne on diseases of the aortic valves, 601.
- Ayres, Mr. on the nature of the fluid in ascites, 224; particulars respecting a case of, 864.
- B.
- Babington's, Mr. flora of the Channel Islands, reviewed, 629.
- Badham, Dr. John, notice of the death of, 559.
- Bainbridge's, Mr. case of large tumor in the brain, 119; case of placental presentation, 203.
- Barrett, Mr. on hæmorrhage from leech-bites, 80; case of puncture of the brachial artery, 229.
- Barham's, Dr. case of glanders, 511.
- Baths, Russian, as remedies against the bite of mad beasts, 475.
- Bentley, Mr. on the preparation of extract of conium, 346.
- Bethlem hospital, report of the Charity Commissioners respecting, 137.
- Billing, Dr. on the causes of the sounds of the heart, 64.
- Bird's, Dr. medico-chemical history of milk, 43; on the occurrence of cerebral disorders in connexion with diseased kidneys in children, 432.
- Mr. cases illustrative of the cerebral symptoms induced by disease of the kidneys, 635.
- Birt's, Mr. singular case of swallowing pins, 582.
- Black's, Dr. manual on the bowels, reviewed, 725.
- Bladder, Dr. Boyd's case of malformation of the, 558.
- Blake, Mr. James, on the increase of mortality at the decennial periods, 195.
- Bleeding from leech-bites, Mr. Spender on, 34.
- Blood, M. Andral's lectures on alterations in the:—General and preliminary observations, 171; importance of attending to the state of the blood, 172; nature of the alteration which this fluid undergoes, *ib.*; such change affects its quantity or its quality, *ib.*; changes of quantity, 173; phenomena attending plethora and anemia, *ib.*; disorders produced by anemia in the functions of nutrition, 217; alterations of the blood as to quality, 218; microscopic researches on the blood, 297; alterations in the composition of the blood, *ib.*
- Blood, Mr. Gulliver on the corpuscles of the, 74.
- , the maternal, Dr. Lee on the circulation of, in the human ovum, during the early months, 833.
- Bloxam, Mr. on the structure of the human placenta, and its connexion with the uterus, 74.
- Blundell's, Dr. principles and practice of obstetric medicine, reviewed, 549.
- Bochdalek's, Dr. pathological examinations on the organs of hearing and speech in the deaf and dumb, 778.
- Bodington's, Mr. essay on the treatment of pulmonary consumption, reviewed, 725.
- Bone, normal and adventitious, Mr. Smee on the structure of, 73.
- Bones, fractured, Mr. Meade on the mode of union of, 517.
- Books, analyses and notices of:—Lindley's theory of horticulture, 36; Newman's history of British ferns, 37; Dr. Hunter on the influence of artificial light in causing impaired vision, and on some means of preventing or lessening its injurious action on the eye, 68; Dr. Burne on the consequences and causes of habitual constipation, 303; Mr. Erasmus Wilson's anatomist's vade-mecum, 306; Dr. Lee's pathological observations on the uterus, 356; Dr. Hamilton's practical observations on various subjects relating to midwifery, 389; specimen of pathology of ancient Greeks, 395; Mr. Owen's odontology, 438, 591; Mr. Streeter's practical observations on abortion, 468; Mr. Percivall's hippopathology, 470; Dr. Blundell's principles and practice of obstetric medicine, 549; Mr. Nasse's elementary exercises for the use of young physicians in observing and judging of disease, 551; Dr. Pagan's medical jurisprudence of insanity, 553; Mr. Stafford on diseases of prostate gland, 626; Mr. Willshire's principles of botany, 628; Mr. Babington's flora of the channel islands, 629; Mr. Northon on blindness from cataract, 664; Dr. Alison on the management of the poor in Scotland, *ib.*; Mr. Davies' practical remarks on iodine locally applied, 66; Mr. Bodington on the treatment and cure of pulmonary consumption, 725; Dr. Black's manual on the bowels, *ib.*; Dr. Combe on the physiological and moral management of infancy, 726; transactions of the Provincial, Medical, and Surgical Association, vol. 13; Dr. Müller on the nature and structural characteristics of cancer, 766, 840; Dr. Bull on the maternal management of children, 770; Mr. Chavasse's advice to mothers on the management of their offspring, 771; Dr. D. D. Davis on acute hydrocephalus, 869; Mr. Hill's cursory

- notes on the morbid eye, 871; Mr. Braithwaite's retrospect of practical medicine and surgery for the year 1840, 947.
- Borrett's, Mr. two cases of acute inflammation following the removal of foreign bodies from the œsophagus, 758.
- Boyd's, Dr. case of polypus of the heart, 445; case of malformation of the bladder, 538.
- Brachial artery, Mr. Barrett's case of puncture of the, 229.
- Brady, Dr. Thomas, on a case of murder by drowning, 365.
- Braithwaite's, Mr. retrospect of the practice of medicine and surgery for 1840, reviewed, 947.
- Breast, case in which a sero-cystic tumor was removed from the, by Mr. T. B. Curling, 429.
- Bright's, Dr. case of intestinal concretion of phosphate of lime, 76.
- Brodie, Sir Benjamin, testimonial to, 128, 759.
- Brodribb, Mr. on the physiology of the iris, 351.
- Bronchitis, Dr. Henderson on the employment of acetate of lead in, 263.
- Brush's, Mr. case of glanders or farcy, 105; case of glanders communicated by a patient in St. Bartholomew's to the nurse, 183.
- Buchanan's, Dr. fatal cases of obstruction and enormous distension of the belly, arising from a peculiar conformation of the colon, 99, 143; remarks on the ergot of rye, 464; case of extraction of a portion of catheter from bladder, 587.
- Bullock's, Mr. case of popliteal aneurism, 266.
- Bull, Dr. on the maternal management of children, reviewed, 770.
- Burials, weekly accounts of, from the Bills of Mortality, 48, 80, 160, 208, 240, 287, 320, 368, 400, 447, 480, 528, 560, 607, 640.
- Burgess, Dr. on apoplexy of new-born infants, 492.
- Burne, Dr. on the nature and causes of habitual constipation, reviewed, 303.
- Busk's, Dr. case of fracture of the leg, with some peculiar circumstances, 97; case of excision of the elbow-joint, 687.
- C.
- Calculus, spontaneous discharge of a, occurring twice in the same patient, 46.
- , biliary, Mr. Taylor on a new species of, 383.
- Campbell's, Dr. case of extraction of pencil from bladder by the lateral operation, 434.
- Cancer of the veins, Dr. Langenbeck on the formation of, 316.
- Cancrum oris, Dr. Cory's account of a case of, in which a legal inquiry was instituted, 876.
- Cape, Dr. meeting of pupils of, at St. Thomas's Hospital, to express their respect towards him, and disapprobation of certain articles published in the *Lancet*, 399.
- Carlisle's, Sir Anthony, letter on the College of Surgeons, 78.
- Carbuncles, method for the cure of, 606.
- Cases or conclusions? editorial article, 471.
- Catheter, Dr. Buchanan on a case in which a portion of a, was extracted from the bladder, 585.
- Cataract, Mr. Harvey on the operation for, 511; Dr. Franz on the solution of, 793; note on the operation for, 816.
- Cavernous sinus, Dr. Mercer on the, with the description of an additional sinus, occasionally found in its external wall, 267.
- Cæsarean operation, notice of the recent performance of the, by Mr. Whitehead, of Manchester, 897.
- Cederschild, Professor, on a case of congenital umbilical hernia, 238.
- Ceely's, Dr. observations on the variolæ vaccinæ, 683, 715.
- Cerebral disorders, Dr. Golding Bird on the occurrence of, in connexion with diseased kidneys, in children, 432.
- Cerebellum, Dr. Greene's case of deficiency of the, 848.
- Charity commissioners' reports on hospitals: St. Bartholomew's, 11; St. Thomas's, 58; Guy's, 90; Bethlem, 137; editorial remarks on the reports of the, 195.
- Chambers, Dr. portrait of, to be presented by the pupils as a tribute of respect on his retirement from St. George's, 120.
- Chambers's, Mr. case of puerperal convulsions, 796.
- Chavasse's, Mr. advice to mothers on the management of their offspring, reviewed, 771.
- Cheyne's, Mr. case of fatal spasmodic affection of the throat, 258.
- Children, Dr. Collin on the diseases of, 234.
- Cholera, notice of a set of tables by Dr. Graves, illustrating the progress of, 360.
- Churchill, Mr. of Dublin, on the effects of parturition on the nervous system of the mother, 186.
- Clarke, Mr. Robert, observations by, on the disease lethargus, 976.
- Clavicle, Mr. Ferrall's clinical lecture on necrôsis of the, 255.
- Clendinning, Dr. on disease of the heart, 284; notice by, of a fibrinous clot in the arch of the aorta, 364; case of cartilaginous deposition on the surface of the spleen, 447.
- Clinical instruction, on the deficiency of, at Vienna, 662.

- College of Surgeons, Sir Anthony Carlisle's letter respecting the, 78; three studentships in human and comparative anatomy established by the, 400; election of president and vice-presidents for the year ensuing, 782; subject for the Collegial triennial prize, *ib.*; for the Jacksonian prize, 783.
- College of Surgeons, list of gentlemen admitted members, 816, 848-960.
- College of Surgeons, Mr. Gray on the examinations at the, 476.
- College of Physicians' degrees, an erroneous notion respecting, corrected, 203; subjects for the examinations at the, 285; Dr. Taylor's remarks on their privilege of granting degrees, 287; on the privileges of, to confer degrees, by M. D., Oxon, 320.
- College of Physicians of Edinburgh, Mr. Phillips's remarks on the pharmacopœia of the, 271.
- Coles, Mr. on vaccination, 625; on the statistics of small-pox, 704.
- Collin, Dr. on the diseases of children, 234.
- Combe's, Dr. treatise on the physiological and moral management of infancy, reviewed, 726.
- Coinum, Mr. Bentley on the preparation of the extract of, 346.
- Constipation, extraordinary case of, related by Mr. Oliver, 227; habitual, Dr. Burne's treatise on the causes and consequences of, reviewed, 303.
- Convulsions, puerperal, Mr. Chambers's case of, 796.
- Conjunctiva, Mr. Hocken's case of hæmorrhage from the, 837.
- Copper, M. Orfila on the detection of poisoning by, 637.
- Cory's, Dr. E. A. case of cancrum oris, in which a medico-legal inquiry was instituted, 875.
- Court appointments, 704.
- Craniotomy, Mr. Robertson's case of, for hydrocephalus, 585.
- Craig, Mr. on a case of rupture of the middle meningeal artery, 206.
- Croton oil, on the external application of, 605.
- Croup, Dr. Hannay on the treatment of, 582; on the pathology and treatment of, 746; Mr. Robbs on the treatment of, 660; Mr. Yate on the treatment of, 907.
- Crowfoot's, Mr. Hinchman, case of fractured spine treated by extension, 600.
- Cuba, Dr. Turnbull on the climate of, 48.
- Cuba honey and wax, 128.
- Cumin, Dr. notice of the resignation by, of the professorships of midwifery in the University of Glasgow, 640.
- Curling's, Mr. T. B. case of sero-cystic tumors of the breast, removed by operation, with observations on the propriety of operating in cases of prostration from extreme apprehension, 429.
- Curling, Mr. T. B. note from, correcting a misstatement in the report of his evidence at a Coroner's inquest in a case of cancrum oris, 928.
- Cursham's Dr. case of atrophy of the gall-bladder, 388.
- Cutaneous eruptions, Dr. Kennedy's notes on iodine as a remedy for, 260.
- Cysticercus cellulosæ, Mr. Estlin's second case of, between the conjunctiva and sclerotica, 35.

D.

- Davies, Mr. on the application of iodine externally, 46.
- Davies', Dr. practical remarks on the use of iodine locally applied, reviewed, 665.
- Davis's, Dr. D. D. treatise on acute hydrocephalus, reviewed, 869.
- Deaf and dumb, some pathological examinations on the organs of hearing and speech in the, 778.
- Decidua, Dr. Murphy on the situation of the, in cases of extra-uterine gestation, in a letter to Dr. Robert Lee, 513.
- Delirium tremens from debauchery, remedy for, 475.
- Diabetes mellitus, Dr. Maitland on the indications to be fulfilled in, 307.
- Disease and mortality in the metropolis, Dr. Gregory on the statistics of, 121.
- Dislocation, spontaneous, of the dorsum of the ilium, Dr. Durrant's case of, 306.
- Dislocation, a rare, Mr. Haydon on a, 912.
- Dorrington's, Mr. case of functional derangement of vision, 838.
- Douglas's, Mr. case of cartilaginous tumor, 509.
- Douglas, Mr. on the nerve of Wirsberg, 228.
- Drinks, Dr. Gallwey on the physiology of, and their influence on the body in health and disease, 353, 379.
- Dropsy, ovarian, Dr. Ogden's case of, 348.
- Dropsy, renal, Dr. Hughes on, 499.
- Drugs, lists of, on sale in the English market, 479, 608, 736, 992.
- Dubois, M. account by, of a case in which premature labour was artificially induced in a dwarf, 237.
- Duffin, Mr. on some of the causes and consequences of failure of the new operation for the cure of strabismus or squinting, 940, 976.
- Duncan, Dr. on the mortality of Liverpool, 205.
- Durrant's Dr. case of spontaneous dislocation of the dorsum of the ilium, 306.
- Durrant, Dr. on congenital peculiarity in the structure of the heart, 509.
- Dwarf, premature labour artificially induced in a, by M. Dubois, 237.

E.

Economus', Dr. Sophocles, specimen of the pathology of the ancient Greeks, reviewed, 395.

EDITORIAL ARTICLES:—London, ancient and modern, 37; Institutions for special diseases, 70; physical condition of the working classes, 110; mortality of the French and English armies, 155; reports of the Charity Commissioners, 195; on exclusive systems in medicine, 230; Poor Law Commissioners' report to Lord Normanby, 277, 357; preliminary examinations, 310; Union surgeons, 396; Foundling hospitals and their effects, 440; cases or conclusions, 471; theory and practice, 514; the vaccination bill, 553; medical reform in Ireland, 597; in France, 629, 726; question of insanity—the trial of Edward Oxford, 663; have our medical examinations improved? 693; medical education in France, 772; health of the navy, 803; management of the poor in Scotland, 844, 871; what is wanted in medical literature, 920; Union surgeons, 922; new prizes for the *materia medica*, 946;

Education, medical, in France, editorial observations on, 772.

Education, continental, remarks on, 917.

Edwards's, Mr. D. O. problems in medical etiquette, 199.

Edwards, Mr. on Mr. French's improvements in the operation for strabismus, 927.

Elbow-joint, Mr. Busk's case of excision of the, 687.

Empyema, Mr. J. B. Thomson's case of, with pneumo-thorax, 795.

Emphysema, Dr. Hutton's case of, of the submucous tissue of the stomach, 559.

Empyema and phlegmasia dolens, Dr. Law on the concurrence of, 366.

England, Dr. on the appearance of hooping-cough more than once in the same individual, 352.

Entozoa of the human eye, Dr. Franz on the, and of other vertebralia, 330.

Ergot, Mr. Lever on the etherial solution of, 109, 240.

Ergot of rye, Dr. Buchanan on the, 464.

Erysipelas, M. Velpeau's clinical lectures on:—various diseases confounded with erysipelas, 809; erysipelas properly so called, 810; angioleucitis, 811; phlebitis, 812; phlegmonous erysipelas, *ib.*; treatment, 827.

Estlin's, Mr. second case of *cysticercus cellulose* between the conjunctiva and sclerótica, 34.

Etiquette, medical, problems in, by Mr. D. O. Edwards, 199.

Examinations, preliminary, editorial observations on, 310.

Examinations, medical, have they improved? 693.

Extra-uterine gestation, Mr. G. H. Park's case of, 640.

— foetation, singular example of, 126.

Eye, Mr. Middlemore on the treatment of certain injuries of the, occurring in infants and young persons, 721.

F.

Faraday, Dr., on the source of power in the voltaic pile, 123.

Farcy and glanders, Mr. Percivall on, 276.

Ferrall's, Mr. clinical lectures delivered at St. Vincent's hospital, Dublin:—periostitis, 113; on mammary abscess, 253; on necrosis of the clavicle, 255; on fungus of the antrum, 256; on gastritis, 412.

Fergusson, W. Esq. professor in King's College, testimonial to, 320.

Fever, Dr. Hughes' report on, 341.

Fleming's, Mr. practical observations on peculiar affections of the throat, arising from abscess between the pharynx and spine, and occurring in children and adults, 855, 985.

Foundling hospitals, editorial observations on the effects of, 440.

Fracture of the leg, Mr. Busk's case of, with some peculiar circumstances, 97.

Fracture, ununited, Mr. Arnott's case of, through a wound on the tibia, 447.

Franz, Dr. on the cure of squinting by dividing the rectus internus muscle, 154; on the entozoa of the human eye, and of other vertebralia, considered with reference to their natural history, and in a nosological point of view, 330; cases of strabismus, 465; physiological observations on eyes operated on for strabismus, 538; report of cases in which the new operation for strabismus proved insufficient, 689; on the solution of cataract, 798.

Franz, Dr. account by, of an instrument for the cure of myopia, 866.

French's, Mr. remarks on the new operation for strabismus, 763.

Fungus of the antrum, clinical remarks on, by Mr. Ferrall, 256.

Gall-bladder, Dr. Cursham's case of atrophy of the, 388.

Gallwey, Dr. on the physiology of drinks, and their influence on the body in health and disease, 353, 379.

Gastritis, Mr. Ferrall's clinical lecture on:—subacute gastritis a frequent complication of other diseases, 412; necessity for being familiar with its symptoms and treatment,

- ibid; cases of subacute gastritis treated by depletion and diet, 413.
- Gestation, extra-uterine, Dr. Lee on the situation of the deciduous membrane in cases of, 436.
- Glanders, on the communicability of, to the human subject, 160.
- Mr. Brush's case of, communicated by a patient in St. Bartholomew's, to the nurse, 183; case of, 105.
- Dr. Barham's case of, 511.
- Mr. Percivall on, in the human subject, 276.
- Gorham's, Mr. case of extraordinary development of the mammae in the human adult, 650.
- Graefe, notice of the death of, 669.
- Grantham, Mr. on the premonitory signs of insanity, 967.
- Graves's, Dr. tables illustrating the progress of cholera, noticed, 360; case of tubercular phthisis, 672.
- Gray, Mr. on the examinations at the College of Surgeons, 476.
- Gregory, Dr. on the statistics of disease and mortality in the metropolis, 121; on the statistics of small-pox, 545; on vaccination, 658.
- Greene's, Dr. case of small-pox pustule in the bladder, 480; case of deficiency in the cerebellum, 848.
- Griffin, Dr. William, on the "reflex function," 750.

Jones, Mr. Wharton, on single vision, 73.

Jones, Mr. on ptyalism from the medicinal use of arsenic, 266.

Joints, Mr. Rutherford Alcock on severe injuries of, and their treatment, 282.

Jörg's, Dr. C. G. medical experiments, 892, 851.

K.

Kemp, Mr. on some re-agents for the alkaloids, 185.

Kennedy's, Mr. J. F. case of arm presentation, 34.

Kennedy's, Dr. notes on the effects of iodine as a remedy for cutaneous eruptions, 260; case of abortion of five fœtuses in the third month, 528.

Kidney, Mr. Phillips on a case of disease of the, 556.

Kidneys, Mr. Bird's cases illustrative of the cerebral symptoms induced by disease of the, 635.

King, Mr. T. Wilkinson, on the influence of the left bronchus in closing the ductus arteriosus at birth, and some correlative circumstances in pathology and comparative anatomy, 622.

Kingston's, Dr. case of adhesion of one of the semilunar valves of the aorta to the surface of that vessel, 202; account of a preparation exhibiting an adhesion of one of the aortic valves to the aorta, and an occlusion of the left coronary artery, 761.

Kreosote, Mr. Ferrall on the efficacy of, in obstinate vomiting, 413.

L.

Labium, Mr. Charles Hawkins on pendulous tumors of the, 283.

Labour, premature, artificially induced in a dwarf, by M. Dubois, 237.

Langstaff's, Mr. case of dislocation of the elbow-joint, 118.

Langenbeck, Dr. of Gottingen, on the formation of cancer of the veins, and the

- possibility of communicating cancer from man to animals, 316.
- Laura Bridgman, an American girl with only one sense, account of, by Dr. Julius, of Hamburg, 313.
- Law, Dr. on the concurrence of empyema and phlegmasia dolens, 367.
- Lawrie's, Dr. cases illustrative of the poisonous and injurious effects of the hydriodate of potash and iodide of starch, 538.
- Lever's, Mr. case of tumor in the pelvis, impeding parturition, 600.
- Leeches, mode of gathering in Russia, 880.
- Leech-bites, Mr. Spender on bleeding from, 34.
- , Mr. Barrett on hæmorrhage from, 80.
- Lee, Dr. on the nerves of the gravid uterus, 41; on the circulation of the maternal blood in the human ovum during the early months, 833; on the situation of the deciduous membrane in cases of extra-uterine gestation, 436; pathological observations by, on the diseases of the uterus, reviewed, 356.
- Leese, Mr. on the degree of reliance to be placed on the records of vaccination, 110.
- Leg, Mr. Busk's case of fracture of the, with some peculiar circumstances, 97.
- Lendrick's, Dr. new instrument for tapping, description of, 815.
- Lethargus, observations on the disease so called, by Mr. Clarke, 970.
- Letheby, Mr. on a new oxyhydræcarbon, 67.
- Lever, Mr. on the etherial solution of ergot, 108; on the etherial solution of ergot, 240.
- Libel, action for: Syme v. Lizars, 281.
- Liquor amarii, notice of a case of jaundice in which it exhibited a deep yellow colour, 128.
- Lindley's Theory of Horticulture, reviewed, 36.
- Literature, medical, what is wanted in, 920.
- Liverpool Medical Institution, resolutions agreed to at a meeting of the, on the subject of the vaccination extension bill, 125; papers read at the:—Dr. Duncan on the mortality of Liverpool, 205; Mr. Craig on a case of rupture of the middle meningeal artery, 206.
- Lomas, Mr. on the cure of congenital strabismus, by dividing the M. rectus internus oculi, 109.
- London University, election of examiners, 281.
- Lumbrici in the hepatic ducts, Dr. Power's case of, 640.
- Lumsden, Dr. on the pathology of acute hydrocephalus, 858.
- M.
- Mackmurdo's, Mr. observations on the operation for strabismus convergens, 802.
- Maitland, Dr. on the indications to be fulfilled in diabetes mellitus, 307.
- Mammæ, Mr. Gorham's case of extraordinary development of the, in the human adult, 659.
- Mapleton's, Mr. singular case of imperforate vagina, and vicarious menstruation from the bladder (?) with uninterrupted regularity for twenty-seven years, 543.
- Matter, Dr. J. C. Hall on secondary depôts of, 897, 936.
- Mayo, Mr. on malignant tumors connected with bone, 55; disavowal by, of having given a certificate in favour of Holloway's ointment, 208; on the effects of dividing the inner straight muscle of the eye, for the cure of strabismus, 434.
- Meade, Mr. on the mode of union of fractured bones, 517.
- Medical reform, observations on, by a Professor in the School of Physic in Ireland, 125.
- Medical association of Ireland, resolutions passed at a meeting of the, 523.
- experiments, by Dr. C. G. Jörg, account of, 892, 951.
- literature, what is wanted in, 920.
- Medicine, editorial remarks on exclusive systems in, 230.
- thoughts on, 808, 926, 960.
- Medicines, indigenous, Dr. Walker on, 386.
- Mellor's, Mr. case of malformation of the œsophagus, 542.
- Mercer's, Dr. observations on the cavernous sinus, with the description of an additional sinus occasionally found in its external wall, 267.
- Meteorological journals, 48, 80, 160, 208, 240, 287, 320, 368, 400, 447, 480, 528, 560, 607, 649, 672, 704, 784, 816, 848, 880, 960, 990.
- Middlemore, Mr. on the treatment of certain injuries of the eye occurring in infants and young persons, 721.
- Midwifery, Dr. Hamilton's practical observations on various subjects relating to, reviewed, 396.
- Military hospital, Edinburgh, report from the, 877.
- Milk, medico-chemical history of, by Dr. Bird, 43.
- Mortality, improved tables of, showing the number of deaths from all causes, 127, 287, 478, 608, 991.
- Mortality of the French and English armies, 155.
- Mr. Blake on the increase of, at the decennial periods, 195.
- Morton, Dr. on some of the changes which are produced in the form and structure of the abdominal parietes by inguinal and femoral hernia, 26.
- Mouth, Mr. Nasmyth on the functions of the, and the structure of recent and fossil teeth, 203.
- Müller, Dr. on the nature and structural characteristics of cancer, reviewed, 766, 840.
- Murphy, Dr. letter from, to Dr. Robert Lee,

respecting the situation of the decidua in cases of extra-uterine gestation, 513.

M'Whinnie's, Mr. case of transposition of the thoracic and abdominal viscera, accompanied with an unusual variety in the venous system, 31.

Myopia, Dr. Franz on an instrument for the cure of, 806.

N.

Nasmyth, Mr. on the functions of the mouth, and the structure of recent and fossil teeth, 203; his reply to Mr. Owen, 545.

Nasse's, Mr. elementary exercises for the use of young physicians, reviewed, 551.

Navy, editorial observations on the health of the, 803.

Necrosis of the clavicle, clinical remarks on, by Mr. Ferrall, 255.

Neuralgia, Dr. Pidduck on the employment of strychnine for the cure of, 759.

Newman's, Mr. history of British ferns, reviewed, 37.

North, Mr. on hydatids of the uterus, 361.

Nose, Dr. Hannay on venereal affections of the, 276.

O.

Obré's, Mr. case of disease of the pons varolii, 77.

Œdema pulmonum in parturient women, 624.

Œsophagus, Mr. Mellor's case of malformation of the, 542.

Ogden's, Dr. case of ovarian dropsy, 348.

Oliver's, Mr. extraordinary case of constipation, 227.

Ophthalmia, Mr. F. Roberts on the causes of, in Malta, 20.

Orfila, M. on the detection of poisoning by copper, 637.

Osborne, Dr. on diseases of the aortic valves, 601.

Ovarian dropsy, Dr. Ogden's case of, 348.

Owen's, Mr. H. K. case of viper-bite, 837.

Owen's, Mr. Odontography, reviewed, 438, 591; reply by, to the review of his "Odontography," 503; rejoinder to Mr. Nasmyth, 637*.

Oxyhydrocarbon, a new, Mr. Letheby on, 67.

P.

Pagan's, Dr. medical jurisprudence of insanity, reviewed, 553.

Paris hospitals, admission of specialities into the, 319.

Park, Mr. on extra-uterine gestation, 640.

Parturition, Dr. Churchill, of Dublin, on the effects of, on the nervous system of the mother, 186.

Paterson, Dr. on the treatment of sprains by starched bandages, 261.

Pencil extracted from the bladder by the lateral operation, by Dr. Campbell, 434.

Percivall, Mr. on farcy and glanders, 276.

Percivall's, Mr. Hippopathology, reviewed, 470.

Periostitis, Mr. Ferrall's clinical lecture on, delivered at St. Vincent's Hospital, Dublin, 113.

Peripneumonia, chronic, Mr. Hingeston's observations on, 763.

Peritonitis, puerperal, Mr. Hutchinson on the identity of, with epidemic erysipelas, 159.

Pharmacopœia of the Royal College of Physicians of Edinburgh, Mr. Phillips's remarks on the, 271.

Pharynx and œsophagus, two remarkable cases of disease of the, 924.

Phillips's, Mr. B. lectures on the principles and practice of surgery—see "Surgery, Mr. B. Phillips's lectures on the principles and practice of."

Phillips's, Mr. Richard, remarks on the Pharmacopœia of the Royal College of Physicians, Edinburgh, 271.

Phillips, Mr. on a case of disease of the kidney, 556.

Phthisis, Dr. Hughes's report of cases of, 618.

Phthisis pulmonalis, old remedy for, 380.

Phthisis, tubercular, Dr. Graves's case of, 672.

Pidduck, Dr. on strychnine in neuralgia, 759.

Pins, singular case, in which a large number were swallowed, 532.

Placenta, the human, Mr. Bloxam on the structure of the, and its connexion with the uterus, 74.

Placental presentation, Mr. Bainbridge's case of, 203.

Poisoning by copper, M. Orfila's method for the detection of, 637.

Polypus of the nose, Mr. Cæsar Hawkins's clinical lecture on, 697, 731.

Poor law Commissioners' report to Lord Normanby, editorial observations on the, 277, 357.

Poor in Scotland, Dr. Alison on the management of the, 280.

Potash, hydriodate of, and iodide of starch, Dr. Lawrie on the poisonous and injurious effects of, 583.

Power's, Dr. J. case of lumbrici in the hepatic ducts, 640.

Prizes at the College of Surgeons, some improvement in relation to the delivery of the, suggested, 528; note from Mr. Rutherford Alcock, in reply, 607.

Prolapsus recti, Mr. Robert on a new operation for the cure of, 878.

Provincial Medical and Surgical Association, Vol. xiii. of the Transactions of the, reviewed, 726.

Provincial Medical Association, account of the meeting of the, at Southampton, 777.

- Public hygiene, editorial remarks on, 729.
- Pulse, Dr. Guy on the frequency of the, at different ages, in males and females, 17.
- Purdon, Dr. notice by, of a case in which the liquor amnii exhibited a deep yellow colour, 128.
- Pylorus, Mr. Ferrall on two forms of organic disease of the, generally distinguishable during life, 413; on stricture of the, without cancer, 414; cancer of the, without stricture, 416.
- Quinine, on the administration of, by the skin, 80.
- Rankin, Dr. on iodine in hydrophobia, 548.
- "Reflex function," Dr. Griffin on the, 750.
- Reform, medical, in Ireland, editorial observations on, 597.
- Reform, medical, in Ireland, editorial observations on, by a "Real Reformer," 775.
- Reform, medical, in France, editorial observations on, 629, 726.
- Reform, medical, Mr. G. Harvey's plan for, 799.
- Reform, medical, the session of parliament passed without any thing having been done towards, 847.
- Reid, Dr. John, on the sounds of the heart, 238.
- Robbs, Mr. on the treatment of croup, 660.
- Robert, M. on a new operation for the cure of prolapsus recti, 873.
- Roberts, Mr. Frederick (Assist. Surg. 59th reg.) on ophthalmia, particularly as it occurs in Malta, 20.
- Robertson's, Mr. case of craniotomy for hydrocephalus, 585.
- Roberton, Mr. on the large proportion of indigent or improvident families in the population of the town of Manchester, 750.
- Rokitansky's, Professor, three remarkable cases of diseases of the pharynx and œsophagus, 924.
- Royal Medical and Chirurgical Society papers read at the :—Mr. Bloxam on the structure of the human placenta and its connexion with the uterus, 74; Mr. Stafford's case of wound of the throat, 75; first meeting of the Pathological department, 75; Mr. Arnott's case of contused artery, 76; Dr. Bright's case of intestinal concretion of phosphate of lime, ib.; Dr. Watson's case of disorganizing inflammation of the valves of the heart occurring in connexion with acute rheumatism, 77; Mr. Obré's case of disease of the pons varolii, ib.; Mr. Langstaff's case of dislocation of the elbow-joint, followed by anchylosis of the ulna to the humerus, with ligamentous union of the radius, 118; Mr. E. Wilson's two preparations, exhibiting a multilocular appearance of the descending colon, 119; Mr. Bainbridge's case of large tumor in the brain, ib.; Mr. Arnott's case of large osseous tumor of the uterus, nearly filling the true pelvis, and occupying part of the left iliac region, 120; Mr. E. Wilson's case of tumor on the exterior of the thorax, 121; Mr. Hutchinson on the identity of puerperal peritonitis with epidemic erysipelas, 159; Mr. Arnott's case of medullary tumors affecting the diploe and cancellated structure, in numerous distinct bones of the skeleton, 201; Dr. Kingston's case of adhesion of one of the semilunar valves of the aorta to the surface of that vessel, &c., 202; Mr. Bainbridge's case of placental presentation, 203; Mr. Rutherford Alcock on severe injuries of joints, and their treatment, 282; Mr. Charles Hawkins on pendulous tumors of the labium, 283; on a case in which a coagulum was found in the femoral vein, ib.; on calcareous deposit on the mucous lining of the bladder, ib.; Dr. Clendinning on disease of the heart, 284; Mr. Thurnam on aneurisms, 360; Mr. North on hydatis of the uterus, 361; Mr. Shaw's two cases of tumors situated between the cerebellum and pons varolii, and compressing these parts, 362; Dr. Clendinning on a fibrous clot in the arch of the aorta, 364; note from Mr. C. Hawkins supplying an omission in the report of his cases of pendulous tumors, 365; Mr. Wickham on a case of aneurism of the innominata, in which the carotid and subclavian arteries were tied, 445; Dr. Boyd's case of polypus of the heart, ib.; Dr. Clendinning on a cartilaginous deposition on the surface of the spleen, ib.; Mr. Arnott's case of ununited fracture through a node on the tibia, 447; Mr. Meade on the mode of union of fractured bones, 587; Dr. Theophilus Thomson's case of aneurism, supposed to have opened into the pericardium a considerable time before death, 517; Dr. Stroud's case of spontaneous rupture of the heart into the pericardial sac, under which life continued for about ten hours, 518; Dr. Boyd's case of gangrene of the lung, ib.; Mr. A. Shaw's four preparations of aneurism of the arteria innominata: 1. Aneurism of the innominata of great size, orifice of the subclavian artery closed, obstruction of the veins, pressure on the axillary nerves, and on the trachea, absorption and disarticulation of the clavicle, 519. 2. Aneurism of the arteria innominata, obliteration of certain veins, obstruction of the thoracic ducts, 520. 3. Aneurism of the innominata, œdema of the head and neck and upper extremities, 522. 4. Aneurism of the innominata, ib.; Mr. Phillips's case of disease of kidney, 556; Mr. Mayo on malignant tumors connected with bone, 557; Dr. Boyd's case of congenital malformation of the bladder, 558; Mr. Arnott's case of fatty tumor lodged under the tongue at the outside of the frænum, ib.; Mr. Hinchman Crowfoot's case of fractured spine treated by extension, 600;

- Mr. J. C. W. Lever's case of tumor in the pelvis impeding parturition, with a postscript by Dr. Merriman, *ib*; Dr. Marshall Hall's third memoir on some principles of pathology in the nervous system, *ib*.
- Royal Society, papers read at the:—Mr. Smee on the structure of normal and adventitious bone, 73; Mr. Wharton Jones on single vision, *ib*; Mr. Gulliver on the corpuscles of the blood, 74.
- Rubeola, Dr. Hughes on, 579.
- Rumsey, Mr. H. W. remarks by, on the vaccination extension bill, 193.
- Russian practice, some account of, 474, 604, 880.
- S.
- Scarlatina, Dr. Hughes's report on, 418.
- Schreiber, Dr. on the external use of living ants, 474.
- Scott, Dr. on dividing the internal rectus muscle for the cure of strabismus, 463.
- Scurvy, on the employment of *allium ursinum* in, 475.
- Shand, Mr. on the agency of sound on the ear, 424.
- Shaw's, Mr. A. two cases of tumors between the cerebellum and pons varolii, 362; cases of aneurism of the arteria innominata, 518.
- Short-sightedness, Dr. Franz on the cure of, 866.
- Siebold's, Dr. case of twins, where one had been long dead, 45.
- Skeleton, a living, 207.
- Slaggett's, Mr. successful case of Taliacotian operation, 348.
- Small-pox and vaccination:—copy of a bill introduced by Mr. Wakley to prevent inoculation for the small-pox, and to extend the practice of vaccination, 444.
- Small pox pustule in the bladder, 480.
- Dr. Gregory on the statistics of, 544.
- Mr. Coles on the statistics of, 704.
- Smee, Mr. on the structure of normal and adventitious bone, 73.
- Smith's, Mr. case of rupture of the right ventricle of the heart, 559.
- Sound, Mr. Shand on the agency of, on the ear, 424.
- Southcomb's, Mr. case of scrotal hernia, with extensive ulceration and perforation of the intestines, 691.
- Spaeth, Dr. notice of a singular case of extra-uterine fœtation recorded by him, 126.
- Special diseases, editorial observations on institutions for, 68.
- Specialities, admissions of, into the hospitals of Paris, 319.
- Sponder, Mr. on bleeding from leech bites, 34.
- Spine, fractured, Mr. Hinchman Crowfoot's case of, treated by extension, 600.
- Sprains, Dr. Paterson on the treatment of, by starched bandages, 264.
- Squint-curing, query regarding, by Solomon One Eye, 990.
- Squinting, Dr. Franz on the cure of, by dividing the rectus internus muscle, 154.
- St. Bartholomew's hospital, report of the charity commissioners respecting: joint report of Mr. Wrottesley and Mr. Smith, 11.
- St. Thomas's hospital, report of the charity commissioners respecting, 58.
- Stafford's, Mr. case of wound of the throat, 75; his essay on the treatment of some affections of the prostate gland, reviewed, 626.
- Steinhæuser, Mr. on the cure of squinting, 336.
- Stokes, Dr. on hyperosteois of the ribs in chronic empyema, 639.
- Strabismus, congenital, Mr. Lomas on the cure of, by dividing the M. rectus internus oculi, 109.
- , various papers on the new operation for the cure of:—by Mr. Steinhæuser, 336; by Mr. Mayo, on dividing the inner straight muscle of the eye, 435; Dr. Scott on dividing the internal rectus muscle, 463; Dr. Franz's cases, 465; Dr. Franz's physiological observations on eyes operated on for strabismus, 538, 689; Mr. French's remarks on the operation, 763; Mr. Mackmurdo's observations on the operation, 802; Mr. J. A. Adams's improved apparatus for steadying the eye during the operation, 839; Mr. Adams on the blunt hook, 866; description of a knife considered to be well adapted for the operation, 910; Mr. Edwards on Mr. French's improvements on the process originally practised by Professor Dieffenbach, 927; Mr. Duffin on the consequences and causes of failure of the operation, 940, 976; Mr. Hocken on the pathology of strabismus, 943; Mr. Walne on, 979; query regarding the operation, by Solomon One Eye, 990.
- Streeter's, Mr. practical observations on abortion, reviewed, 468.
- Stroud's, Dr. case of spontaneous rupture of the heart into the pericardial sac, under which life continued for about ten hours, 518, 904.
- Strychnine, Dr. Pidduck on the employment of, in neuralgia, 759.
- Sunflowers in Russia, uses made of, 848.
- Surgery, Mr. B. Phillips's lectures on the principles and practice of:—
- LECT. 22.—Diseases of the skin, 1; warts, corns, *ib*; diseases of the cellular tissue, 2; furuncle, *ib*; anthrax, 3; tumors, 5; lipoma, encysted, *ib*; hydatid,

7; sarcomatous, fibro-nervous(?) 8; diseases and injuries of arteries, 9; general remarks, ib.

LECT. 23.—Wounds of arteries, 49; varieties, ib.; diagnosis and treatment, 50; astringents, styptics, absorbents, cauterisation, suture, acupuncture, 51; electro-puncture, seton, compression, 52; machure, refolement, torsion, ligature, 53; arteritis, 57.

LECT. 24.—Ossification of arteries, 81; dilatation, 82; contraction, obliteration, aneurism, 83; definition, varieties, ib.; spontaneous aneurism, 84; state of coats in, ib.; most common seat of, 85; causes, ib.; dissecting aneurism, 86; state of the blood in the sacs, 87; changes in the sac, 88; effects of pressure of sac on neighbouring organs, ib.; termination, symptoms, 89.

LECT. 25.—Prognosis of aneurism, 129; treatment by Valsalva's method, ib.; by cold, 130; by compression, ib.; by ligature of the sac, ib.; by tying above the sac, 131; consequences of the ligature—hæmorrhage, enlargement of tumor, gangrene, torsion, machure, &c., ib.; ligature beyond the sac, 133; agents acting upon the sac, 134; result of different methods, ib.; traumatic aneurism, 135; symptoms, prognosis, treatment, ib.; varicose aneurism, 136; symptoms, ib.; treatment, 137.

LECT. 26.—Diseases of veins, 161; symptoms, treatment, 162; inflammation or phlebitis, 163; characters, ib.; local signs, 164; general symptoms, 165; treatment, 168; air in veins, ib.

LECT. 27.—Varices, their nature, 209; varieties, ib.; treatment, 210; compression, ligature, incision, caustic, needles, extirpation, 211; muscular and tendinous systems, 212; wounds, contusions, ruptures, ib.; retractions and their treatment, ib.; club-foot, 214; nature, variety, modes of production, ib.; treatment, 215.

LECT. 28.—Reparation of tendons, 241; appreciation of means of treatment, ib.; permanent flexion of the leg, 243; causes, treatment, ib.; wry neck, nature, causes, 244; treatment, 245; strabismus, 247; retraction of the fingers, ib.; nature, causes, ib.; treatment, 249; diseases of tendinous and subcutaneous bursæ, their nature and treatment, 249.

LECT. 29.—Diseases of fibrous tissues, 289; inflammation of the periosteum, ib.; nature, symptoms, varieties, ib.; treatment, 292; diseases and injuries of osseous tissues, ib.; wounds of bone, ib.; fractures, 293; nature, varieties, ib.; symptoms, prognosis, 296.

LECT. 30.—General treatment of fractures, 321; nasal and malar bones, 328;

superior and inferior maxillary bones, 329.

LECT. 31.—Fracture of the sternum, ribs, costal cartilages, 369; ossa innominata, 370; scapula—body, spine, inferior angle, coracoid and acromion processes, neck, 371; clavicle, 372; humerus, 375; fore-arm, 377; radius, 378.

LECT. 32.—Fracture of the ulna, olecranon, and coronoid processes, 401; carpus, 402; metacarpal bones, ib.; fingers, 403; the femur, ib.; inferior extremity of the femur, 407; separation of the epiphyses, 408; great trochanter, ib.; lesser trochanter, ib.; neck of the femur, 409; symptoms, ib.; diagnosis, 411; prognosis, ib.

LECT. 32.—Treatment of fracture of the neck of the femur, 449; osseous union of neck, why unfrequent? ib.; patella, 450; symptoms, ib.; diagnosis, prognosis, treatment, 451; bones of the leg, 453; tibia and fibula, 454; bones of the foot, calcis, and other bones, 456; starch bandage, 457; inflammation of bone, 458; abscess, 459.

LECT. 33.—Caries, 481; necrosis, 485; tubercles in bone, 489; exostosis, 490.

LECT. 34.—Cysts in bone, 529; softening of bone, 530; rickets, 531; brittleness or fragility, 533; spina ventosa, ib.; osteo-sarcoma, 535; diseases of the articulating system, 537; sprains, their nature and treatment, ib.

LECT. 35.—Dislocations generally considered, 561; particular dislocations, 564; lower jaw, ib.; os hyoides, 566; luxation of bones of the pelvis, ib.; relaxation of pelvic symphyses, 567; luxation of the ribs and their cartilages, ib.; clavicle, 568; humerus, 569.

LECT. 36.—Dislocation of the humerus, 609; elbow-joint, 612; radius, 615; ulna, 616; radio-carpal articulation, 617.

LECT. 37.—Dislocation of os magnum, first metacarpal bone, ib.; fingers on the metacarpal bones, 642; phalanges, 643; femur, ib.; knee-joint, 649.

LECT. 38.—Dislocation of the patella, 673; fibula and foot, 674; astragalus, 676; tarsus, ib.; metatarsus and toes, 677.

LECT. 39.—Diseases of joints generally, 705; synovial inflammation, ib.; thickening of synovial membrane, 706; ulceration of cartilages, 707; scrofulous disease, 708; coxalgia, or morbus coxarius, 709.

LECT. 40.—Disease of the knee-joint, 737; anchylosis, 738; loose cartilages, 740; injuries of the head, 743; wounds of the scalp, ib.

LECT. 41.—Fracture of the cranium, 785; simple and compound fracture, ib.; counter-fracture, 686; separation of the

sutures, 787; wounds of the brain or its membranes, *ib.*; concussion of the brain, 788; compression of the brain, 791.

LECT. 42.—Inflammation of the brain, or encephalitis, 817; nature, *ib.*; symptoms, 818; treatment, 819; the operation of the trepan, 820; circumstances under which its employment is justifiable, 824.

LECT. 43.—Consequences of abscess of the liver, 849; encephalocele, or hernia of the brain, 850; treatment, 851; hernia of the cerebellum, 852; fungous tumours of the dura mater, *ib.*; causes, symptoms, 853; prognosis and treatment, 854; injuries and diseases of the spine, *ib.*; spina bifida, 855; treatment, 856; dislocations of the spine, 857; occipito-atloidal and atlido-axoidal articulations, *ib.*; treatment, 858.
